XXVII. A. G. was an Indian, about twenty years old. A bullet, probably of small caliber, entered the right thigh two inches above the knee-joint, on the inner side, and passed through, fracturing the femur and splitting it down into the joint. The point of exit was two inches higher than the point of entrance. Gangrene had already commenced, but amputation in the middle third of the thigh was eminently satisfactory in saving the man's life and leaving a good stump.

XXVIII. A. H. was a Mexican, thirty years old. A large bullet, commencing at a point about four inches above the inner malleolus, somewhat posteriorly, and going upward, tore off the calf of the left leg for about six inches. The wound when first seen was in very bad condition, and considerable sloughing followed. There was less loss of tissue than might have been anticipated, and comparatively little contraction and lameness.

XXIX. A. L., an Indian, twenty-six years old, was very slightly wounded. A small bullet passed through the soft parts of the right thigh, externally to the femur, doing but little damage, and uncomplicated recovery followed.

XXX. R. G. was a Mexican, twenty-four years old. A small bullet had removed the soft parts on the anterior surface of the left thigh, three inches above the knee, to a depth of about three-fourths of an inch; the wound being about four inches long and three inches wide. It was filled rapidly by granulation.

XXXI. G. M. was an Indian, forty-nine years old. A small bullet passed through the soft parts of the left thigh, six inches above the knee, externally to the femur. Uncomplicated recovery followed.

XXXII. R. G. was twenty-four years old. A small bullet, coming from the left, blistered the skin of the penis and passed through the right thigh, entering at a point on its inner anterior aspect, three inches below the symphysis pubis, and passing out in the same horizontal plane, leaving a canal about three-and-a-half inches long. The finger thrust into the canal was found to be in contact with the femoral artery above, which the bullet had just missed. Fortunately, there was but little sloughing, and the wound healed by granulation, very slowly.

XXXIII. J. S. was a Mexican, thirty-eight years old. The bullet had passed from behind forward, through the soft parts of the left thigh, about seven inches above the knee, and externally to the femur. No complications arose to retard a good recovery.

XXXIV. J. M. was an Indian, forty-two years old. A small bullet passed through the soft parts of the right thigh, five inches above the knee-joint, and internally to the femur. Uncomplicated recovery ensued.

XXXV. A. A., an American, thirty-seven years old, presented a number of wounds, and said that they were all made at the same time and by the same bullet, while he was lying on his back on the ground. The ball passed through his left foot, between the third and fourth metatarsal bones, entered the thigh about four inches above the knee, passed upward through the thigh, superficially, for about six inches; it next entered the abdominal wall about two inches above the center of Poupart's ligament, passed upward and inward, and was found at, and removed from, a point about two-and-a-half inches below and to the left of the umbilicus. The man made a very good and rapid recovery.

XXXVI. J. C. was an Indian, thirty-four years old. This case is presented with apologies for the unscientific nature of the treatment. The wound was

a simple one to the soft parts of the right thigh, and attracted no especial attention until the third day, when the right leg became very stiff and sore, which condition progressed rapidly until the diagnosis of tetanus was clear. The Indian companions of the patient brought some twigs and pieces of root of a plant which was by them considered an antidote and cure for snake-bite and lockjaw, and asked that the remedy be tried in this case. A strong infusion was made, and twenty minims injected hypodermatically every three hours. By the time the second injection was made the convulsions were very violent and there was extreme opisthotonos. After the second injection, however, these symptoms did not increase in severity, and by the time of the eighth injection they had commenced to subside. Invariably the injection seemed to relieve the spasms. This treatment was continued for three days, by which time the patient seemed to be rapidly recovering. After the fourth day the case went to a good recovery. There was resultant abscess in both arms from the injections. I did not positively recognize the plant, but it very much resembled the cinchoneæ, and was probably one of that large family.

In these twenty-two cases of wounds of the lower extremity are included three in which gangrene had set in when first seen, and two of which died. In a total of seven deaths four were from injuries to the knee-joint, of which there were seven cases. There were six amputations of the thigh, with three recoveries, and four cases of gangrene with one recovery.

WOUNDS OF THE TRUNK.

XXXVII. J. D., an Indian, twenty-two years old, was seen two hours after being shot with a thirty-eight caliber revolver at short range. Hypodermatic injections of whiskey were given to relieve shock, which was very great. On examination it was found that the bullet had entered one-and-one-half inches to the left of the median line and three inches below the left nipple. Careful introduction of a probe was followed by the escape of a small amount of bloody serum, and the impulse of the heart, beating against the probe, could be distinctly felt. The bullet was found lying superficially on the line of the twelfth dorsal vertebra, and two inches to the left of the median line. It was removed on the third day, leaving a wound that healed rapidly. A drainage-tube was inserted into the entrance-wound to the depth of three-and-one-half inches, and gradually withdrawn as the wound closed from below. Pus was discharged for three weeks. There were no symptoms of pneumothorax, and temperature, pulse, and respiration were normal until the seventh day, when, contrary to instructions, the patient sat up in bed and ate some solid food. Six hours later the temperature was 105°, the pulse 150, and a large amount of pus was discharged from the drainage-tube. These unpleasant symptoms were relieved by calomel and aconite, and the case went on to a good recovery. The bullet probably passed just beneath the apex of the heart, was deflected downward by the bodies of the vertebræ, and so made its exit. Seven months later the man was seen, and was perfectly well.

XXXVIII. M. L., an Indian boy, fourteen years old, was accidentally shot with a thirty-eight caliber revolver at short range, and was seen three hours later. The bullet passed through the left arm in front of the humerus, entered the thorax by passing through the sixth rib, went behind the heart, and entered the right lung. There was double pneumothorax, and the pulse ranged from 114 to 210, the respirations from 34 to 64, and the temperature from 100° to 103°. Death occurred on the fifth day.

XXXIX. S. C. was an Indian boy, twelve years old. The boy was seen two hours after having been shot accidentally with a thirty-two caliber revolver, the bullet striking first a stone wall, from which it glanced and wounded the boy in his right shoulder, passing from behind forward, immediately beneath the clavicle, and, strange to say, doing no damage to any of the important structures in that locality.

XL. J. M. was an Indian, twenty-three years old. A small bullet, nearly spent, entered at a point two inches to the left of the median line over the sixth rib, and was deflected, passing around the thorax, and lodging about three inches to the left of the vertebral column. Rapid recovery followed removal of the bullet.

PAINFUL GASTRIC NEUROSES: THEIR NATURE, SYMPTOMATOLOGY AND ETIOLOGY.

BY ALLEN A. JONES, M.D.,
CLINICAL INSTRUCTOR IN MEDICINE AND INSTRUCTOR IN PRACTICE, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

PAIN in the stomach is always evidence of some disturbance of the sensory innervation of that organ, and the success that attends the endeavor to cure a painful gastric condition will be commensurate with the completeness of the removal of its cause. In perfect health, no sensation whatever is experienced in the stomach from the presence of a reasonable quantity of food therein, nor from the act of digestion. Frequently, however, an overloaded stomach gives discomfort, if not real pain. If the nerves of the stomach are not disturbed by direct or remote irritation, or by disorder of their nutrition from chronic disease or certain forms of toxemia, digestion takes place without sensation. Doubtless many instances of pain in the stomach are of the nature of neuralgias, as the pain is complained of when the stomach is empty as well as when it contains food; and the chemistry of gastric digestion is not infrequently normal while pain is present.

In considering the painful neuroses of the stomach the organic diseases of the organ, such as carcinoma and ulcer, are necessarily left untouched. A good deal of difficulty arises sometimes in distinguishing between the sensory disturbances that are functional and those that are organic in origin, and the most exhaustive means of diagnosis at our command may

have to be brought to bear upon a case in order to reach a satisfactory decision. This is especially true of ulcer and carcinoma, when gastralgia occurs in patients who bear many of the stigmata of one or the other of these diseases. Gastralgia independent of ulcer, and ulcer accompanied by intense pain, are each common in young women, while gastralgia without carcinoma, and carcinoma with pain, are each of frequent occurrence in old people. Particular reference to the pain in hyperchlorhydria is omitted in this connection, as this secretory neurosis is so closely allied to ulcer of the stomach; it is, furthermore, best considered under the head of secretory disturbances.

It is not uncommon, however, to find definite disorder either of secretion or of motion in cases of gastralgia, but it is not always easy to trace a causative connection between these and gastralgia. For instance, a woman under my care who had attacks of severe gastralgia, also presented the condition of gastric anacidity, in which the stomach-contents were certainly non-irritating, as they were persistently subnormal in acidity. Occasionally the motion became hurried, and the stomach was found completely empty two hours after the ordinary mixed meal.

The most severe form of gastric pain is that which we designate essential gastralgia. It is of a paroxysmal nature, occurs most frequently in hysterical women, comes on for the most part independently of the time of eating or of the character of the food, and is accompanied by great nervous perturbation. The duration of the paroxysms of gastralgia varies in different cases and in separate attacks in the same case. Several patients under my care suffered twelve hours in some attacks when not relieved by treatment. There is a noticeable tendency on the part of patients to exaggerate the pain. One of my patients always became extremely excited in describing her attacks, and repeatedly declared she could not live through another paroxysm. This exaggeration is often more marked during the pain, and this patient cried and screamed alternately, while otherwise behaving in an unreasonable manner.

The location of the pain in essential gastralgia is often in the region of the pylorus, which fact sometimes confuses the exclusion of biliary colic in differential diagnosis.

Of the less severe forms of gastric pain, the time of onset, the character, and the location, are of chief importance. Some complain of pain after eating, others of pain an hour before meals, while a proportion of cases have pain at irregular periods. A few cases complain of constant pain in the stomach. One lady, about thirty-five years old, who has been a pronounced neurasthenic for many years, says she never knows what it is to be free from gastric pain. As she is constantly thinking of and crying about herself, one is inclined to think she exaggerates her stomach-trouble, as she does everything connected with herself and her suffering. The gastric chemistry in this case is irregular. At one examination I found it normal, while at the next there was lactic-acid fermentation and subnormal hydrochloric acid. Her stomach was not slow in emptying itself, although constipation was quite persistent. Another case is in the person of a young girl, aged twenty, who has complained of various neuralgias for a year and a half. Upon two direct examinations of her stomach, motion and secretion were found normal, and absorption was good. At the present writing, this girl declares she has constant pain in her stomach, but this is scarcely credible, as she is so prone to suggestion that she will say she has pain in any imaginable part of her body. Nevertheless, she suffers as such neurasthenic creatures do, and her case is a good example of the influence of the psychic state upon gastric sensation. This girl's vitality is low, her nutrition is imperfect, her skin is "muddy," she is constipated, her arteries are tense, the capillary circulation poor, and she is decidedly hyperopic. It is not surprising that these conditions are accompanied by headache and stomach-ache.

Cardialgia is the predominant form of pain in some cases. It may or may not be accompanied by regurgitation or by belching of gas. It is usually associated with a high total acidity of the gastric contents, or it results from hyperesthesia of the sensory filaments about the cardiac opening which renders them painful under the stimulation of normal acidity and intra-gastric pressure. Sometimes spasm of the cardia is accompanied by severe pain. In a woman treated two years ago for gastroptosis with some dilatation and a pronounced gastric catarrh, upon several occasions the cardia contracted tightly around the stomach-tube, and it was necessary to wait until the spasm had subsided before withdrawing the tube. The patient showed evidence of suffering when the contraction took place and put her hand over the lower end of the sternum. She said the pain there was intense for a few moments. This incident suggests that spasm of the cardia may sometimes cause cardialgia. Not only is severe gastralgia sometimes felt in the region of the pylorus, but less severe pain occurs at this point. The same considerations apply here as apply to pain at the cardia, with the exception that in differential diagnosis carcinoma and ulcer are more frequent at the pylorus, and whereas in cardialgia pressure over the region of pain often gives relief, in pain near the pylorus tenderness upon pressure is usually quite noticeable even in the absence of

organic disease The anatomic proximity of the pylorus to the cardia is worth remembering when we consider the comparative remoteness of the areas to which patients refer pain.

As regards the character of gastric pain, it is variously described as shooting, boring, gnawing, burning, or tearing. A dragging, dull, heavy ache is also described by some. Thus it will be seen that abnormal sensations in the stomach assume a variety that accounts for the difficulty many patients experience in describing their peculiar form of discomfort.

Etiology. Neurasthenia exists in many instances without any complaint whatever of the stomach. In another class of neurasthenics intermittent stomach-trouble is present; while in a third class "the *ego* in the cosmos" of the neurasthenic centers in the stomach, and that forms the chief complaint. This is the "neurasthenia gastrica" of some writers. This last class of patients may be divided into those who have pain but normal digestion, and those who have pain with some defect in gastric chemistry or motility. In the first the condition is a simple sensory neurosis; in the latter it is a mixed neurosis with pain. The relation between neurasthenia and gastralgia is one that often involves the question of the etiologic factors underlying the former condition; nevertheless, pain in the stomach is very commonly associated with the symptom-complex that we call neurasthenia, and the relief of the gastric symptoms is often commensurate with the improvement in the general and nervous conditions. For instance, a married woman, aged twenty-five, the mother of two healthy children, presented herself in May, 1893, complaining of pain and distress after eating, although her appetite was enormous. She also had headache, backache, and pain referred to the ovarian region. For years she had been wretched generally, but not sick in bed. Her physician, a homeopath, had faithfully tamponed, supported, and otherwise treated her uterus during all that time, and had thoroughly impressed upon the patient that her trouble all originated in her pelvic organs. At the time of my examination she was thin, pale, weak, nervous, and constipated. Her heart and lungs were normal; the stomach was low but not dilated; the kidneys were in place; the colon was loaded with fecal matter. The uterus was freely movable and in its proper position. There was some leukorrhea. The woman said she never was able to read half an hour without getting a severe headache. Upon refraction she was found simply hyperopic and was fitted with + cyl. 0.75 D, ax. 90°, for each eye. Her urine was mildly acid, clear yellow, with a specific gravity of 1015. No sugar or albumin was present. There was a trace of indican. Volume in 24 hours 1280 c.c., urea 14.080. Her blood registered 35 with plate and 43 with spectroscope. Her stomach showed normal HCl, with an absence of organic acids after a test-meal of lean meat, bread, and water. Gastric motion was somewhat slow; but on the whole digestion was accomplished well, and upon several direct examinations there was found no apparent cause for the gastric pain. This patient was directed to wear her glasses constantly, to flush the colon, to take a cold spinal douche every morning, to adhere to a carefully selected mixed nutritious diet, and she was given large doses of strychnin before meals, with aloin as a laxative. Emulsion asafœtidæ was given in one-ounce doses four times a day. Improvement commenced and steadily progressed until she reported herself in about two months entirely free from gastric pain, and said she never felt better in her life. I have since learned from the patient that she remains well.

It is difficult to draw a sharp line of distinction between neurasthenia and hysteria so far as they bear an etiologic relation to gastralgia. Those cases manifesting intense gastralgia, while apparently in good health, sometimes behave in an excited and unreasonable manner, as is illustrated in the case of a healthy woman who, when attacked by gastralgia, not infrequently spoke unkindly to and slapped her sisters and daughters, while they were endeavoring to give her relief, and afterward said she was sorry for her behavior, but that she did not know what she did or said when in pain. Another woman became so terrified when she felt the first twinge of pain that she occasionally hurried to the office excited and trembling in fear that the pain would become severe.

Locomotor ataxia is the cause of gastric pain in some cases. The pain, to be at all characteristic, comes in the nature of a crisis, and is very severe, but the lesser forms of pain may be present in this disease. The other evidences of the disease may be latent and the diagnosis be thus confused. Other cord-diseases and affections of the spinal column occasionally cause gastralgia.

Chlorosis is sometimes accompanied by gastric pain, and the point of chief importance in such instances is the differentiation between ulcer and simple gastralgia. My associate, Dr. Stockton, was consulted some years ago by a young girl with chlorosis, and during the course of his conversation with the patient he told her to go home and to bed at once, or else she would have another attack of vomiting and would vomit blood. She disregarded the advice, and about twelve hours later a message came that she had vomited a large amount of blood. This girl's chief complaint was of pain after eating with occasional vomiting of very sour contents, and she was the color of white wax.

In chlorosis the conditions are ripe for the onset of various neuralgias, and in many cases the pain in

the stomach is not associated with ulcer or with the hyperchlorhydria that accompanies ulcer. Indeed, chlorosis exists not infrequently with subnormal HCl. Grave anemias following acute diseases, like typhoid fever, are sometimes accompanied by severe pain in the stomach, with low HCl, retarded motion, and some fermentation.

The general malnutrition caused by lithemia, gout, rheumatism, malaria, tuberculosis, syphilis, and renal insufficiency is often associated with painful gastric disturbances of mostly a neurotic character. With my associate, Dr. Stockton, I have observed a number of cases of gastralgia in men that yielded to potassium iodid after resisting other forms of treatment. Dr. Lyman,[1] in a paper entitled "Gastro-enteric Rheumatism," which he read before the Association of American Physicians, June 1, 1894, says the pain so commonly associated with excess of hydrochloric acid and ascribed by many observers to the irritating action of the acid upon the walls of the stomach, is in truth a definite rheumatic gastralgia depending upon irritation of the gastric plexus of nerves by toxins resulting from hepatic and renal insufficiency. Dr. Lyman calls particular attention to the arthritic cases having attacks of gastric pain. My very modest experience in this matter does not lead me to call these cases "gastric rheumatism." Sometimes stomach-trouble with pain may be traced to the excessive use of alcohol, tobacco, coffee, cocain, opium, or to the habit of masturbation.

Finally, we come to consider the most fruitful of all sources of painful gastric neuroses, consisting in the effect of mental fatigue, worry, excitement, and the various sources of reflex irritation upon gastric innervation. Overworked business men who are under a hard strain fail first in appetite and digestion. They begin by feeling weight and distress in the epigastrium after meals, and end by living on milk or broth because they fear solid food will bring the pain they know too well. Financial anxieties or reverses, which keep a man in a state of high nervous tension for a long time, are a fruitful source, not only of gastric disturbance but of many a general breakdown which may never be recovered from even after years of travel and treatment. Then the men who work from eight until six in a close office, and spend every night until two o'clock smoking, drinking, or what not, are finally made aware that a stomach needs rest, oxygen, and good innervation in order to functionate well and painlessly. Women are subject to innumerable disturbing influences in every-day existence: Late hours, late suppers, loss of sleep, continual social dissipation, crosses in love, constant emotional excitement for some, and for others loss of husbands or children, husbands gone wrong, neglectful or abusive, household cares, financial hardships, and other things that harass the nervous system; for shop-girls, long hours, insufficient and improper food, lack of sunshine and fresh air, coupled with discontent—these and many other influences work havoc with the innervation of the stomach and bring about the "American dyspepsia," so called.

Of the reflex disturbances of the stomach arising from derangement of other organs, those that play the most prominent part are eye-strain, uterine or ovarian disorder, and floating kidney. Of rarer occurrence are reflexes from urethral disease, varicocele, or disease of the rectum.

The state of secretion and motion in painful nervous disorders of the stomach varies widely in different cases. In some cases motion, absorption, and gastric chemistry are normal, while in others motion alone may be at fault, or secretion may be abnormal. It is unnecessary to enter here into a close discussion of the possible disorders of motion and secretion that may be coupled with a painful state of the stomach; suffice it to say that the chief object of direct examination of the stomach is to exclude organic disease, and subsequently the tube may be used as a means of treatment.

(To be concluded.)

[1] American Journal of the Medical Sciences, June, 1894.

A REPORT OF THE ULTIMATE RESULTS OBTAINED IN EXPERIMENTAL EYE-TUBERCULOSIS BY TUBERCULIN-TREATMENT AND ANTI-TUBERCULOUS INOCULATION.[1]

By E. L. TRUDEAU, M.D.,
of Saranac Lake, N. Y.

At the last two meetings of the Association I presented rabbits, illustrating the beneficial effects that may result from treatment with tuberculin in experimental eye-tuberculosis and the marked inhibitory action exercised over this type of disease by preventive inoculations. In a morbid process, however, following so irregular a course, and of so relapsing a nature as tuberculosis, time must ever be the crucial test that should be applied to any apparently favorable results obtained, and I therefore report briefly the further results of these experiments.

The curative effects of tuberculin on the eye-lesions, which, as I showed, may go on apparently to absolute disappearance of the tuberculous process in the eye, is in but very rare instances permanent, and a strong tendency to relapse sooner or later becomes apparent. Even after the eyes have remained free from any morbid manifestation for as

[1] Read before the Association of American Physicians, Washington, May, 1894.

long as twelve months, will this tendency to recurrence manifest itself. Little by little, signs of vascular irritation appear in the eye and around the remaining trifling and apparently extinct foci, and these slowly show evidence of renewed activity. The course of the relapse in the great majority of cases, however, seems essentially chronic, and the destructive and inflammatory processes resulting in caseation are less marked than those that occur after the primary inoculation.

The tendency to recurrence after treatment with tuberculin exists, therefore, though to a much less degree, experimentally as clinically, and the extent to which the tuberculous process can be influenced favorably seems to depend upon the degree and character of the irritation induced about the tubercle and the length of time during which this irritation can be maintained as a result of the treatment rather than upon any direct germicidal effect or upon the production of a lasting immunity.

In lupus we note that the manifest and marked good effects of the treatment last only so long as the injections of tuberculin cause, in a varying degree, vascular changes and cellular infiltration about the tuberculous areas, and cease as soon as the remedy is powerless to produce these. In the rabbit's eye this slight irritation can be maintained much longer than in lupus in man, and the result is correspondingly better and more permanent. How powerful a factor in antagonizing the progress of tuberculosis an artificially induced irritation of the surrounding tissues can be is shown by the complete cures that often follow resection of tuberculous joints, even though much of the infectious mass may unavoidably have been left in the joint. It has also been demonstrated clinically, and of late experimentally as well, that in tuberculous peritonitis the traumatism of a celiotomy and the exposure of the serous membrane to the air are capable of producing a reactive irritation which enables the tissues to smother the onward progress of the more chronic bacillary infection, and apparently cures the disease.

In weighing the evidence offered by this study of the effect of tuberculin on the initial tuberculous lesion as it occurs in the rabbit's eye, it should be noted that the eyes of the control-animals are all destroyed, often many months, before relapses begin to occur in the treated ones, and that the relapsing lesions run a very chronic course. This treatment may be said, therefore, to produce a marked and undoubted curative influence upon the disease, but an influence which, though inhibitive in its action for long periods of time, but rarely leads to a permanent cure in the initial lesion. I have not had an opportunity to study the effect upon these relapsed eyes of a renewal of the treatment.

The results of preventive inoculation are much more satisfactory and apparently more enduring. The rabbits which have survived the subcutaneous inoculation of living cultures of the avian tubercle-bacillus of gradually increasing virulence and in graded doses have undoubtedly acquired a certain degree of immunity to subsequent eye-inoculation with the mammalian cultures, which in some animals under my observation has persisted for over a year without the slightest evidence of a relapse. These eyes appear almost normal, little or no evidence of the virulent inoculation remaining, save the corneal scar and slight adhesions of the pupil to the lens. Unfortunately here, as in the case of animals treated with tuberculin, apparent relapses occur, though a study of the changes in the eye does not point so much to a true relapse as to imperfect and only relative protection, the disease from the first merely running a very chronic course. These cases are, however, by no means the rule, and the degree of immunity obtained appears in many instances of long duration. To test the permanence of the apparent immunity, reinoculation was, after six months, practised in the sound eyes of several of the animals. The changes in the eye produced by this followed to some extent the same typical course as in the first instance, and the disease ran a very chronic course, and in one instance aborted entirely, the second eye being restored, as the first had been. This striking result is shown in the photographs of animal A, in which the eyes, both six months and a year after the virulent inoculations, remain apparently normal. This was, however, the only animal in which so good a result was obtained. Other photographs were made from the same rabbits shown here last year, and were taken one year after the test-inoculation. They illustrate admirably the degree and uncertainty of the protection realized, which may be either complete, partial, or entirely lacking.

As I pointed out, the reaction produced in the surrounding tissues by the introduction of the mammalian bacillus into the eye differs greatly in the prepared animals from that observed in the controls. In the controls the slight degree of irritation caused by the traumatism having passed away, but little is to be noted in the eye for ten days or two weeks, when the evidence of a gradually progressive tuberculous process appears and goes on uninterruptedly to more or less complete destruction of all the structures of the eye. In the prepared animals, on the other hand, the introduction of the infectious material into the eye gives rise almost at once to signs of violent and at first steadily increasing inflammatory reaction, which, however, in two or three weeks slowly begins to subside and may finally entirely disappear. The more marked and more immediate this inflammatory reaction, the better the prospect

that the tuberculous process will be ultimately aborted, and that almost complete restoration of the eye will ensue in the animal under observation. Indeed, a very fair estimate of the degree of protection conferred may be made, according to the early appearance and intensity of this primary reaction. Even in cases in which it is slight, the tuberculosis runs a more chronic course than that observed in control-animals, but nevertheless it may ultimately end in complete destruction of the eye. It is evident that a profound impression of some kind has been made upon the defensive resources of the animals by the preventive treatment, for the manner in which they react to the test-inoculations has been manifestly altered. This is in accordance with the observation of Kitasato, who, having succeeded in curing five guinea-pigs out of twenty-five treated by injections of tuberculin, found that cutaneous reinoculation was at once followed by intense local irritation, ending in the separation of a slough, which left behind it a healthy, granulating surface, no systemic infection of the animals resulting.

The introduction of living bacilli would appear necessary to the production of this relative immunity, and the inoculation of merely chemical substances contained in the cultures powerless to produce it, for all attempts which I have made to protect rabbits with sterilized growths of the avian bacillus, whether killed by heat, light, time, or carbolic acid, have proved negative. Curiously, however, in animals which have been prepared by treatment with dead cultures, the peculiar early reaction of the tissues to the virulent inoculation occurs to a certain extent, but the process goes on uninterruptedly to caseation and destruction of all the structures involved. The principle upon which the relative immunity thus obtained rests seems analogous to that which has governed Pasteur in his anti-rabic inoculations—*i. e*, the gradual habituation of the organism to a virus of greater virulence than that of the virus with which the test-inoculation is to be made.

In accordance with this view it may be noted that the occurrence of a tuberculous process that has become arrested does not protect against another and frequently rapidly fatal invasion of the disease, and all attempts at protective treatment with attenuated cultures of less virulence for the animals than those used in the test-inoculations have, as far as I am aware, and many times in my own experience, proved entirely unsuccessful. We find, also, that while the rabbit, which is very much more susceptible to the avian than to the mammalian bacillus, may acquire a certain degree of immunity to the latter by preventive inoculations of the former, the guinea-pig, which can rarely and with great difficulty be killed by the avian microbe, even when enormous doses of these cultures are injected, is in no way protected by this treatment, a fact that I have several times tested experimentally myself.

All attempts at the production of artificial immunity to tuberculosis in animals have hereto resulted in an unbroken record of failures, but recently Grancher and Martin claim to have succeeded in protecting rabbits. and Richet and Héricourt dogs, by preventive inoculations of avian bacilli. Their results show the same danger to the animals' health and life from the preventive treatment, the same uncertainty as to the production of immunity and the degree of production that it affords, as noted in my own experiments on the rabbit's eye. Richet and Héricourt have yet given no evidence as to the duration of the immunity they claim to have produced in dogs. Grancher and Martin's rabbits, however, outlived the controls by many months and even years, but in most cases ultimately succumbed to some complicating organic lesion other than tuberculosis, which is thought to have been the result of the toxic products injected in making the preventive inoculations.

Faint and fragmentary, therefore, as is the evidence that artificial immunity against tuberculosis is as yet anything more than a dream, this preliminary study of the effect of preventive inoculation upon the primary lesion in the rabbit's eye, when taken in connection with the experiments of the observers named, indicates a possibility of producing at least a relative degree of artificial immunity in this disease, and warrants the following conclusions:

1. Preventive inoculations of living cultures of avian tubercle-bacilli cannot be made in rabbits without some danger to the animal's health and life.

2. The tuberculous process induced in the eyes of rabbits which have been subjected to the preventive inoculations differs in its course from that observed in the controls, and may even entirely abort, ending in an almost complete restoration of the infected eyes—a result never observed in the controls.

3. Uncertain, imperfect, and generally only relative, as this artificial immunity against tuberculosis appears, it is nevertheless sufficiently marked to be demonstrable.

A MODIFICATION OF HEDIN'S HEMATOKRIT.[1]

BY W. F. ARNOLD, M.D.,
PASSED ASSISTANT SURGEON, U. S. NAVY.

I DO not know that there is any necessity to apologize for bringing up this matter when the direct references to it in the English medical literature accessible to me are contained in Von Jaksch's

[1] Read before the San Francisco Bacteriological Society, August 1, 1894.

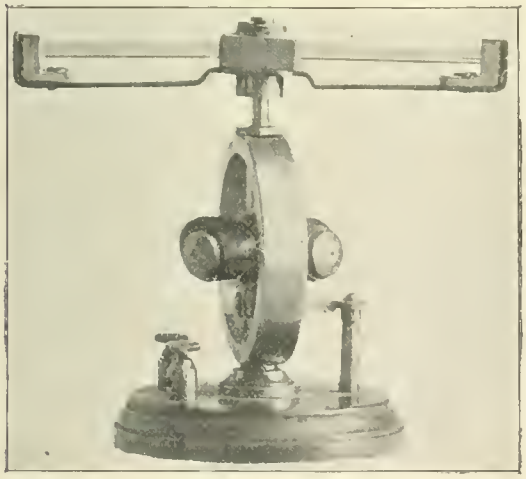
Clinical Diagnosis,[1] and the *New York Medical Journal*, February 3, 1894, p. 151. The latter reference gives an abstract of the contents of a paper by Dr. Judson Daland, read before the New York Academy of Medicine on January 16, 1894, to which I refer those interested for nearly all the practical information extant upon the subject. Dr. Daland, with Dr. Carl Sadler, of Prague, has for some time been collecting data relating to the instrument, in the ultimate usefulness of which he expresses an abiding faith on what appeals to me as a most rational basis.

My own irregular mode of life, almost devoid of free moral agency, from the very nature of my position, has prevented me up to the present time from adding any connected observations to those cited. I can only state that I have found the estimates of the numbers of the corpuscles by percentage-volumes, as given by Dr. Daland, correct within the limits assigned by him in the comparative estimations that I have made, using the Zeiss-Thoma hemocytometer; but these have been few in number, and not in all cases above reproach as to the exactness of their technical performance.

I hope to be able to make a number of observations upon the members of the crew of the U. S. Coast-Defense vessel *Monterey*, and upon opportunity to extend them so as to include pathologic blood-states; but this is a matter of conditional promise, and, like *obiter dicta*, of little binding force and effect.

On February 15, 1894, I devised a modification of Hedin's instrument, substituting rubber blocks

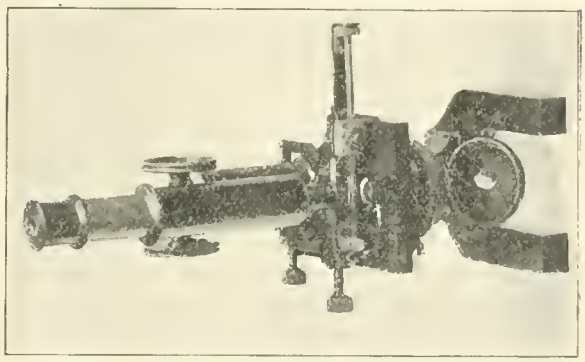
FIG. 1.



for the springs used to hold the tubes in place and to prevent leakage; it is shown in Fig. 1, in place upon a small electric motor hereinafter to be described.

It was with this now discarded design that nearly all of my observations have been made. I think it satisfactory as an hematokrit of the kind promulgated by its originator; and I believe that the further modification that I have introduced, of measuring the heights of the columns of corpuscles by direct reading with low powers (× 200 or less) of the microscope from the limb graduated for record-

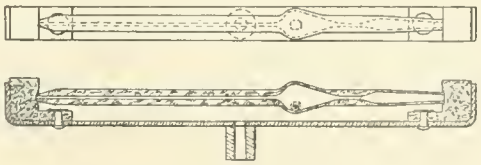
FIG. 2.



ing the lateral motion of the mechanical stage, instead of the set graduations upon the tubes containing the diluted blood, is really an improvement worthy of the name. The method of taking the reading is shown in Fig. 2, the microscope resting on a support upon the edges of its stage and of its foot, to prevent bevelling of the tops of the columns of the corpuscles, which occurs in other positions, from gravitation. Of course, some forms of microscopic stands will not lie in this position, but very little ingenuity would obviate this difficulty.

Within the past week, considering the sources of error introduced and the trouble involved in the

FIG. 3.



process of transferring the diluted blood from the capillary tube, for measuring and mixing, to the tubes of the hematokrit, I have designed a frame capable of receiving and holding during rotation the tube for measuring and mixing itself. This is shown *in situ* in Fig. 3, which is a reduced working drawing, complete even to the conventional hatchings for the representation of composition, of rub-

[1] Charles Griffen & Co., London, 1893, p. 25.

ber, and of glass. For this refinement I am indebted to a messmate, Passed Assistant Engineer G. S. Willits, U. S. Navy, who has made both the frame and this drawing of it.

With this arrangement the blood is diluted, and, after thorough mixing in the bulb, the capillary portion of the tube is filled with the mixture to its tip and placed in the frame and secured upon the motor, or upon the train of gearing for rotating. The result of effective rotation will be that all of the fluid above the center of form of the tube (its tip being considered as the lower end) will run into the bulb and that part of the tube above it, while the longest possible column of blood (for a given length of tube) of constant length and of absolutely exact dilution will be separated into its particulate and fluid components.

Then, either the graduations on the tube, or the microscope and its mechanical stage (and I prefer the latter as more nearly conforming to the best scientific methods of measuring with great accuracy), may be used to get the percentage-volume. The capillary tube that I employ is that furnished with the Zeiss-Thoma apparatus for counting the colorless blood-cells. There is no reason why the finer tube supplied for counting the red blood-cells should not be used instead. I employ the first named because it is more easily cleaned.

I am sorry that my experience does not enable me to speak definitely about the best diluent to be used. Separation is certainly easy with solution of potassium bichromate (2.5 per cent. strength, recommended by Daland[1] as the best of nineteen fluids tried); but I have found a liberation of gas—presumably oxygen—to be associated with the use of this, and it has proved troublesome by disturbing the layer of the colorless corpuscles. I have seen large bubbles rise and carry a line of red cells high into the supernatant liquid when the tube was under microscopic observation as depicted in Fig. 2.

By most fixing-solutions, such as Hayem's, separation is made impossible.

Coagulation vitiates the results in all cases in which it occurs, by entanglement of the cells in the meshes of the fibrin and by the bulk of the fibrin itself. It would be a great aid if it could be prevented by some vaporous agent, which would obviate the necessity of diluting the blood.

It would be a great mistake to imagine that, using blood thus diluted, the layer of colorless blood-corpuscles will obtrude itself upon the notice of even a reasonably careful observer. It is not, at least in normal blood, nearly so wide as a church door; and it is best described as a cream-colored or buff-colored tip upon the comparatively long column of red blood-corpuscles. Daland[1] indicates briefly this indefiniteness. I have found Müller's fluid, deeply tinged with methyl-violet, to aid somewhat in differentiating the layer of colorless corpuscles. It has the disadvantage of coloring the blood-plaques, which would, in that event, vitiate the result in proportion to their number. Daland says that this occurs in the absence of stains, or rather he notes a case in which the blood-plaques proved a source of annoyance.

Obviously, therefore, this instrument cannot replace the hemocytometer, which, with all its faults, will remain a claimant for interested favors, if not of affection, at our hands. But it may save time, and the great nervous strain inseparable from counting the squares, by indicating those cases that unequivocally demand its assistance. Personally, I have never found any employment so irksome as the accurate use of this excellent instrument of precision; hence I am willing, at the risk of imputation of laziness to myself, to allow electricity to remove this irksomeness, if it can be done (as I think it can be) in a perfectly trustworthy manner.

I hope sincerely that some of the gentlemen of the Bacteriological Society of San Francisco, or others of the medical profession to whom this product of enforced idleness may come, will find the subject of sufficient interest to enlist their aid in determining the limitations and the usefulness of the principle embodied in the instrument described. My own *clientèle* is limited perforce to men so carefully selected that dyscrasiæ, such as leukocythemia, should not, and as a matter of fact do not, often occur; so that the best results I could secure under exceptionally favorable conditions would deal only with states of comparative health, and these seem to be of the least importance of all the data necessary for the present status of the hematokrit, and its early establishment as a factor for constant use in diagnosis.

A word regarding the motor shown in Fig. 1, which is one-half size; it is, I believe, the invention of a New York dentist, and its resemblance to the gyroscope is apparent, the limbs of the moving part of that toy being the magnets, and the spindle upon which they revolve the shaft of this machine. The analogue of the frame of the toy is here the armature, composed of "soft" iron, and the presence of the current in it adds to the efficiency of the motor very decidedly, but in a manner not easily explicable, so electricians inform me. It will run at a speed of from 1200 to 2000 revolutions per minute in circuit with an ordinary incandescent lamp; and four Daniell or bichromate

[1] Loc cit.

[1] Loc cit., and American Journal of the Medical Sciences, vol. cvii, p. 511.

cells, or any good cautery battery, will drive it well with a fair load. I have used it for two years for centrifugal separation in urinalysis and for the little use I have made of Charcot's and Luys' *miroir rotatif*. It may be obtained from Frank Wilks, Scott's Wharf, Newport, Rhode Island, to whom I am indebted for much valuable information, and whose thoroughness as a designer and as an accomplished artisan it affords me much pleasure to acknowledge.

STOCKINET COTTON AS A MATERIAL FOR BANDAGES; ITS ADVANTAGES AND USES.

By W. A. CROSS, M.D.,
of Jenkintown, Pa.

In calling attention to stockinet cotton as a desirable material for bandages I will state what it is, what I conceive to be its advantages, and some of the conditions wherein it is well adapted to meet the requirements of the individual case.

The material itself is simply the woven cotton as it comes from the loom, in long double strips, of different widths and thicknesses, suitable for being cut and shaped into stocking-legs. It possesses qualities that peculiarly fit it for so many of the requirements demanded of a bandage. It is soft, pliable, and elastic, easily adapting itself to inequalities of surface, giving firm pressure and support, yet so yielding that it admits of comfort and motion when motion is desired. It may be made of any length, width, or thickness; it may be washed and ironed just as a stocking is laundried, care being taken not to stretch it lengthwise, but drawing it out sidewise previous to rolling or folding it for use.

My attention was first directed to the use of stockinet for bandaging purposes by an article by Dr. W. W. Bremner, of New York City, and published in the *Medical Record* some two years ago. In that article attention was called to the superior qualities of this material for bandaging the lower extremities in the treatment of ulcers and varicose veins.

All physicians know how unsatisfactory the muslin bandage often is; and even the flannel bandage will not always meet the requirements. These need to be applied with the greatest of care and expertness, and even after the most careful application, we find upon their removal that the part has had very uneven pressure, as indicated by the many creases, depressions, and bulgings present.

The stockinet bandage is very easily applied—in fact, so simple is its application that any person of ordinary intelligence may be considered competent to put one on after a little instruction, and the material is so soft and elastic that it will easily conform to the contour of the part to which it is applied.

The various conditions of the lower extremities that necessitate the bandaging of those members can best be met by the use of this material, and will most plainly exemplify its qualities and advantages.

The lower extremities are always the dependent parts; the returning venous blood has the force of gravity to overcome; as assistants to the return we have the elasticity of the coatings of the veins, the valves which prevent the backward flow, and the contractions of the surrounding muscles when in action. If from long-continued pressure, or other form of obstruction, this return circulation is interfered with, the blood overloads and distends the veins until they lose their elasticity, just as a piece of rubber that has been overstretched loses its contractile quality. When this elasticity or tone is lost, the veins become varicose, and there result, by imperfect circulation, malnutrition, ulceration, and various other undesirable conditions. When this varicosity exists in a leg, a cut, scratch, or contusion may occasion an edematous state of the foot and leg, with long-delayed healing.

There is no form of treatment that will give such satisfactory results in the conditions enumerated as bandaging and rest. The very best place to get this care is in a hospital, but unfortunately, only a few of the many sufferers from these troubles can avail themselves of the advantages of hospital-treatment. The majority cannot have the care at their homes which is desirable; the father must earn the daily bread, the mother must care for her children and the numerous household affairs; the physician does the best he can under the circumstances, but how disappointing are his results in the majority of such instances.

To successfully treat varicosities, ulcerations, and other conditions that accompany and are dependent on these lesions, particularly when it is necessary for the patient to be on his feet from eight to ten hours out of the twenty-four, it will be necessary to give support to the over-distended veins and the relaxed tissues. As a rule, the rubber stocking is depended on for this support, but it is an uncomfortable thing to wear, it is expensive, and it rarely fulfils the purposes for which it is employed.

Stockinet as a bandage more nearly meets the requirements for the successful treatment of these cases than any other material with which I am acquainted; its easy application, thinness, and flexibility admit of exercise being taken with perfect freedom; it does not need to be removed and reapplied oftener than every two or three days.

In the treatment of wounds and ulcerations of the leg, when one wishes to use a local application, and should this dressing be of an oily nature, it may be

applied on fine lint or ordinary absorbent cotton, or such cotton rolled or compressed into sheets, and this covered with oiled silk that has a rubber finish, and the bandage adjusted; the stockinet will conform to the inequalities occasioned by the dressing, and even pressure will not be interfered with.

In all leg-bandaging we could do no better than follow the directions given by Dr. Bremner, as follows:

"The patient, seated in a chair of ordinary height, should place his foot on a stand of the same height, or on the corner of the chair on which the operator sits, and, wherever the wound may be situated, the bandaging should always be commenced at the foot. The first turn should be made over the center of the ankle, going under the foot in a figure-of-eight; the second turn should go half an inch higher than the first, again going under the foot, and one turn around the front of the foot close to the root of the toes; the third turn should go half an inch below the first, then under and once around the foot again; the fourth half an inch over the second, and the fifth half an inch under the third, each turn going under and around the foot once only for each turn around the ankle and coming just to the root of the toes. In cases where the wound or ulcer is below the ankle it is necessary, in addition, to make two or three turns directly under the heel, coming over the instep in front.

"The bandage must then be made to ascend the leg by spiral turns of about half an inch each until the center of the calf is reached; above the center the turns should ascend from an inch to an inch-and-a-half each. It is very important to attend to this point, as the bandage exerts all its force at the calf, and if too many turns are put on, the circulation beneath is obstructed. No reverses should be employed. If you use a six-yards bandage and more than two rolls are used, all but the last should be commenced at the foot; the last roll in every case should be applied from above downward in inverse order to the first. A stocking can easily be drawn over the bandages without disturbing the folds.

"In applying the bandages the greatest care should be taken to regulate the pressure in such a way as not to cause stagnation of the venous circulation in the foot. This can be done by always applying rather more pressure to the foot than to the leg. The ideal is to have the pressure graduated in such a manner as to be greatest at the foot, and evenly and gradually less in ascending the leg."

The interference with the venous circulation in the lower extremities which occurs so frequently during the period of gestation, which occasions such distress and does violence to the integrity of the coatings of the veins, may be successfully combated by this form of bandaging, and will not greatly interfere with the movements of the patient. In fractures of the long bones it is a very desirable bandage to use, but only in exceptional cases has it any advantage over the ordinary roller bandages of muslin or gauze.

In the dislocations and sprains occurring in the extremities it is of the greatest service. Having had the professional oversight of one of the teams connected with the Inter-Academic Athletic Association for several years, I have had quite an experience in the treatment of the various injuries unavoidably associated with the exercises of the gymnasium and with the playing of the games of foot-ball and base-ball.

In this class of injuries the bandage plays a most important part in the treatment; whether it is desired to secure the proper compression and support, with absolute rest for a season, or whether limited motion is permissible or desirable, nothing has met the requirements so satisfactorily, in my experience, as the stockinet bandage. In cases in which a joint has been injured by dislocation or strain, and in which it has been the usual habit to depend on the rubber cap for support, I have found stockinet to meet the requirements in a much more satisfactory manner, so that I use it to the exclusion of all other appliances. My praise and advocacy of the use of stockinet as a superior material for bandaging may seem somewhat inordinate, but it has proved to be so serviceable and satisfactory that I have wished to bring it to the attention of the profession in order that its qualities may be tested, proved, and appropriated.

CLINICAL LECTURE.

EXTERNAL PERINEAL URETHROTOMY.

A Review of Nine Cases.

BY W. B. ROGERS, M.D.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE MEMPHIS HOSPITAL MEDICAL COLLEGE.

YOUR attention is requested to-day, gentlemen, to a detailed review of the salient points in the nine cases of external perineal urethrotomy that you have witnessed at this clinic within the past few months.

On the board you see diagrams of the conditions existing at the time of operation in the first eight cases, in all of which stricture of the urethra existed. The ninth operation was exploratory in a case of cystitis, which proved irremediable. It is hoped that you have kept careful notes of these cases and that you will follow me closely. I do not feel that any apology for this review need be made. The importance of the subject warrants its frequent presentation.

Collectively these cases present nearly every condition for which you will be called on to do the operation of external perineal urethrotomy and nearly every local complication you will likely encounter in a lifetime-practice in this department of surgery; therefore, I trust this review will neither prove uninteresting nor unprofitable.

The operation was imperative as a life-saving measure in at least four instances, and sooner or later the same condition would have been reached in four others. Of the evident relief afforded in all but one case you can testify. The ninth case was exploratory upon the bladder.

In no case was there hemorrhage of any consequence. In none was there a history of traumatism to the urethra to account for the stricture; hence the contractions were attributed to admitted gonorrhea.

External perineal urethrotomy is done for various

purposes, namely: To facilitate the use of instruments within the bladder in the removal of tumors, calculi, and foreign bodies introduced from without; to facilitate the use of instruments in operations on the prostate gland and removal of prostatic calculi; for the removal of calculi engaged in the urethral canal; for the relief of stricture of the membranous urethra; to insure drainage, as well as free escape of urine, in cases of a urethra ruptured traumatically or otherwise, as well as to divert the urine and give rest to the anterior urethra after operations thereon; to give a more direct course to the bladder for the introduction of the catheter in cases of retention from enlarged prostate; lastly, as a part of the operation for securing drainage and consequent rest to a chronically inflamed bladder.

When preparatory treatment can be instituted do not fail to thoroughly cleanse the alimentary canal, preferably by the use of calomel and soda.

Always examine the urine for tube-casts. Sometimes they admonish not to operate; again, when operation is imperative, they modify the prognosis.

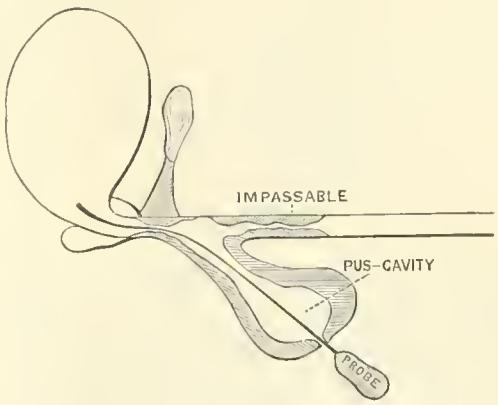
If the urine is hyperacid give an alkali; if alkaline from decomposition in the bladder, benzoic acid is serviceable, five grains every four hours. For scanty urine give lemonade in abundance. Before doing any cutting or dilating in the urethra never fail to thoroughly irrigate the canal and all pus-infected surfaces when they can be reached, and never fail to repeat the irrigation (including the bladder) after doing an external perineal urethrotomy. Always retain a catheter in the bladder to prevent contact of urine when this is of bad quality.

Quinin, either as preventive or curative of rigors following manipulations or operations on the urethra, has proved a masterly failure in my experience. If the patient is bilious and comes from a malarial climate, quinin, with mercury, is indicated, because shock often brings on a malarial chill, but for rigors *per se* and recurring, no benefit follows from the administration of quinin. Opium hypodermatically does more to prevent rigors than all else in the way of drugs. Protect the cut or dilated surfaces from contact with urine. Correct abnormal conditions of the urine before operating, and if there be no kidney-complications, rigors will not be of serious import. Lastly, a sound, full size, under anesthesia, local or general, should be introduced between the third and the fifth day after the operation, and reintroduced at intervals of from three to six days, until the wound has healed, and its use continued at proper intervals so long as there is any tendency to recontraction when the operation has been undertaken for the relief of stricture.

CASE I. *October 1, 1893. Impassable urethral stricture; urinary scrotal abscess.*—Robert S., a white, thirty-two years old, presented a temperature of 103°, a pulse of 140, and a history of fever, and an average of three rigors to the twenty-four hours for the previous ten days. The secretions were all bad. The bowels were constipated. The scrotum was immensely swollen, and red, and fluctuation was distinct at its base. The urine escaped by driblets continually, but by forced effort the bladder could be nearly emptied. The first indication was the evacuation of the scrotal abscess. On incision a quantity of pus and decomposing urine escaped. No effort was made to enter the bladder through the urethra, as the urine was now easily voided through the scrotal opening. A urinary fistula was therefore completed. Cathartics were prescribed, and on the next morning our patient was free from fever and quite comfortable. Ten days elapsed before you again saw him. His general condition had meanwhile much improved, and time had allowed the local condition to mend. Much of the inflammatory thickening had disappeared, but the parts were not in good condition for operation, and yet an evening rise of temperature warned that the bladder needed relief.

Accordingly, exploration of the urethra was made. You will recall that there existed a stricture, as indicated in Fig. 1, which failed to admit even the filiform guide.

FIG. 1.

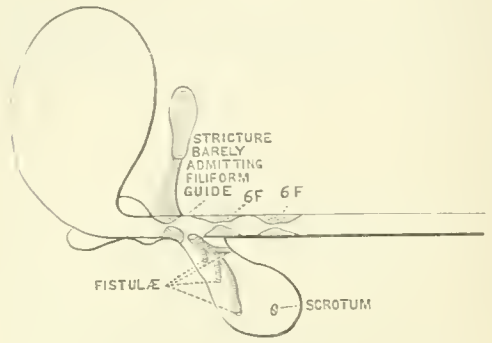


Just behind the stricture was the opening in the urethra, and it was by this channel that the urine came originally into the scrotal abscess-cavity, now a fistula. You will recall how much difficulty was encountered in passing a probe through the fistula, to the urethra, in through this opening, and on down the rugged cicatricial perineal region. However, the probe was finally located in the membranous urethra, after first being introduced and then withdrawn from several sinuses which honeycombed the perineum. The section was made on the probe as a guide, and after washing out the bladder, the urethra was followed forward to the meatus, the urethrotome introduced, and all contractions cut, so that a No. 32 F. sound passed the entire length of the canal. The hemorrhage was slight. A catheter was placed in the urethra and bladder, and retained for a few days. The patient made an excellent recovery; the fistula healed, and a No. 29 sound passed easily. Let me remind you that this is the patient whom I found in almost the same condition, and whom I afforded the same relief by external perineal urethrotomy eight years before. The case should teach you the same lesson that I hope he has learned, not to neglect the use of the sound after operations for stricture. The dribbling of urine resulted from an over-filled bladder, which, with the aid of the abdominal muscles, could be partially emptied, but some urine was always left, called residual urine. The fever resulted from the infiltration of the scrotum when first presented; later on the residual urine by decomposition caused the evening rise of temperature. When there is an acute inflammation, with pus and putrid urine in the

tissues, you will often find, after evacuating the focus of infection, that a little delay will afford a better field-tissue to work in, and consequently a better result.

CASE II. *October 7, 1893. Multiple stricture, with fistulæ and infiltration of urine.*—Andrew Y., fifty-eight years of age, was referred to the clinic by Dr. Wright, of Mississippi, with a history of long-standing urethral obstruction, which, on examination, was found to be due to three narrowings, as shown in the accompanying diagram (Fig. 2). There was active inflammation of all the

FIG. 2.



tissues surrounding that portion of the canal contained within the scrotum. Six fistulæ were discharging pus through the scrotum and at the base of the penis. Nearly all the urine was voided through these fistulæ. The general condition of the patient was miserably bad.

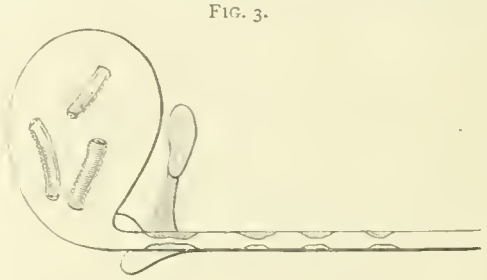
It was with much care and patience that a filiform guide was passed into the bladder, and, over this, Rogers' tunnelled urethrotome, aided by a little firm pressure, was guided past the membranous portion of the canal; then the bulb was formed, and the contractions cut to full size as the instrument was withdrawn. The deep stricture was cut in the floor of the canal, and the instrument was then reversed so as to cut the penile contractions in the roof. A staff was readily passed into the bladder, and on this the perineal urethra was laid open its full length from without. The various fistulæ were explored with a grooved director and laid open, so that thorough drainage was secured for these pus-infiltrated parts. The bladder was then emptied of a pint of foul urine and thoroughly irrigated. Examination of the bladder with the finger through the dilated prostatic urethra failed to disclose a calçulus. That no urine might come in contact with the newly-cut surfaces until granulations were well established, a soft-rubber catheter about the size of the urethra was now passed into the bladder, but before this was done a double silk ligature was passed through the wall of the catheter (avoiding encroaching on its caliber), about three or three-and-a-half inches from its point; then when the catheter was passed the ligature was found lying in the wound. A piece of gauze, folded to a size to fill the wound, was packed into it, and tied to the catheter by means of a ligature. This tampon of gauze served two purposes. It kept the catheter from escaping from the bladder, and it also checked the hemorrhage. The usual dressings of gauze and cotton, and a T-bandage were now applied, and the patient was put to bed.

External perineal urethrotomy was not only the safest procedure in the treatment of the deep stricture, but it was indicated to give rest to the anterior portion of the canal surrounded by fistulous tracks; besides, a thorough digital exploration of the bladder in such cases is highly satisfactory, and often reveals the presence of unsuspected foreign bodies.

Hemorrhage was but slight, and the patient made an excellent recovery. Sounds were reintroduced at proper intervals, and the patient returned to the clinic for dilatation up to March 8th, when all of the fistulæ had healed. A No. 30 F. sound could now be passed. There still existed much peri-urethral induration.

CASE III. *November 19, 1893. Cystitis; multiple stricture; foreign body in bladder.*—H. W., thirty-six years old, who was sent to the clinic by Dr. Branch, had suffered more or less with cystitis for five years, and had had a stricture for about the same length of time. His suffering had become intense, and urine was passed every few moments. Examination of the urethra revealed several contractions, as shown in the accompanying diagram (Fig. 3). External perineal urethrotomy

FIG. 3.

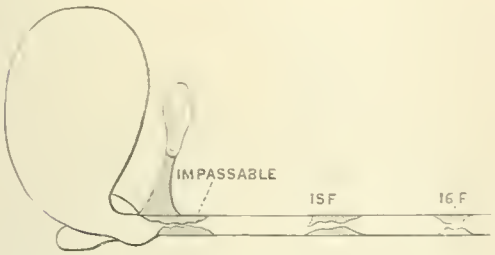


was determined upon, because of the number and the small caliber of the strictures. Free escape of urine through a perineal incision is safer than allowing the fluid to pass over multiple urethral incisions. Moreover, the contractions were very resistant to the sound, arguing against treatment by gradual dilatation. A small staff was passed and the perineal urethra laid open from without. My finger was passed into the bladder and a foreign body felt. With forceps three segments of a soft-rubber catheter, as you see here, averaging an inch each in length, were extracted. They are encrusted with phosphates precipitated from the urine. Here you have an example of a foreign body acting as a nucleus to a stone, and this case ought to re-impress upon you the advisability of putting your finger in the bladder whenever this is practicable. The urethra was cleared of all contractions. The patient, on coming from the anesthesia, recalled the time two years before when he lost the piece of catheter, but had forgotten to tell us before operating. He made an excellent recovery.

CASE IV. *November 22, 1893. Cystitis; multiple stricture.*—H. R., thirty-nine years old, suffered intensely with chronic cystitis. His symptoms began many months before, and had gradually grown worse, finally necessitating the act of urination every twenty minutes. The stream was very small. Examination with bulbous sounds located two penile contractions of the caliber as shown in the appended diagram (Fig. 4), while the membranous urethra here was so narrowed that it was impassable to instruments. Treatment by gradual dilatation was contra-indicated by reason of the impassability

of the stricture and the urgency of the symptoms. The bladder loudly demanded rest. A small staff was passed just into the membranous urethra. It was firmly pressed against the stricture and then reversed, its point being thrown toward the perineum, after Fleuhrer's practice, and the canal was opened by an incision through the perineum. Thus we were at the distal extremity of the membranous structure. The lips of the wound in the

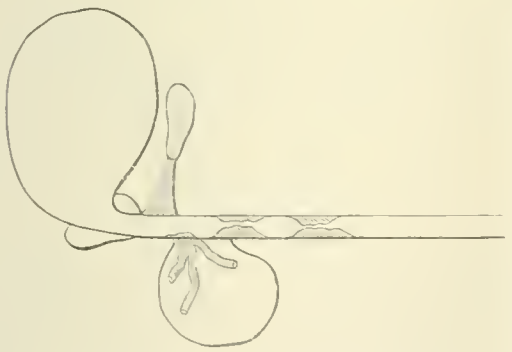
FIG. 4.



urethra were seized with forceps and held apart, and then with much teasing the small probe was passed along the tortuous and narrow canal into the bladder. Along the side of the probe a grooved director was forced until a drop of urine appeared, showing that the bladder was reached. The probe was withdrawn and the floor of the membranous urethra laid open upon the director. Internal urethrotomy on the two anterior strictures gave easy admission to a No. 32 F. sound. On January 4th the patient was dismissed, after passing in your presence a No. 32 F. sound.

CASE V. *December 19, 1893. Two penile strictures; multiple urinary fistulæ.*—G. G., forty-five years old, presented two pronounced urethral narrowings, as shown here in the accompanying diagram (Fig. 5). The pos-

FIG. 5.

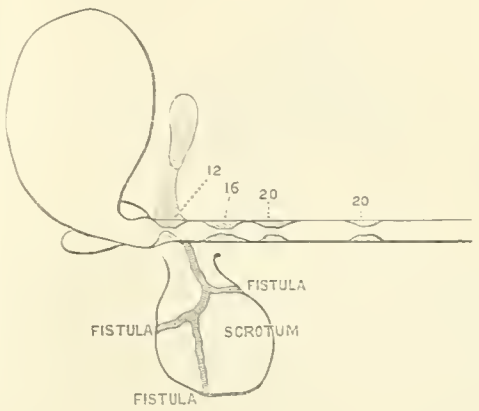


terior one involved the bulbous portion of the canal, and was so small in caliber that the urethra behind it, from the pressure of urine forced by the inflamed bladder, had given way. The urine first gave rise to the formation of an abscess, and later found vent through the three fistulous openings, as shown. All of the urine escaped through the fistulæ at the time the man was presented. His condition was bad in the extreme. Fever, pain, emaciation, constant and slow poisoning from the presence of pus in the scrotal tissues, together with cystitis, promised an early death. In this case internal urethrotomy alone might have been done and relief possibly obtained, but I greatly prefer doing the perineal operation from without in such cases, in addition to the internal penile urethrotomy. The posterior outlet affords rest to the inflamed anterior segment of the urethra, and you get more rapid improvement, both local and general; and this case truly exemplified such teaching.

The external perineal urethrotomy was done, and the bladder explored and irrigated. The patient steadily improved during the eight weeks of his attendance here, but, like most of this class of patients, as soon as the fistula had healed and he was getting along well he gave up treatment. The probability is that we shall see him here again next year in the same condition.

CASE VI. *January 9, 1894. Multiple stricture; four urinary fistulæ.*—G. R., thirty years old, had had repeated attacks of gonorrhea, which had resulted in numerous contractions of the urethra, as shown in the appended diagram (Fig. 6), which shows four pronounced stric-

FIG. 6.



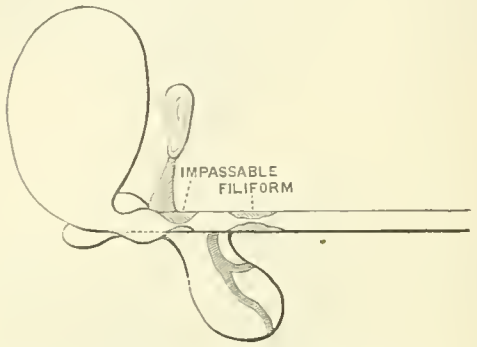
tures, ranging from a caliber of No. 20 down to No. 12 F. You will recall that the first step was an internal urethrotomy on the anterior urethra, cutting everything to size No. 30. Next, the point of a small staff was engaged in the membranous urethra; then the instrument was reversed so that the convexity was directed toward the pubis and the point bulged in the perineum. This is a procedure suggested and practised by Fleuhrer, and is worth remembering. It has frequently done me good service. With the point of the staff pressing toward the perineum the opening was easily made. The membranous urethra was laid open its full length. A No. 30 F. sound was passed. A catheter was then introduced and retained in the urethra by the means described in the report of Case II. Through this catheter the bladder was thoroughly irrigated; and the patient was sent to bed.

On February 1 sounds Nos. 30 and 32 were passed. The patient left the hospital, but returned frequently for the introduction of the sound, and is doing well. All of the fistulæ have healed.

CASE VII. *February 20, 1894. Two strictures with fistulæ; operation without a guide.*—O. W., thirty years old, gave a history of repeated attacks of urethritis. He passed water with much difficulty. There were two strictures, with two fistulous openings, as shown in the

accompanying diagram (Fig. 7). The perineum was inflamed, hardened, and infiltrated with pus. Every effort to pass a filiform guide into the bladder failed, and an incision was made through the perineum without a guide. The case was rendered especially difficult by reason of the condition of the perineum already described. No anatomic landmarks in the soft tissues were left, and reliance had to be placed on the sense of touch, aided by a good light. The perineum was carefully incised, keeping line by line well in the middle, with the left index finger guiding until the corded urethra was located, exposed, and seized with a tenaculum. The canal was then opened, and the small probe passed into the bladder; then this small director, on which the stricture was divided. The prostatic urethra was dilated, and the

FIG. 7.

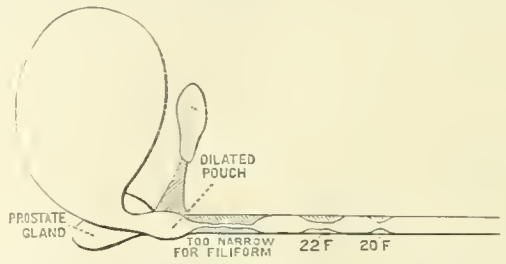


finger explored the bladder. Internal urethrotomy was next performed at this point, as indicated by the stricture, and a No. 32 F. sound was passed the full length of the canal. The sinuses were laid open. A soft rubber catheter was introduced and retained in the urethra for three days in the manner described In the report of Case II.

On March 8th the patient was doing well, and a No. 30 F. sound was passed.

CASE VIII. *Multiple impassable strictures; external perineal urethrotomy without a guide.*—G. B., thirty-eight years old, a white man, gave history of repeated attacks of gonorrhea. A stricture was known to have been in existence for several years. When the man presented himself he passed a pin-hole stream of urine with much pain, and was having fever every evening. The urine was voided with pain every half-hour, both by day and by night. You will recall that under anesthesia every effort was made to pass an instrument into the bladder, but without success. The filiform guide, even, failed to enter. The appended diagram (Fig. 8) shows the location of the various contractions and the caliber of each. The guide would not enter the perineal urethra. There was no peri-urethral collection of pus, no false passages to mislead. The perineum was in its normal condition. External perineal urethrotomy was done without a guide. You will further recall that very little trouble was experienced in finding the urethra just anterior to the prostate gland, where, as I have shown you on the diagram, this dilated condition existed. Upon opening the urethra in this dilated part, the next step was to explore the bladder with the finger, and allow me to again recommend that you do not fail in these cases to do this. No stone was found. The canal was then traced forward, the urethrotome freely used, and a full-sized sound passed. After ten days the patient was up and left the hospital, able to pass a No. 30 F. sound.

FIG. 8.



You will rarely find a case suitable for external perineal urethrotomy without a guide presenting so anatomically clear a perineum; and the ease of performance of the operation in this case should not mislead you to consider it a trivial procedure. A correct understanding of the anatomy was all that was needed in this instance, but do not forget Case VII, which presented such a contrast to this.

The pouch-like condition of the urethra is said by Cocke to exist in all cases of impassable stricture of the membranous urethra. The mechanism of the formation of this pouch I have more than once explained to you.

CASE IX. *February 10, 1894. Chronic cystitis.*—Wm. McD., a white man, twenty-three years old, had been for twelve or more years a sufferer with cystitis, the origin of which he could not explain, never having had any venereal disease. Aside from the bladder-complaint his general health was excellent. His left hip-joint was ankylosed and the limb was a little shortened in consequence of an arthritis in early childhood. The call to urinate was almost constant, and had to be complied with every half-hour during the day, and his getting up at night, urinating and returning to bed, had become so nearly automatic, that though for years he arose a score of times each night, his health had suffered little or none. He was able to attend regularly to his work as cashier in a retail store. His urine had never contained blood, but frequently was clouded with pus. There was not much pain in the act of urination, though much discomfort was caused by an effort to retain more than a few ounces. The patient had been under observation for some months. At no time had I found tube-casts or epithelium in the urine pointing to a kidney-complication. There was, however, an abundance of pus, and the urine was either neutral or alkaline in reaction. At times the urethra showed inflamed patches when viewed through the endoscope. There was no urethral narrowing. Each introduction of an instrument into the deep urethra, whether cocainized or not, caused dizziness and, if persisted in, fainting.

I had failed after repeated explorations to find any stone. Medicinal therapeutics had been appealed to, but had signally failed to afford any relief. Irrigation of the bladder had not afforded benefit, and I found that the bladder would not retain more than three ounces of warm solution. An effort was made to overcome the

contracted bladded by hot-water injections, but I was unable to increase its holding-capacity. Having exhausted all of these resources for relief, I determined on digital exploration of the bladder. The viscus was not susceptible of dilatation, so that suprapubic cystotomy was not practicable. A subpubic route was thus forced upon us. The ankylosed hip caused but little inconvenience in performing external perineal urethrotomy. With my left forefinger introduced into the bladder I found the walls of the viscus (as felt between the finger within the cavity and the right hand pressing down above the pubis) hypertrophied to at least an inch in thickness. The vesical cavity was divided into two compartments, so to speak, by a slight transverse narrowing, while the surfaces felt very rugged and ulcerated. As nearly as I can describe the condition, it resembled the inner surface of a hide newly taken from a beef by a novice at skinning. I could easily explore the entire surface within, and found neither tumor, pocket, nor calculus. The case was one of chronic inflammation of the bladder; the question of causation was obscure and of no interest now, because we had before us the effect of prolonged inflammation, a thickened, hypertrophied bladder, not amenable to any treatment. The neck of the bladder was forcibly dilated, and paralyzed temporarily. At the end of a week the patient was up, with the wound nearly closed, and able to retain urine for an hour and a half at a time. After four weeks the bladder had resumed its former half-hour regularity of action. The patient was fitted with a rubber urinal for use day and night.

In this case you saw a condition that needed treatment —one like many that you will encounter in practice, whose cause you cannot remove, because you cannot locate it, and, in fact, an original cause often ceases to act, leaving behind it a morbid condition, which sometimes is one that we cannot remedy.

CLINICAL MEMORANDUM.

THREE CASES OF GLYCOSURIA COMPLICATING ATTACKS OF APPENDICITIS,

With the Report of a Case illustrating Nature's Rôle in Effecting a Cure.

BY JOSEPH LEIDY, M.D.,
OF PHILADELPHIA.

So far as I have been informed, glycosuria has not been noted as a condition complicating appendicitis. The following notes of several cases that have come under my observation during the past three years may prove of some interest to those interested in this, one of the most important affections that the physician and surgeon has been called upon to treat during the past decade.

The first case is that of a young woman, referred, during the fall of 1890, to the Pennsylvania Hospital by the late Dr. D. Hayes Agnew.

L. H., twenty-nine years of age, single, of good family history, enjoyed good health until the age of twenty-three, six years ago, when she was seized with an attack of obstruction of the bowels (which was the diagnosis made at that time). Since then she has been the subject of recurrent attacks of inflammation in the right iliac fossa, presenting the classic symptoms of appendicular troubles. A firm irregular tumor formed in the right iliac fossa after the first attack, and this has remained. Examination upon admission to the hospital showed the presence of an indurated mass in this region, which had become firmly adherent to the overlying tissues. At a point midway between the anterior superior spinous process of the ileum and the spine of the pubic bone, two inches above, in the line of the iliac artery, is a sinous opening, which had formed since the last attack, three weeks before. Upon the introduction of a probe the point of the instrument came in contact with a hard foreign body, one and a half inches from the opening. The patient applied for treatment, an operation if necessary, to relieve her from her suffering. Her physical condition was fair, notwithstanding her complaint, which, however, was fully explained by future developments. An examination of the heart and lungs proved negative. Urinary analysis showed the urine to have a specific gravity of 1032, and to be pale-amber in color, alkaline, with some sediment. Microscopic examination proved the presence of oxalates and epithelium; and chemic examination disclosed sugar, 2½ per cent.; no albumin or casts were present.

Owing to the inflamed condition of the surface of the skin in the iliac fossa, with the presence of a foreign body, a large flaxseed poultice was applied over the tumor. On the second day there presented at the mouth of the sinus a hard mass, three-eighths of an inch in diameter, which proved later, upon examination, to be inspissated feces; this was removed. Under local treatment the mass rapidly subsided, and before the woman's discharge from the hospital the sinus had healed perfectly, with complete absorption of the induration. This patient made a perfect recovery. The sugar gradually disappeared from the urine, and six months later it had entirely disappeared. It is now four years since the woman came under treatment, and she enjoys perfect health; there has been some gain in weight, and she suffers no disability. The urine is negative. The physical condition of this patient was good upon her admission to the hospital, and was doubtless to be attributed to the attempt on the part of Nature to effect a cure by throwing off the materies morbi, the irritating factor, through an external channel. It is interesting as showing an important rôle which Nature often plays in inflammatory conditions—never, unfortunately, to be depended upon.

The second case was that of J. R., forty-six years old; single; a housemaid; who presented herself at my office during May, 1892, having been under the care of several medical advisers during the previous two weeks, for attacks of acute indigestion. She had always enjoyed perfect health.

The following I transcribe from my case-books: "Temperature 103.4°; pulse rapid, 110; respiration 28; a thickly furred tongue. The patient complains of much nausea, with pain about the umbilicus; the bowels are constipated. Examination of the abdomen showed the presence of a hard mass, the size of a duck-egg, in the right iliac fossa, where there is sensitiveness to pressure. The patient is perspiring from weakness, following the physical examination." She was sent home and placed in bed. An examination of the urine at this time showed a trace of albumin and considerable sugar, with a

specific gravity of 1028. She was the following day transferred to the Pennsylvania Hospital; here she remained thirteen weeks. Frequent examinations of the urine showed the presence of sugar in varying quantities. Under non-operative treatment this patient improved. Unfortunately, after her discharge all trace of her was lost.

My third case was that of A. S., a male, twenty-five years old, single, and greatly emaciated, owing to frequent attacks of appendicitis. He had been treated for several attacks of inflammation of the bowels and for lung-trouble during the past two years. This patient was seen for the first time six months ago, during an attack of severe abdominal pain, attended with exquisite sensations over the whole abdomen, high fever and constipation, which suggested a beginning peritonitis. The focus of pain could not be located. Under absolute rest and medical treatment the inflammatory condition slowly subsided, and soon became localized to the right iliac fossa. After a week of the treatment outlined, all pain and tenderness had disappeared, except over a small area that could be covered by a silver dollar. Over the so-called McBurney's point, upon deep pressure an irregular, indurated nodule could be felt. A continuance of absolute rest, liquid diet, local treatment in the form of poultices and enemata, enabled me to subject the whole abdomen to the severest pressure, without eliciting the slightest pain except over the nodule spoken of. An examination of the urine at the beginning of this attack showed the presence of sugar, a trace of albumin, no tube-casts, and specific gravity 1032. Owing to the extreme emaciation of this patient, with signs of beginning pulmonary disease, with the possibility of the etiology of the condition being tuberculous, operation was postponed until he had regained sufficient strength. At an unfortunate moment during convalescence, feeling so much better, he left his bed to indulge in a too generous meal. This induced an attack of indigestion, followed by constipation, and a relapse worse than the first attack, which he feared would terminate in a general peritonitis, However, he made a fair recovery, and after a prolonged convalescence gained sufficient strength to leave the city. He has steadily improved, and this I was informed has always been the case when at the seashore. During convalescence the sugar disappeared, only to recur in varying quantities. This patient has gone a week without the slightest trace of sugar being found. At this writing sugar has been noted but once during the past four weeks. He remains under treatment, and I shall again report as to the progress of the case.

These cases present the condition of glycosuria complicating appendicitis. In one case the sugar entirely disappeared; in the second the result is negative, owing to my inability to trace the patient; in the third there was a decided betterment. The first case presents Nature's part in her rôle as a friend to the surgeon.

That irritation of the lymphatic nervous symptom has occasioned glycosuria, so-called reflex glycosuria, has been recognized, and in all probability is the explanation of the existence of glycosuria in these cases. The symptom may be considered rare, as in a large number of patients suffering from this condition which have come under my observation I know of but one other, and that is the case to be reported by Dr. T. S. K. Morton. This, I believe, however, is a case of true diabetes.

THERAPEUTIC NOTE.

OXALIC ACID IN COMBINATION WITH IRON AND MANGANESE PEPTONATES AS AN EMMENAGOGUE IN CHLOROSIS.

BY HOMER C. BLOOM, M.D.,
INSTRUCTOR IN GYNECOLOGY IN THE PHILADELPHIA POLYCLINIC AND OUTDOOR SURGEON TO THE GYNECEAN HOSPITAL.

NEARLY a year ago I reported a number of cases in which I obtained successful results from the use of oxalic acid as an emmenagogue and oxytocic.[1] Since that time I have been able to gather a larger number of cases, making the clinical data more satisfactory, as well as establishing this therapeutic procedure upon its true basis. The apparent success at the time seemed to indicate that oxalic acid was indeed the ideal emmenagogue, but subsequent experience has shown that it, like all other drugs or supposed specifics, frequently disappoints in its results.

It is not the intention of this article to belittle or undervalue the therapeutic position of oxalic acid as an emmenagogue, but, upon the contrary, to place it in its true position; for I look upon it, other conditions being equal, as the surest and safest emmenagogue. My early enthusiasm was, I confess, excessive, as more recent clinical studies have shown; and it is to correct as nearly as possible the unintentional over-valuation of the power and value of the drug that these introductory remarks are made.

Since October, 1893, I have employed oxalic acid as an emmenagogue in over one hundred cases, including all forms of amenorrhea; for instance, that dependent upon pelvic disease, the functional perturbation consequent on exposure to cold during the menses, traumatic injuries, and emotional shocks.

Here I would note that the only rational explanation of the frequent cases of amenorrhea occurring among girls or young women following a sea-voyage is to be found in some peculiar nervous phenomenon which is emotional in character; and these cases strengthen the theory recently announced of the nervous origin of menstruation, for in the great majority there seems otherwise to be little deviation from health. It is in this class of cases that oxalic acid will establish the menses in nine cases out of ten in which there is no serious nutritive disturbance.

In cases in which there is a deviation from health which acts as the predisposing cause of the amenorrhea, oxalic acid, uncombined with other treatment looking toward the establishment of a better hematosis, to an improved general nutrition, and to a more nearly normal action of the nervous system, will utterly fail.

From experience gained since the publication of my first article on this subject, I am disposed to think that there are many cases of pregnancy in which oxalic acid fails to display ecbolic power, although in a certain number of cases it is a reliable and safe oxytocic; so that I would trust it in all such cases as the safest and most expedient remedy for the termination of a pregnancy for legitimate purposes.

[1] See THE MEDICAL NEWS, October 14, 1893, p. 431.

When my previous article appeared I had very little experience with the use of oxalic acid in the treatment of chlorosis, and I asked for the drug a more extended trial. Since that time I have had abundant evidence to demonstrate its uselessness in the large majority of cases, uncombined with other drugs looking to the correction of the function of hematosis.

Once in a while a case has been met with in which the anemia was not very pronounced, and in which the acid has seemed to govern, in some way or other, the function of hematosis and bring on the menses.

In a certain number of cases of chlorosis all the usual therapeutic measures fail. A large percentage of cases of amenorrhea are in turn due to chlorosis, and the suspension of menstruation may be viewed as a conservative effort on the part of Nature to spare the system every unnecessary tax or expenditure.

The therapeutic indication, therefore, is not alone the re-establishment of the menstrual flow, but rather the restoration of the general health. With this in view, I have employed a combination of iron and manganese peptonates, which I found to be readily and easily assimilated.

It acted well in cases of deranged functional hematosis, in which there was pronounced chlorosis, with amenorrhea, although it failed in a large number of cases to reëstablish the menses long after the anemia had disappeared. Why this should be so I cannot say. We know from clinical observation that after the entire disappearance of the condition of chlorosis itself, there is often a persistent amenorrhea; and we further know that in these cases there is a strong neurotic element, which may account for the derangement of function which manifests itself in the form of amenorrhea.

With these points in view, and having had my attention so strongly attracted to the peculiar action of oxalic acid in certain cases, and especially in chlorotic cases in which the nervous phenomena were more or less pronounced and the amenorrhea failed to yield to the betterment of the function of hematosis induced by the administration of ferruginous salts, I was led to prescribe oxalic acid in combination with iron, with the result that the amenorrhea was cured; and with a restoration of the menses the nervous phenomena disappeared.

The formula used is as follows:

R.—Ferri peptonat.	. . . .	gr. xij.
Mangani peptonat.	. . .	gr. ij.
Acid. oxalic., C. P.	. . .	gr. ij.
Alcoholis	. . . .	℥iij.
Aquæ	. . . q. s. ad	℥iv.—M.

S.—℥ij t. i. d.

While the results are obvious, the mode of action of the drug is not so clear. Perhaps this is to be found in an influence exerted on the nerve-supply of the organs directly concerned in the function of menstruation.

1427 WALNUT STREET.

The New York State Association of Railway Surgeons will hold its annual meeting on November 15, 1894, at the New York Academy of Medicine. All railway surgeons of the State are invited to be present.

NEW DEVICES.

A SIMPLE AND EFFICIENT TEST FOR BINOCULAR READING.

BY CARL WEILAND, M.D.,
CLINICAL ASSISTANT, EYE DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

IT is frequently of importance to know whether both eyes assist each other properly in the act of reading, or whether one eye only is used, while the other deviates or otherwise neglects its duties. The usual test of holding a prism, base up or down, in front of one eye and observing whether or not a point looked at is seen double, is not quite decisive; because such a high prism always throws the image of its eye outside of the macula lutea, and thus gives rise to an entirely abnormal and unphysiologic condition. We are not allowed to assume from this test that the eye which receives the retinal

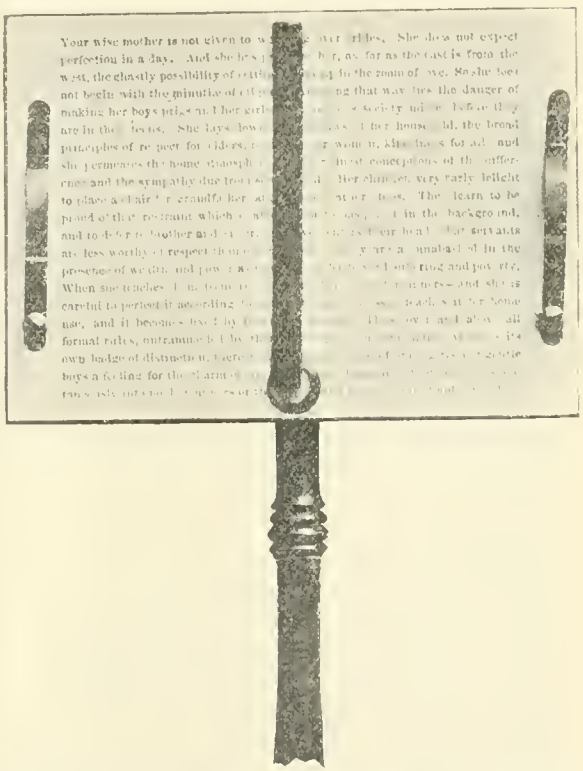


image thrown outside of the fovea will therefore also take part in the act of reading, as the fovea might be affected with a scotoma, or the whole eye be in a position of heterotropia, and avoid diplopia by suppressing its image. For this reason a little apparatus is here brought forward which allows a test under strict physiologic conditions, and which, in one form or other, has probably been employed already by some ophthalmologists.

It consists, as the figure shows, of a rectangular piece of wood, into which a brass rod, five mm. in diameter, is screwed. This rod is bent at a right angle, so that the free part extends parallel to the surface of the wood at a height of about fifty mm. Upon this wooden base

some print is fastened of a size that corresponds to about fifty cm.; but any finer or coarser print may be used, if the case requires it, for which purpose two springs have been added.

This little contrivance is now held by the patient at the usual reading-distance, while the head and hand are kept in the same position. It is evident that in this situation there are *two* places on each line of the print from which the rays can enter only *one* eye, being intercepted for the other by the rod. But as one eye always can see what on account of the rod is not perceived by the other, there can be no gap in the line if both eyes are used at the same time. As soon, however, as one eye does not perform its function there is a black line across the printing matter, so that the words covered by it cannot be seen at all.

This little test may now be used for the following purposes:

To determine whether the patient employs both his eyes in the act of reading, or whether one deviates. If he uses only *one* eye the black line will appear; and if the other eye only deviates it will, on covering the first, read the print also distinctly, but the black line will appear in quite a different position as with the first eye.

To see whether both eyes, after having been made emmetropic for distance, have the same accommodation. For if this is not so, if there is a complete or partial cycloplegia in one eye, there will be certain words on each line that appear indistinct and blurred, though not entirely absent, as before, when one eye was not employed at all.

To detect a malingerer who claims to be blind in one eye. Of course, if he can read a whole line he is convicted.

To make physiologic experiments as to the question of simultaneous unequal accommodation of both eyes, and to study the difference in the retinal images of both eyes, and the heterophoriæ necessarily connected with anisometropia, especially in certain positions of the print.[1]

315 North Sixth Street.

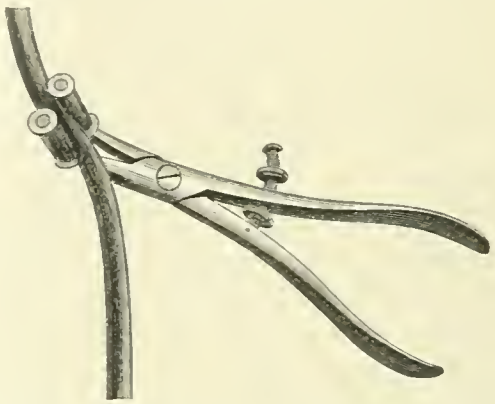
THE TUBE-STRIPPER.

By A. L. BENEDICT, A.M., M.D.,
LECTURER ON DISEASES OF THE DIGESTIVE ORGANS, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO; CONSULTANT IN DIGESTIVE DISEASES, RIVERSIDE HOSPITAL, BUFFALO.

The instrument to be described was devised in the spring of 1893. Its construction was suggested by the difficulty of removing the stomach-contents through the usual tube. Cases in which expression of the gastric contents is practicable by forcible pressure over the organ are rare, while an attempt to strip the tube with the fingers is tedious and, on account of friction, causes an annoying jerking. At the same time, it is evident that the ordinary aspirators and the rotary surgical pump might cause hemorrhage by too powerful suction.

The instrument consists of the levers of a heavy cutting-forceps. A roller, with flanges to prevent the slipping-off of the tube, is attached at an angle of 105° to each cross-piece of the forceps. The rollers are, of course, parallel, whether the levers are open or shut. An angle a little greater than 90° was chosen, so that the hand would not interfere with the tube as it passes between the rollers. By holding the handles together and running the rollers down the tube the air is forced out, while the elasticity of the rubber causes a vacuum into which the stomach-contents rush. At the same time the suction of an ordinary length of tube is not sufficient to damage the stomach-wall should it be drawn into the openings in the tube, unless some serious ulceration or vascular degeneration exists. In such cases the passage of the stomach-tube would, at any rate, be contra-indicated.

A threaded bar is fitted into one handle of the instrument and passes through an opening in the other handle. A nut with a milled margin is placed on this bar between



the handles, so that exactly the desired degree of compression can be exerted. A second nut outside the handle serves to lock the instrument, although this is seldom necessary.

The instrument has proved satisfactory as an adjunct to the stomach-tube. I have had but one opportunity to test its usefulness in other directions, namely, in a case of pleurisy with effusion. About a yard of rubber tubing was fitted into the end of a simple aspirating-needle, which was plunged into the chest with all aseptic precautions. The tube was stripped with the instrument, an assistant pinching the tube near the canula when it was necessary to reapply the rubber. About 400 c.c. of dark fluid were removed, when the patient began to cough and aspiration was discontinued. It was not necessary to tap again.

The cost of the tube-stripper is about $2.50, so that the entire cost of an aspirating outfit will be less than $5. While too feeble and slow in its action for many of the purposes for which a surgical pump is needed, this instrument has the advantage of compelling extreme caution, and, in many cases it will be found an efficient, simple, and cheap substitute for various expensive aspirators.

A NEW COVER-SLIP FORCEPS.

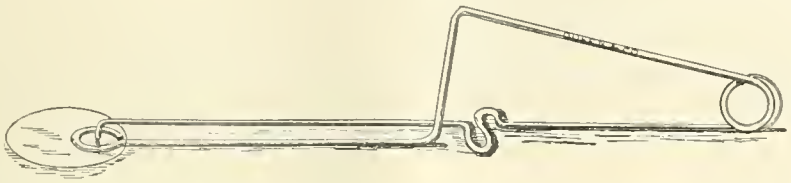
By H. R. GAYLORD, M.D.,
RESIDENT PHYSICIAN IN THE PHILADELPHIA HOSPITAL.

It has occurred to me that there is need of a simple and inexpensive cover-slip forceps. The least expensive forceps of this kind which is satisfactory is retailed at a cost of sixty-five cents, a price somewhat too high to

[1] This test is manufactured by Queen & Co., 1010 Chestnut Street, Philadelphia.

warrant their free distribution in laboratories, where they are likely to be mislaid or lost. It was the necessity of having to share a pair of cornet forceps with two other students which first suggested the forceps here presented. It is simply the development of the bent hair-pin which we have all used.

The forceps is made of nickel-wire, bent in the shape shown, and so constructed that the stain will not "run" on the forceps, and that when placed on a plane surface it stands upright, holding the cover-slip in a horizontal position.



It is admirably suited to "smear-work" of the clinical sort, and can be used even for section-work, although not so well adapted to this use.

The principal claim to be made for the device is the extreme low cost of its manufacture, which adapts it to laboratory-use. If purchased in quantity the expense would be trifling. At present it can be bought for about one-third the cost of the cornet forceps. Messrs. Queen & Co., of this city, have kindly undertaken the manufacture.

MEDICAL PROGRESS.

Hernia of the Bladder.—Rose (*Lancet*, No. 3700, p. 194) has reported the case of a woman, twenty-four years old, who had been the subject of a hernial tumor for three years, and had been anemic for a number of years. The hernia was reducible, but a truss had been worn until three weeks before the woman came under observation, when the hernia became so painful that the pressure of the truss was unbearable. Nine months previously there had set in pain on micturition, and at times the woman had gone twenty-four and thirty-six hours without passing urine; she had an impression that at these times the swelling always increased in size. Micturition had become so painful at times that she had to support the rupture with the hand to secure relief. An ovoid swelling, about an inch long and half an inch wide, was present in the left inguinal region, with its long axis in the direction of the canal, and extended downward and forward toward the center of the left labium majus; there was a distinct though slight impulse on coughing, and at times the swelling became as large as a small hen's egg. When the patient had been gotten ready for operation and was anesthetized, and was placed in the recumbent posture on the table, all trace of the swelling disappeared. An oblique incision about three inches in length was made, with its center over the external abdominal ring, which was clearly defined, but no protrusion was found and no laxity of the abdominal wall felt. At this moment the patient fortunately vomited, and a small protrusion occurred through the external abdominal ring. This was drawn well down, and after clearing the fascia away it was incised. The wall was much thicker than was expected, and a few drops of a straw-colored fluid escaped, which proved to be urine, indicating that the cavity of the bladder had been entered. The wound was at once douched with a 1:40 carbolic lotion, and the vesical incision closed by a double row of fine catgut stitches, which included everything but the mucous membrane. During the necessary manipulations a second attack of vomiting caused the protrusion of a small swelling just external to the preceding one. On laying hold of this the peritoneal membrane gave way and a fine piece of omentum protruded. As this latter was somewhat extensive, it was ligated in successive portions and removed, the stump being returned into the abdomen. The peritoneal sac was now well drawn down, transfixed with catgut and tightly ligated and cut away, the upper part at once retracting within the abdomen. Three deep sutures were now passed through the parietal wound and the canal closed, whilst the external wound was sutured and dressed in the usual way, a drainage-tube being introduced. After the patient had been put to bed a rubber catheter was tied in the bladder and the urine permitted to run off. The first few ounces that passed were blood-stained, but subsequently the secretion came away quite clear, twenty-one ounces being voided in the first fifteen hours. There was no vomiting and the case progressed to convalescence without a hitch. The patient subsequently had one or two slight attacks of retention, although there was no return of the pain or discomfort previously complained of. The cicatrix in the groin became firm, and there was no return of the hernia.

Suture of a Divided Sciatic Nerve.—Dallas-Pratt (*Dublin Journal of Medical Science*, September, 1894, p. 198) has reported the case of a poorly nourished lad, sixteen years old, who came under observation two hours after suffering an injury causing a wound of the right thigh seven or eight inches long close to the fold of the nates, at right angles to the long axis of the member and extending nearly from the middle line on the inside to within a short distance of the middle line on the outside. All of the structures at the back of the thigh were divided down to the femur, including the great sciatic nerve; the wound gaped to the extent of at least five inches. There was comparatively little pain and no hemorrhage. A quantity of machine-black, lubricant, and portions of clothing had been ground into the wound. The lad was at once anesthetized with ether and the wound cleansed with a 1 to 40 carbolic lotion. The ends of the divided nerve were found in a badly lacerated condition, so that it was necessary to remove nearly half an inch of each in order to secure a clean and solid surface to suture. Then it became necessary to stretch the ends until they came together without tension, when they were united by means of three sutures of fine carbolized silk introduced by means of a small needle; two were passed

through the sheath of the nerve on either side, and the third through the substance of the nerve at the center. In the case of all six sutures the distance of the punctures from the cut end was about a quarter of an inch. The muscles were sutured with silk and the skin brought together by means of hare-lip sutures. The surface was dusted with iodoform, a dressing of gauze was applied, and the thigh extended and the leg flexed as much as possible and fixed in that position on a splint. For a few days the patient had some pain, but the wound maintained a good appearance. The only complication was the formation of a number of trophic ulcers on the toes of the affected extremity, which, however, healed without much trouble. After the lapse of eighty days the patient had recovered use of the member sufficiently to be able to walk fairly well; sensation had returned in all parts of the extremity except the dorsum of the foot and toes.

Indications for Thoracentesis.—In an elaborate article, Causade (*Gaz. des Hôp.*, 1894, No. 50; *Centralbl. f. innere Med.*, 1894, No. 34, p. 831) defines the indications for paracentesis thoracis as follows: The procedure is urgently demanded in cases of serous pleuritis, in which the amount of exudate reaches 1800 c.cm. Under these circumstances the upper border of percussion-dulness in the sitting posture is at about the level of the second intercostal space. No time is to be lost in making the puncture, as the presence of this quantity of fluid in the pleural cavity is attended with the danger of sudden death, even in the absence of dyspnea or other alarming symptom. In cases of serous pleuritis complicated by disease of the heart or by pericarditis, in cases of carcinomatous or tuberculous pleuritis, and in cases in which the dyspnea is pronounced, puncture is indicated as a palliative measure, even when the amount of the effusion is not large. The same indication exists in cases of pneumothorax. In the following conditions the indication for thoracentesis exist, though not urgent: (1) In cases of serous pleuritis of protracted course, with elevation of temperature and tardy or failure of diminution in the effusion; in such cases the course of the disease is shortened. (2) In cases of empyema in children, as well as in cases of empyema whose causative microörganisms are on examination found to possess a low degree of virulence; of particularly favorable prognosis are cases of empyema dependent exclusively upon the pneumoniacoccus. (3) It is an open question as to whether or not thoracentesis should be practised in cases of hydrothorax and pneumothorax; in some cases beneficial palliative results will be obtained, but no rigid indications can be laid down.

Chlorosis and Amenorrhea with Symptoms of Brain-disease.—Thomson (*British Medical Journal*, No. 1742) has reported the case of a school-teacher, twenty-three years old, who first menstruated at the age of sixteen and a half years, and was regular until the age of twenty. From this time menstruation had been irregular and scanty, sometimes stopping for as long as three months. For nearly a year there had been general weakness, loss of appetite, headache, giddiness, attacks of vomiting and drowsiness. The headache came on especially after movement, sometimes keeping the patient in bed all day, and also at times preventing sleep at night. The headache was frequently accompanied by severe vomiting, which took place independently of meals and occurred most often in the mornings. Attacks of faintness and giddiness were exceedingly frequent, so that the patient had to seize hold of anything within reach to avoid falling; they came on in bed on turning from one side to another, and mostly ended in vomiting. Sleep was heavy and disturbed by dreams. On one occasion diplopia was present with more or less severity for about four weeks. The face, conjunctiva, and lips were extremely pallid. Objects viewed with the left eye appeared smaller than with the right. Both eyes presented optic neuritis. There was a hemorrhage near the disc in the left eye. Under treatment with iron, strychnin, and aperients there was constant improvement in vision and in the general condition. Subsequently iron and arsenic were given, and the woman progressed to perfect recovery.

A case of chlorosis and amenorrhea presenting symptoms of brain-disease is reported by Burton-Fanning, and one of amenorrhea, presenting similar symptoms, by Jollye in the *British Medical Journal*, No. 1747, p. 1354.

THERAPEUTIC NOTES.

The Medicinal Treatment of Chronic Epilepsy.—As the result of an extended series of observations carried out at the Alabama Insane Hospital, Bondurant (*American Journal of Insanity*, July, 1894, p. 23) arrives at the conclusion that borax, antipyrin, acetanilid, phenacetin, and many other alleged anti-epileptic agents are, save in rare instances, without influence over the course of chronic epilepsy associated with insanity. Beta-naphthol is occasionally beneficial, but probably not more so than catharsis. The bromids will postpone the occurrence of the convulsions, but will in most cases do more harm than good. In dealing with the maniacal attacks seclusion may be necessary. Sedatives should be employed very rarely, if at all. The best single remedy in the *status epilepticus* is bloodletting. Of drugs, the most valuable is chloral.

For the Lubrication of Catheters.—To facilitate the exploration of the urethra and bladder in his wards in the Necker Hospital, Professor Guyon (according to the Paris correspondent of the *Lancet*) is in the habit of using the following formula: Powdered soap, 4 drams; glycerin and water, of each, 2 drams; mercuric chlorid, 1 grain. This ointment is said not to be irritating to the urethra, and to be endowed with much greater lubricating powers than either oil or glycerin.

For the Night-sweats of Tuberculosis.—

℞.—Liq. potassii arsenitis } . āā ♏lxxij.
Tinct. belladonnæ }
Aquæ laurocerasi . . . f ℥j.—M.

S.—Fifteen or twenty drops to be taken at about 5 P.M., and if necessary to be repeated at bedtime.—Skézely, *Sem. Méd.*, 1894, 44; *Corr.-bl. f. Schw. Aerzt.*, 1894, 17.

SATURDAY, SEPTEMBER 29, 1894.

A GRADUATE IN CRIME.

THE criminal annals of the State of Pennsylvania do not furnish, so far as we know, the record of a more significant event than the murder just committed at Lebanon by a released convict. It was the triumph of a legalized assassin; the crowning event in a career made possible only in a civilized State. It was a baccalaureate achievement wrought by the hands of a recent graduate in crime. It was done by one who had taken every course, save one, in our tribunals and our jails, and who will doubtless soon receive the final pass for his master's degree at the hangman's hand.

From authentic sources we learn that this convict, GARRETT, was discharged from the Eastern Penitentiary, in this city, on September 12, 1894, after serving a term of four years for a murderous assault on an aged man. On the same day he returned to his home in Lebanon, this State, and on the following morning he murdered his young wife by cutting her throat. He then escaped. He had made threats against his wife while still in the Penitentiary, because it seems she was making a laudable attempt to be divorced from him; and at this writing he is supposed to be still lurking about Lebanon, intending to kill a lawyer and two detectives, whom also he had threatened.

The career of this jail-bird is full of interest. When he was eighteen years of age he was convicted for larceny, and since that time, he being now only twenty-nine, has "figured *eight times* before the County Court, charged with offences ranging all the way from larceny to riot and attempted highway robbery." For his last offence—the assault upon an aged man—he was sent for the short term of four years to the Penitentiary, and thence, his inadequate term having expired and the authorities not having any alternative, he was discharged, to go at large once more and to rob and murder. Not thus would it have been if a rattlesnake or a mad dog had been set loose upon the street. So far as we know, no warning cry was given out when this monster was ejected from the portals of the penitentiary. No one ran ahead calling upon men and women to beware. The *posse comitatus* did not sally forth from Lebanon to annihilate him at the gates. The lawyer and the detectives were not scared. The wife sat peacefully and awaited her doom. Law slept, justice cowered, reason turned away her face, and science, as usual, was ignored. And why? Because this man was under the ægis of the law; in theory a reformed criminal, with the great seal of the Penitentiary on his diploma, with his sentence commuted for good behavior (save the mark!) and the crimes of his past life expiated on bread and water!

We conceive that this whole affair is atrocious beyond the power of pen to write, and disgraceful to civilization almost beyond credence.

As a counterpart of the case here discussed comes the report from England of the murder of a woman by her insane husband, who had been at different times in various insane hospitals and who suffered from homicidal delusions. In spite of the facts the man was released from time to time and permitted to procreate a family of eight children. The woman was delivered of a child about a week before death, but the husband would not allow her to receive medical attention. Besides, there was evidence that the man had severely beaten the woman. In this case the jury that held the inquest rendered a verdict of manslaughter.

The congenital criminal, we know, for science teaches, is beyond reclaim, but he is not beyond salvation. The law makes the fatal mistake of not recognizing him; science makes the equally fatal mistake of recognizing him in too technical a manner. It is unwisdom in the law to cling to an

exploded theory of crime and an antiquated procedure for "punishing" it; but it is useless for science to merely formulate that "atavism has hurled the congenital criminal back thousands of years and has placed him beside his pithecoid ancestor." We need something more enlightened than such law; something more universally intelligible than such science.

For, as we have said, the congenital criminal is not beyond salvation; but first of all he needs salvation from himself. He is not fit to be a social unit, nor even to be a unit unto himself. The State must step in and possess him. He is not to be "punished," but to be appropriated. The stigmata of degeneracy, of a fatal heredity, are upon him. If the law is not satisfied with the teaching of science, let the courts demonstrate the facts. Let them convict once, and then twice, and then thrice—and then, if it be not too late, let the State step in and settle the matter forever. We contend that an incorrigible criminal must be isolated for the term of his natural life, and that this is not only better for society, but is more humane for him.

Are our jails the universities of crime, and are our courts their preparatory schools? Was not Buzzard, the Lancaster brigand, "converted" in the penitentiary, and then discharged to prey (not pray) at his leisure? He is now convicted again; lucky, perhaps, that he has not killed someone, and ready once more to receive grace and disgrace at Cherry Hill. He doubtless will be graduated again—and then let all who are concerned beware!

We do not raise here the question of insanity, although it is inextricably interwoven with this subject of inveterate criminality. This malefactor Garrett, we are credibly informed, was not believed to be insane while in prison; in fact, he had reason to suspect his wife's fidelity. Neither do we reflect upon the officials at the Penitentiary, who have no authority to detain a convict whose sentence has expired. But we condemn without measure a system of criminal jurisprudence which is responsible for such a crime.

EDITORIAL COMMENTS.

The Anti-Opiate Society of America is the name of an association formed in New York City for the laudable purpose of using such means as may from time to time be considered best to prevent the unnatural use and the abuse of such drugs as opium and its derivatives, cocain, chloral, and other drugs whose use is both pernicious and injurious.

The means now being used by the Society to attain this end are as follows: 1, the calling of public attention to the enormity of the evil; 2, the free dissemination of leaflets, pamphlets, books, and other literature bearing on the subject; 3, agitation of the matter in the press of the country; 4, efforts to secure legislative enactments regarding the sale of the drugs and preventing indiscriminate traffic therein; 5, also the enforcement of such laws when made.

Some States possess laws prescribing the manner in which opiates may be sold and used, but very few of these laws are enforced.

According to reliable statistics there are at present in the United States 1,500,000 men and women who habitually use opium in some of its forms, while twenty years ago there were less than 300,000 opium-users in the same territory. It is said that in the city of Chicago 25,000 persons are addicted to the habit, in New York City over 50,000, and in St. Louis about 20,000. The amount of money expended in this connection will reach millions of dollars.

It is the object of the Anti-Opiate Society to reach especially such persons as are unfamiliar with the powers and dangers of narcotic drugs, and among other things to point out that the morbid craving is in many cases the result of the use of patent medicines, soothing syrups, and cough-mixtures, most or all of which contain opium.

The Society earnestly solicits the active coöperation, in word and deed, of all who desire to aid in its objects. It is the first of its kind, and deserves the warmest encouragement and support. It is maintained entirely by voluntary contributions. W. Ten Eyck Hardenbrook, No. 128 West Sixty-seventh street, New York City, is the Secretary.

The Iron Process of Water-Purification.—In view of the agitation in favor of the filtration of public water-supplies, it is opportune to call attention to a method that is both interesting and efficient. Experiment indicates that iron and its oxids have much influence in the destruction of organic matter, living and dead. Some iron oxids make excellent filtering material. Spongy iron produced by heating certain ores in reducing gases has long been known to be an efficient agent for removing microbes and dissolved organic matter from water, but it fails completely in time. It was an ingenious suggestion of an English chemist some years ago that the function of the iron might be restored by constantly agitating it so as to maintain a fresh surface. Experiments finally led to the invention of a simple, efficient, and economical method of purifying water. Scrap-iron in the form of turnings or punchings are placed in an iron cylinder which slowly rotates on a horizontal axis, while the water passes through in a steady stream. The iron is converted into ferrous carbonate, which on exposure to the air (in a trough through which the water flows upon its escape from the cylinder) is converted into ferric oxid, to which both dead organic matter and living microbes adhere. On filtering the turbid water through sand, a clear and wholesome filtrate is obtained. The presence of the iron oxid enables more rapid filtration to be carried out and involves less filter-cleaning. The iron would quickly become inert if allowed to lie in the water, but the constant rolling keeps the surface clean and active.

This process is now in successful operation at Antwerp, where the original water is of very bad quality, and at Paris, operating on Seine-water. A successful experimental plant was also operated on Schuylkill-water some years ago.

Air-borne Infection.—The *Provincial Medical Journal* discusses at some length the possibility of infection of meat through the practice of carrying it through the streets uncovered. It admits, of course, that cooking must get rid of almost, if not all, the microbes that may lodge thereon, but the question of infection carried through the air is one of much wider scope than the lodgment of microbes on a few articles of food. In cities the streets are almost entirely paved with non-absorbent materials, and unless such surfaces are flushed frequently and thoroughly, and in the intervals of flushing constant cleaning is maintained, much dust will be produced. It is generally admitted that tuberculosis is frequently, perhaps principally, transmitted by the inhalation of the fine powder into which is ground sputum indiscriminately ejected in public places, and modern investigation has shown that the most virulent microbes are found in the discharges from the intestines, and the fact that our common domestic animals, especially the horse, discharge their excreta freely on our streets, must render the dust of cities dangerous. It may some day be shown that this dust is a distributer of various skin-affections and some of the contagious febrile diseases. Exact investigations by several competent observers have shown that sewer-gas is not a carrier of germs, and that there is little reason to ascribe to it a direct causation of disease; but we doubtless much underrate the dangers that lurk in the pulverized filth that is raised in clouds on our streets.

Are Negroes and Brunets Peculiarly Subject to Electric Retinitis?—Dr. James P. Parker, of St. Louis, Mo., in a private letter writes that he has had a number of cases—thirteen up to the present time—of electric retinitis in negroes or dark-skinned persons, and he believes that this affection will not be found in those of blond type. He finds that the incandescent light has a peculiar effect upon the negro and the brunet, and that when such people suffering from this effect come to the physician, the latter fails to recognize the retinal injury on account of the very evident conjunctivitis. The changes in the retina consist in an increased pigmentation of the central or macular region, together with lessened visual acuity, hyperemia, etc., and occur, not immediately after the patient complains of conjunctival and other symptoms, but follow only about ten days after this time. Dr. Parker thinks that the impairment of vision will be permanent in all these cases. The greater the natural pigmentation of the retina the more disastrous the result. We make mention of this observation here in order that others may be on the lookout for similar cases and that the truth may be ascertained by a number of different clinicians.

First Care of the Newborn.—Dr. Th. S. Egge, of Moorehead, Minn., informs us that while travelling in Norway a few years ago, at a time when the nights were cold and foggy and the landscape was covered with a heavy frost, the stones and banks of the numerous creeks and brooks presenting a coating of ice, he found a gypsy woman bathing in a pond her child born but three hours previously. On being remonstrated with, the woman explained that it was the custom among the parturient women of the community of which she formed a part to wash their newborn for the first time in cold, running spring water, with the idea of training the children from infancy to withstand the buffets of a cold and unsympathizing world. The contention was that if the child should die as the result of this early exposure it was just as well, as it would otherwise die early at any rate. The practice is said to be common among the Laps and Finns.

CORRESPONDENCE.

THE MARRIAGE OF SYPHILITICS.

To the Editor of The Medical News,

Sir: For the purpose of securing reliable statistics on the subject of the marriage of syphilitics I desire to enlist the assistance of those of your readers who have had experience that will be of value in determining the period when this disease ceases to be communicable and inheritable. I shall, therefore, esteem it a great favor on the part of any physician who will send me answers to the following questions. Due credit will be given in a future publication to those who aid me in this work.

1. What is the latest period from the date of the initial lesion that you have known the disease to be communicated by a patient who has been from the first under your observation?

2. What is the latest period from the date of the initial lesion that you have known (*a*) a syphilitic man or (*b*) a syphilitic woman become the parent of a syphilitic child?

3. Have you ever known syphilis to be either communicated or handed down, at a later period than four years from the date of the initial lesion, by an individual who has been constantly under your observation during that time?

In answering these questions I should like a brief but complete history of each case and an account of the treatment that has been pursued.

I hope by this means to obtain the experience of a large number of observers and to reach a fairly reliable conclusion as to the time when we may safely permit our syphilitic patients to marry.

Yours, very truly,

Burnside Foster.

St. Paul, Minn.

NEWS ITEMS.

The Collection and Preservation of Anatomic Material.—At the last meeting of the Association of American Anatomists, J. Ewing Mears, Thomas Dwight, and Joseph D. Bryant were appointed a committee to "consider the question of the collection and preservation of anatomical material, and to report at the next meeting what in their opinion are the best means of accomplishing these objects."

In order to make the work of the committee as comprehensive as possible, and to obtain information which will be of service in arriving at definite conclusions as to the best methods of accomplishing the purposes indicated in the resolution, the committee has deemed it desirable to send to the teachers of anatomy, not only in

this country, but abroad, this circular-letter, with the questions appended, and respectfully to request answers thereto, as fully as they can be made.

1. Is anatomical material obtained in accordance with a legal enactment, wholly or in part?

2. If there is an anatomical law in your country or State, please send a copy of it to the chairman of this committee, Dr. J. Ewing Mears, 1429 Walnut street, Philadelphia, Pa. Please state whether the law is satisfactory, whether it is readily obeyed by those upon whom duties are imposed by it, and mention any improvements you would suggest as to its requirements.

3. Is the material received in good condition?

4. What disposal is ultimately made of the remains?

5. Please state what means are employed to preserve anatomical material for the purposes of dissection or operative surgery. If injections of preservative fluids are used, state their composition and the methods of use, at what point injections are made, whether at the heart or in the larger arteries, and their effect in accomplishing the preservation, with any changes in the color or character of the tissues. What length of time can material be used in dissection by the methods employed by you? If preservation by means of "cold storage" is employed, please state the cost of the machinery which it was necessary to construct for this purpose, and what means are taken to prevent decomposition after the subject is placed upon the table for dissection.

6. Please state the cost, by the method employed by you, for each subject, (*a*) for receiving it, (*b*) for injecting and preserving it.

7. Do you obtain an adequate supply of material for the purposes of anatomical instruction? How many students are assigned to each subject, and what is the method of allotment?

8. Please give any information which you may deem of importance. As the report will be general in character the name of the informant or institution will not be mentioned by the committee unless requested.

Your compliance with the request of the committee *at an early date* will be fully appreciated as rendering assistance to it in accomplishing its work, and it desires to thank you for the same in advance.

THE EMPLOYMENT OF CENTRIFUGAL FORCE AS AN AID TO THE EXAMINATION OF SPUTUM.

BY THOMAS G. ASHTON, M.D.,

CHIEF OF THE OUT-PATIENT MEDICAL DEPARTMENT IN THE JEFFERSON MEDICAL COLLEGE HOSPITAL AND DEMONSTRATOR OF CLINICAL MEDICINE IN THE JEFFERSON MEDICAL COLLEGE;

AND

A. H. STEWART, M.D.,

CLINICAL ASSISTANT IN THE OUT-PATIENT MEDICAL DEPARTMENT IN THE JEFFERSON MEDICAL COLLEGE HOSPITAL.

To facilitate the examination of sputum for tubercle bacilli, and to render more conclusive such examinations when but few bacilli exist in a given specimen of sputum, as well as to offer a substitute for the complicated methods now in vogue for the detection of fibers of elastic lung-tissue, are the objects of the present paper. When sputum contains tubercle bacilli in but scanty numbers it frequently happens that repeated examinations are necessary before their presence can be satisfactorily demonstrated; and even then their existence at times fails of detection, as will presently be shown, when by the aid of the centrifuge that they exist in such sputum can be readily made clear.

So also the application of centrifugal force, in the manner about to be described, to the detection of elastic fibers will be found a great improvement over the present methods. For this purpose at present the plan most generally adopted is that advocated by Fenwick, which consists in boiling the sputum in a dilute solution of caustic potash, then allowing it to settle for twenty-four hours, and examining the sediment for elastic fibers under the microscope. To those who are in the habit of employing this method it is not necessary to call attention either to its complications or to the uncertainty of its results, both of which render its employment practically useless in the ordinary routine of clinical work. Nor is the simpler method advocated by von Jaksch, of adding some potash solution directly to the sputum as it is placed upon the slide, with the object of dissolving the pus and allowing the elastic fibers to be seen, to be any more strongly recommended, as it is open to the chief objection that characterizes Fenwick's method, viz: its uncertainty, and the number of examinations usually necessary before, if at all, the elastic fibers can be found.

The observations about to be described were made from sputa taken from patients presenting themselves at the out-patient medical department of the Jefferson Medical College Hospital; and because in the present paper it is desired to describe the effect of centrifugation only as it may apply to the tubercle bacillus and elastic fibers of lung tissue, none other than tuberculous sputum is included. This is done, too, notwithstanding that sputa belonging to other diseases of the lungs have been similarly treated, as, for example, the sputum from cases of bronchial asthma, in which we have found that Charcot-Leyden crystals and the spirals of Curschmann can also be very readily demonstrated.

The mode of procedure is as follows: The instrument utilized to produce the required centrifugal force is a machine made by F. F. Metzger, of Philadelphia, under the direction of Judson Daland, as a modification of the hematokrit of Blitz-Hedin, with the difference that the caliber of the glass tube in which the precipitation is to take place is two-and-one-half millimeters in diameter, instead of one-half millimeter, as is the case with the hematokrit. In both instruments the length of the tube is the same, about fifty millimeters. Inasmuch as the greater the number of revolutions of the precipitating tube we are able to produce in a given time so much less time will be required in the manipulations, thereby simplifying the procedure, the machine made by Metzger is advocated, as no instrument yet brought to the attention of the writers has been found to approach it in speed. Though as yet untried, the force derived from a small electric motor might be utilized with advantage for the purpose of furnishing the necessary power for the operation of the centrifuge.

The preparation of the sputum before placing it in the precipitating tube is extremely simple. A small quantity is placed in a porcelain dish, and actively stirred for a few moments with a glass rod. Under this treatment the sputum soon becomes, without the addition of any diluting fluid, a thin liquid, free from lumps, and apparently of homogeneous character. The precipitating tubes are then filled, the sputum being drawn into them by means of rubber tubing having attached to one end a small rubber bulb to produce the necessary suction. We have used for this purpose an ordinary medicine-dropper with its attached bulb, inserting the nozzle end of the dropper into the end of the

rubber tubing, the other end of which is applied over the end of the precipitating tube. This method has been adopted to render unnecessary suction by the mouth which, were there no other reasons why it should not be resorted to, might not be free from danger in the case of tuberculous sputum. For the purpose of elucidation a drawing of this simple apparatus is given, and so easy of application is this method that its use has been resorted to for the drawing up of the blood into the precipitating tube of the hematokrit, as it has been found that the column of blood is thus more susceptible of control than it is with mouth suction.

Fig. 1.

Medicine dropper attached by rubber tubing to precipitating-tube.

The two precipitating tubes filled with sputum thus prepared are now placed in the centrifuge, and rapidly revolved for at least two minutes. With a speed of ten thousand revolutions per minute, which is easily attained by the improved apparatus made by Metzger, two minutes is quite time enough to produce complete precipitation of the more solid portions of the sputum, along with which, as shall presently be shown, go the objects of our search.

Precipitation thus having been accomplished, to the unaided eye the sputum will be found to have separated into two layers; that at the distal or peripheral end of the tube being yellowish or greenish in color; that at the proximal or central end appearing as a slightly turbid, almost transparent watery fluid, which by the microscope is found to contain no cellular elements whatsoever. In the peripheral end of the tube, however, the microscope reveals, closely packed together, but their integrity not in the least impaired, the various forms of epithelial cells and pus cells contained in the sputum. The more purulent is the character of the sputum, the greater the amount of desquamation of epithelium, of course the greater will be the depth in the precipitating tube of the purely cellular portion of the sputum—an observation possibly not without its value.

Undoubtedly the most important evidence that a destructive process is taking place in the pulmonary structure is to be found in the discovery of elastic fibers in the sputum. With obscure symptoms and signs pointing to a pulmonary tuberculosis, their significance is even greater than the presence of tubercle bacilli, unless in large numbers, as bacilli may be found in sputum when the lungs are in no wise diseased. The finding of elastic fibers is positively indicative of destruction, and the other destructive diseases of the lungs, such as bronchiectasis and pulmonary abscess, are not by their symptomatology likely to be confounded with tuberculosis. Pulmonary gangrene is not here classed with diseases of the lungs characterized by destruction of the lung-tissue, and to be compared with tuberculosis, because, as was first pointed out by Traube, the sputum expectorated in cases of pulmonary gangrene rarely contains elastic fibers, for the reason that they are probably completely destroyed within the gangrenous area. Therefore, the presence of elastic fibers in the sputum, with signs and symptoms pointing to pulmonary tuberculosis, even though these be obscure, and even though the presence of the tubercle bacillus may not be demonstrated, would clearly establish the diagnosis of pulmonary tuberculosis. Hence, that which will supplant the complicated and uncertain method of Fenwick, or the somewhat less complicated but none the less uncertain method of Von Jaksch for the detection of elastic fibers, cannot fail to be of great practical value when the importance of the subject is taken into consideration.

From the large number of observations we have made, now amounting to many hundreds, it has been definitely demonstrated that elastic fibers are precipitated by centrifugal force in the largest numbers to the very extremity of the peripheral end of the precipitating tube. The sputum occupying this portion of the tube, when rich in cellular elements, is found to be quite thick in consistence, and is usually extruded as a mold of the interior of the tube. Without any dilution, or any means for the solution of the pus cells, a small portion of this sputum taken from the periphery of one of the tubes—the contents of the other tube being reserved for the examination for tubercle bacilli—is spread somewhat thinly upon a slide, the cover-glass being pressed down to effect its equable distribution. Examined in this way, if the sputum contain any tissue its presence cannot fail of discovery. Examining the contents of the precipitating tube throughout its entire extent for elastic fibers, they are found to rapidly diminish in numbers as we pass from the periphery; and this is found to be the case even when the sputum contains lung-tissue in abundance, as was clearly demonstrated in one case especially, in which in the first slide were discovered ten separate collections or bundles of fibers, while in the second slide but three were found, and in the third but one, none being found beyond the third slide. The bundles of fibers were much larger in the first slide. In the thin, watery portion of the sputum, or that which remains after the precipitation of the cellular and other solid elements, elastic fibers are absent altogether. Elastic fibers examined by this method do not differ in appearance from those found after the methods usually practised for

their detection, and the accompanying drawings of collective fields of sputum taken in succession, beginning at the peripheral end of the precipitating tube and proceeding toward the central end, present good illusrations both of the appearance of the cast-off lung-tissue and its relative frequency in the slides, as the examinations take place away from the periphery of the precipitating tube.

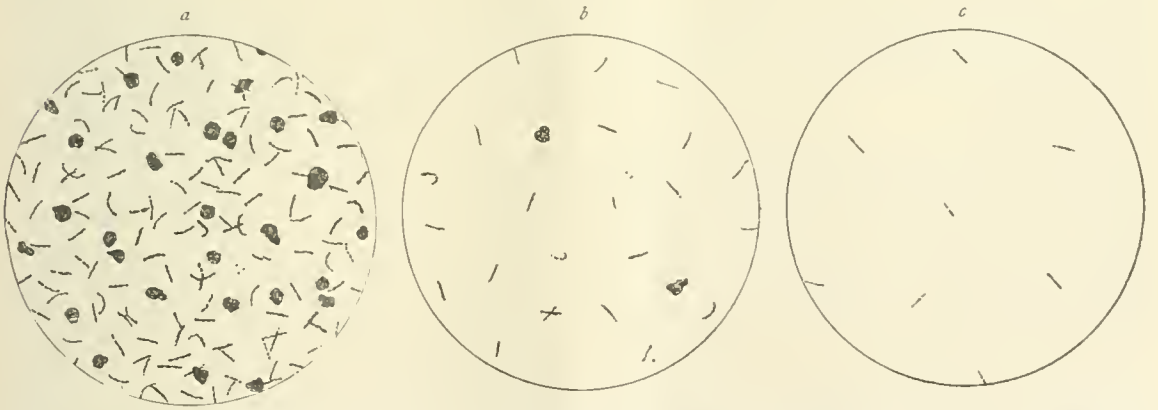
FIG. 2.

Elastic fibres. D objective, ZEISS. *a*. Slide prepared from extreme periphery of precipitating tube. *b*. Collective field from a slide taken 5 mm. from peripheral end of tube. *c*. Collective field from a slide taken 1 cm. from peripheral end of tube.

It is the experience of everyone accustomed to examine sputum for the tubercle bacillus that in those cases in which the number of bacilli is very small the result of the examination is often disappointing, and a number of such examinations have to be made before the presence of the bacilli can be demonstrated. Indeed, cases are not infrequently met with in which bacilli are not found in the sputum even after repeated examinations, and yet such cases will have presented well-marked evidences of pulmonary tuberculosis.

By centrifugal force, together with the pus cells and the various forms of epithelium, the tubercle bacilli are carried along. Thus it is that they are found in greatest abundance at the peripheral end of the precipitating tube. Centrifugal force does not separate them and assign them a place of their own, but they rather share the fate of the cellular elements of the sputum, which therefore carry the bacilli along with them. Hence it is, that with the bacilli as with elastic fibers, as we pass from the peripheral toward the central end of the precipitating tube they are found to rapidly diminish in numbers, until when the watery portion of the sputum is reached their presence fails of demonstration. That this is the case and the extent to which it is so, the appended drawings of slides prepared and stained from different portions of the tube will clearly show.

FIG. 3.



Tubercle bacilli. Homogen. immers. $\frac{1}{12}$, ZEISS. *a*. Slide prepared from extreme periphery of precipitating tube. *b*. Slide taken 5 mm. from peripheral end of tube. *c*. Slide taken 1 cm. from peripheral end of tube.

The value of centrifugal force as an adjunct to the examination of sputum for tubercle bacilli when they exist in only few numbers can scarcely be overestimated. Again and again have our observations demonstrated to us the facility whereby in such cases the presence of bacilli can be discovered by the aid of centrifugation, and in cases, too, in

which at the same time they were found only after much trouble and repeated examinations by the ordinary methods. This was especially noticed in a case in the wards of the Jefferson Medical College Hospital, which presented well-marked signs of advanced pulmonary tuberculosis, among them being the physical signs of a large cavity below the left apex anteriorly. In August, 1894, this case died, and the autopsy fully confirmed the diagnosis of pulmonary tuberculosis. The sputum of this case had been examined repeatedly by the ordinary methods, not only by ourselves but also by others expert in making sputum examinations, and at no time were bacilli found; and yet in this very case, by the aid of centrifugation bacilli were found in the sputum at the first examination, the number being very few.

In the course of these observations we have tried various ways of previously diluting the sputum, and have also considered the advisability of endeavoring to secure the solution of the pus corpuscles, thinking that by these means the tubercle bacilli and the elastic fibers would be more closely collected together.

We also subjected sputum to a series of examinations according to the method advised by Biedert, which, as described by Von Jaksch, consists of the following procedures: "Ten to twenty cubic centimeters of the sputum are boiled in a watch-glass with a little dilute caustic soda; water is added, and the mixture again boiled until it is thinly fluid. It is then allowed to stand in a conical glass for two or three days, after which the sediment is added to a small quantity of egg-albumin, and examined for bacilli in the usual manner." Instead of allowing two or three days for sedimentation, the mixture was at once subjected to centrifugation, but the result was far from satisfactory.

In this connection reference should also be made to the method recently described by Ilkewitsch (*Centralblatt für Bakteriologie und Parasitenkunde*, Feb. 5, 1894, Bd. xv, Nos. 5, 6, p. 162), the preliminary procedures of which consist in mixing with a half cubic centimeter of sputum in a porcelain dish twenty cubic centimeters of distilled water. To this are then added eight to twenty drops of a 30 per cent. solution of potassium hydroxid, and the mixture warmed until vaporization occurs, until which time it is constantly stirred. Under the influence of the heat and the potassium hydroxid, complete solution of the sputum is supposed to take place, at which time a small amount of casein is added to the mixture and dissolved. The fluid is then poured into a test-tube and acetic acid added, drop by drop, until the first sign of coagulation of the albumin is observed. The liquid is then placed in the cylinder of the centrifuge and rotated until separation of its elements takes place. When the separation has occurred a small ball suspended by a thread is lowered into the cylinder upon the collected sediment, and the superimposed fluid allowed to flow out. The sediment is then treated according to the special method which it is the object of the paper of Ilkewitsch to set forth.

In the course of our work upon the subject we found that dilution of the sputum as a preliminary measure to centrifugation is not only unnecessary, but interferes materially with the success of the examination, as it lessens the actual amount of sputum precipitated and diminishes the number of bacilli and elastic fibers available for observation, as well as increases the difficulty of staining. It is further rendered unnecessary because the sputum, by the process of trituration as above described, is rendered sufficiently fluid for proper manipulation; indeed, such sputum, even though abundantly rich in cellular elements, after centrifugation is found to be composed of more than one-half water.

The same objections apply to the various methods resorted to for causing a solution of the sputum, and it seems to us that such methods as those advised by Biedert and Ilkewitsch needlessly complicate what should be only a very simple process. The object of both of these methods is especially directed to the collecting together of bacilli, from sputum containing them in but scanty numbers, within a limited space. For accomplishing this purpose that method which is the simplest in its details, and which requires but a very few moments for its completion, provided that its object is effected with the same precision as by the more complicated means, is the method that will prove most practicable in the routine of clinical work. Furthermore, other things being equal, why should methods that are both complicated and time-consuming be followed when one presents itself in which both these objections are lacking? That we are not overestimating the value of the simple method just described, we think we have abundantly proved.

In looking into the literature of the subject we find but few references to the adaptation of centrifugal force to sputum examination, and the few obtained refer only to the precipitation of tubercle bacilli, and nowhere do we find recorded any observations upon the effect of centrifugation upon elastic fibers. We therefore feel that the observations made in the present paper, so far as they refer to this part of the subject at least, are original.

In conclusion we would say that, as a result of the above investigations, in the centrifugal machine we possess a very important adjunct to the present methods in use for the examination of sputum. Nor in its adoption will clinical medicine be burdened with a new instrument, as the centrifuge has

so many well-demonstrated uses that in any clinical laboratory its presence is indispensable. In the form of the hematokrit its value is now acknowledged, and as a means for procuring the sedimentation of urine it possesses sufficient importance to warrant its possession were that the sole claim for its adoption; and, finally, that it is of practical value in the examination of sputum has been conclusively proven in the clinical laboratory of the out-patient medical department of the Jefferson Hospital, where for the past six months the routine examinations of sputum have been conducted with its aid.

PAINFUL GASTRIC NEUROSES: THEIR DIAGNOSIS AND TREATMENT.

By ALLEN A. JONES, M.D.,
CLINICAL INSTRUCTOR IN MEDICINE AND INSTRUCTOR IN PRACTICE, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

(Continued from page 346.)

Diagnosis.—In order to arrive at a diagnosis of a painful gastric neurosis it is necessary to exclude gastric and duodenal ulcer, carcinoma, and other organic disorders of the stomach, biliary colic, chronic pancreatitis, acute pancreatic hemorrhage, rheumatism of the abdominal walls, referred pain from renal colic or appendicitis, and intercostal neuralgia.

It is by no means always an easy task to differentiate between some of these affections and nervous gastralgia. I have already spoken of the difficulty that may attend the distinction between gastric pain in chlorosis accompanied and unaccompanied by ulcer. If HCl is present in excess, with vomiting of blood, and sharp boring pain be localized to one small spot in the epigastrium, a little to the right of the median line, and shooting through to the back, the diagnosis of ulcer is justified. On the other hand ulcer may exist without any of these stigmata, so that all manner of obstacles may be thrown in the way of a clear diagnosis. Duodenal ulcer is more frequent in men between thirty and forty years of age, and is generally accompanied by vomiting of dark, changed blood and profuse bloody stools. HCl in excess is the rule in this affection, as it is in gastric ulcer. Gastric carcinoma may be present without coffee-ground vomitus, and without distinguishable tumor, but if these are present in a person of advanced years, and if there is a persistent absence of free HCl, with a steady failure of strength and loss of weight, a diagnosis of carcinoma may be made. Yet in two cases of severe gastralgia in women, first seen three years ago, the diagnosis was for many months in grave doubt, owing to the fact that both were well on in years; both gave a history of pain, vomiting and loss of flesh, and in both there was a continued absence of HCl, with retarded motion. After some months of treatment HCl appeared in one case, and the gastric chemistry thereafter remained fairly good. In the other case HCl was found but once. Both patients were relieved by the intra-gastric application of the galvanic current, and are better to-day than they were three years ago.

Biliary colic is distinguished from neuro-gastralgia by a history of gall-stones, pale stools, perhaps icterus, and bile-stained urine. Nevertheless perplexity may arise in this connection. About a year and a half ago a healthy-looking man, about forty years of age, presented himself, suffering with severe pain that he referred to his stomach. Upon direct examination I found good digestion, with a copious supply of HCl. Lavage and gastric sedatives gave him relief. He went to California, and was well while there. Upon his return to Buffalo he again had a severe attack of pain referred to the right epigastrium. The pain was tearing, gnawing and intolerable. The intra-gastric conditions were again found normal. The pain continued in spite of ordinary remedies, and he was sent to bed. Morphin alone gave relief, and in a few days moderate jaundice developed. Recovery took place some days later. No biliary calculi were found in the stools, nor were the latter noticeably pale. A similar case in the person of a healthy man of about the same age came under my observation last autumn.

Chronic interstitial pancreatitis is accompanied by emaciation, vomiting, glycosuria, fatty stools, epigastric pain, and occasionally salivation and lipuria. Acute pancreatic hemorrhage is usually accompanied by symptoms of profound shock, and death soon follows.

Rheumatism of the abdominal walls may be noted by tenderness upon movement, somewhat as motion is painful in lumbago.

Referred pain from renal colic will usually be attended with manifest nephralgia and the urinary condition incident to that disease, together with a history of nephritic colic. Appendicitis will be discovered if the temperature is taken and the region of the appendix examined. Intercostal neuralgia will be detected by the presence of the tender points of Valleix.

The treatment of neuro-gastralgias aims to stop the pain in the first place, and in the second place to remove the causative elements in the case. When it is possible to apply lavage with water at a temperature of about 110° F. during an attack of severe gastralgia very great relief often follows, and sometimes the pain ceases at once. The direct application of the galvanic current to the walls of the stomach acts in some cases like a charm in dispelling the pain. The positive pole should be used inside of the stomach and the strength of the current should be from four to twenty milliampères. If the gastric

contents are of a high total acidity large doses of sodium bicarbonate or light magnesium carbonate frequently afford relief. As a local sedative in gastric hyperesthesia, a combination of cerium oxalate, or bismuth with magnesium carbonate, is usually very efficacious as a remedial agent. Occasionally one-eighth grain of cocain in tablet or in solution allays even severe pain. Chloroform or chloroform-water is also useful during an attack. A dessert-spoonful of smooth whiskey or brandy sometimes gives relief. Hoffman's anodyne has not proved satisfactory in my experience. Dilute hydrocyanic acid in five-drop doses is very effective in some cases. Cannabis indica, combined with belladonna, aconite, or hyoscyamus, lessens the pain in a few cases. Antipyrin, phenacetin, and acetanilid have not proved valuable remedies in gastralgia. Occasionally a twenty-grain dose of quinin sulphate will cut short an attack. Finally, morphin hypodermatically, may be necessary in the event of failure with other measures.

Other procedures are often helpful in the treatment of an attack of gastralgia. Sponging the spine with water as hot as the patient can bear appears to give some comfort. The old-time hot fomentations upon the epigastrium, or a mustard plaster, assists in quieting the patient and the pain. The application of hot and cold water thrown alternately in a fine jet upon a small spot on the epigastrium is useful. A hot enema sometimes gives relief from gastralgia, as it does from enteralgia.

The treatment of the condition underlying painful gastric neuroses involves the removal of the cause as far as is possible in a given case, while local treatment of the stomach is frequently to be carried out together with careful attention to the general nervous state of the patient.

If the case be one of neurasthenia all possible sources of reflex disturbance ought to be eliminated if practicable. If the patient be a so-called lithemic, or if the kidneys are sluggish, active elimination by way of the bowels and skin should be effected. The diet should in each case be regulated according to the gastric chemistry. Constipation should be effectually overcome. Massage, exercise, general faradization, and the various uses of cold water for its tonic effect, are all beneficial in many cases in improving the blood and the nervous tone.

Among the drugs that may be used with advantage for the purpose of improving the innervation of the stomach as well as improving the general condition of the patient, nux vomica or strychnin is of great value. Strychnin is a good blood-maker by stimulating the functional activity of the digestive organs and the hematopoietic apparatus. In the milder forms of gastric pain and discomfort after eating, good-sized doses of nux vomica or strychnin sulphate very often suffice to do away with the pain. Phosphorus and arsenic are often well tolerated by these patients, and are very useful. In a few cases of moderately severe gastralgia five-grain doses of quinin sulphate night and morning have been successful. Iron should be used if indicated, as the mere existence of neuro-gastralgia is no contra-indication to its use. Asafetida in emulston is a drug of signal service in hysterical cases, especially when nervous belching is a marked symptom. In some mild cases a mercurial purgative followed by Carlsbad salts in the morning, and thereafter, for a while, by the daily exhibition of Carlsbad, will be sufficient to break the morbid cycle, and, in otherwise healthy individuals, restore gastric comfort.

An ocean voyage, mountain scenery, a stay at the seaside, may effect a cure in the absence of all medication or other forms of treatment.

OBSTETRIC INSTRUCTION.

BY EDWARD P. DAVIS, A.M., M.D.,
CLINICAL PROFESSOR OF OBSTETRICS, JEFFERSON MEDICAL COLLEGE.

IT would be strange indeed if the advances made in the instruction of medical students in other branches should not apply also to the study of obstetrics. The saving of human life and suffering which the knowledge of proper methods of diagnosis, familiarity with antisepsis, and education in obstetric operations have brought about in the hands of the few and skilled, must be reflected in the teaching given to students. Where a monarchical government is not at hand to dignify science by official recognition, and to control its wards, the problem of dealing with indigent patients in hospitals and in their homes is much more complex than in the government hospitals of the Continent. It is evident that in American cities, while a certain proportion of obstetric cases are confined in hospitals, a considerable number remain at home, and the teacher of obstetrics must be prepared, not only to exemplify in his wards an advanced stage of scientific work, but to make practical application of the same amid the less favorable surroundings of the looging or tenement.

In considering the practical application of this question, we must emphasize first the fact that labor is a physiologic and spontaneous process *only* in physiologic individuals. The rarity with which one meets with perfectly healthy individuals proves that a large proportion of labors are neither physiologic nor spontaneous, but require intelligent treatment.

It may next be said that a medical student is not legally competent to attend such a case. No person without a license from the municipality in which he or she lives should be allowed to attend a con-

finement, and the infringement of this regulation, which is a law in some communities, should subject the offender to prosecution. Under these conditions the indiscriminate assignment of confinement cases to medical students during their tutelage is an offence against medical science and municipal law. The student, however, should visit cases of confinement in the homes of patients and in hospitals under intelligent supervision. He may with propriety and benefit under such instruction act as nurse, although it is a question whether he will not learn more from observing the work of a competent district nurse who visits the patient, than from attempting to care for her after his own fashion.

These premises, it seems to me, call for the following organization in the corps of a medical staff for obstetric teaching: first, the head of the department, a man able and willing to perform, in the best modern methods, any obstetric operation at any time and place. This man should be physically capable of the exertion which pelvic and abdominal surgery requires in difficult operations. He should be possessed of the requisite instruments and apparatus to operate at any time in the hospital or in private houses. He should have the energy and devotion to his work which will lead him to undertake operative treatment when necessary, and the honesty of purpose which will lead him to promptly accept a responsibility that rightfully belongs to him. His field of operation should include Cesarean section, symphysiotomy, the high application of the forceps, version; if the case be complicated, embryotomy, the treatment of inversion of the uterus, eclampsia, and dangerous hemorrhage. He should personally decide in cases of puerperal sepsis whether or no operative interference is indicated of any nature whatever. He should instruct medical students by lectures and clinics, and the entire material of the service, both in and out-door, should be absolutely at his disposal.

Next in rank to him may come his assistant and demonstrator. This man should be versed in palpation and auscultation, in the immediate operation for the laceration of the perineum, in methods of treating hemorrhage and eclampsia, and in all obstetric operations by which faulty presentations are corrected. He should be a graduate of several years' experience, and a man of vigor and energy and sufficient devotion to his work to enable him to willingly undertake a considerable amount of arduous physical exertion.

In obstetric hospitals it is often best to add to this service the third graduate physician, namely, the resident physician. He may be appointed by competitive examination immediately after graduation. His province is to attend regularly the wards of a lying-in hospital and patients confined at their homes. He is expected to deliver normal cases, to assist at abnormal cases, and to learn by every opportunity presented. In accordance with his intelligence he will be taught the use of the forceps, obstetric manipulations during labor, the technique of intra-uterine douching and curetting, and the management of the healthy infant. He should report immediately to the demonstrator any abnormality occurring in his practice, and should be immediately under the supervision of the demonstrator.

The undergraduate medical student should be allowed to observe, but not to interfere. He should be present at labors normal and abnormal. When the labor is conducted by the resident physician, the demonstrator points out the salient features of the case, not only in the management by the resident, but in the work of the nurses. When the resident attends cases in the houses of patients he may be accompanied by several students, who shall witness the labor and assist him during its course.

Under the supervision of the resident or demonstrator, the student should be taught antisepsis, and allowed to examine patients when suitable for diagnosis. The student should be taught palpation and auscultation, the signs of pregnancy, the examination of urine, and obstetric antisepsis. He is, however, not qualified to attend or prescribe for an obstetric case in any manner whatever, and should be informed that he is liable to prosecution if he does so. The medical student should attend lectures upon obstetrics, didactic and clinical; should be drilled in palpation and auscultation, and should be thoroughly taught the mechanism of labor by instruction upon the manikin. He should also be instructed in the contour of abnormal pelves, and in pelvimetry.

The instruction of obstetric nurses should first include graduation in a good hospital, perhaps without an obstetric ward. At least three months' service should then be procured in an obstetric hospital, where, in addition to the usual course, the nurse should be instructed in the examination of urine, chemically but not microscopically, and in the administration of ether and chloroform. If she displays suitable intelligence she can be thus taught to become a most efficient aid to a physician in private practice.

Whenever possible, visiting nurses should be employed to attend cases in the houses of patients, and their visits should be so timed that the resident and students may be present at the visit, observing her methods of work.

In the complications of labor, the resident should promptly summon the demonstrator and such students as may be needed for assistance. If an operation be demanded, especially an abdominal

section, visiting nurses should be added to the number to secure proper antisepsis. If the patient can be taken promptly to an obstetric hospital in an ambulance, so much the better. If not, visiting nurses will supply sufficient clean linen to secure asepsis. The chief of the department of clinical obstetrics should bring with him a suitable operating table and portable sterilizer, and the instruments, ligatures, and dressings requisite for any operation. The case should then be dealt with in a complete and thorough manner, the medical students acting as assistants, and continuing in their attendance upon the case after the operation. In the event of the death of the patient, the same students should be present at an autopsy, if obtainable, and also be required to take portions of specimens to the pathologic department of the college, and there to personally examine them under the supervision of the pathologic staff. A medical student should be given distinctly to understand that attendance upon lectures is the most rudimentary step in medical education. The resident physician should understand that by virtue of his competitive examination he has secured opportunities for study not obtainable by others.

In selecting demonstrators, professors of obstetrics would do well to secure such as have a working knowledge of the modern languages. In this manner a professor and his demonstrator may together study constantly current literature, and furnish from time to time papers and clinical reports of value.

ORIGINAL LECTURE.

NERVE-SUTURING—NEURORRHAPHY—NERVE-GRAFTING.[1]

By DE FOREST WILLARD, M.D., Ph.D.,
of Philadelphia;
Clinical Professor of Orthopædic Surgery in the University of Pennsylvania; Surgeon to the Presbyterian Hospital.

NERVE-SUTURING.

The operation of nerve-suturing may be performed primarily or secondarily. Primary suture is performed immediately after or within a few days of the division of the nerve. Secondary suture is done at any time thereafter, even years later—the hope of success diminishing with the length of time, the loss of nerve-substance, etc. These operations have now been sufficiently numerous to show that the fear of tetanus is ungrounded, no deaths being reported from this cause. Suture of a divided nerve would certainly result in tetanus if division of a nerve, inflammatory conditions, and the presence of foreign bodies were causes of tetanus. Practical experience shows that with cleanliness of person and of instruments the operation is a safe one.

It is best performed after wounds by squaring the divided ends with a very sharp knife, not with scissors, and suturing in such a manner as to prevent any twisting or infolding of filaments. Catgut, very fine, chromicized or made thoroughly aseptic in boiling alcohol, should be employed. Fine sterilized silk is equally good. A round needle is better than a cutting one. The suture should pass directly through the body of the nerve and include both sheath and fibers. A second suture at right angles to the first is often desirable.

Secondary suturing is performed by freeing the imprisoned nerve from all its surrounding cicatricial connective tissue, stretching it freely, and removing a small section, so as to give good opposing surfaces.

It is not well to remove successive sections from the end of a nerve to secure good nerve-filaments and tissue, as the gap may be made very wide before good tissue is reached. It is better, after getting rid of the dense central connective tissue, to draw moderately good ends together and unite them. A nerve will stretch very considerably if it is thoroughly cleared for some distance from the surrounding tissues.

Fig. 1.

Fig. 2.

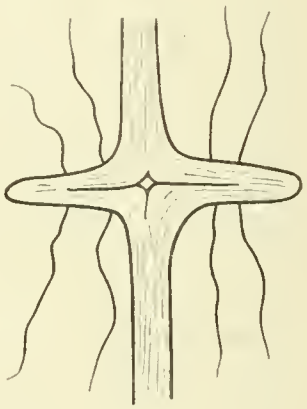


Fig. 3.

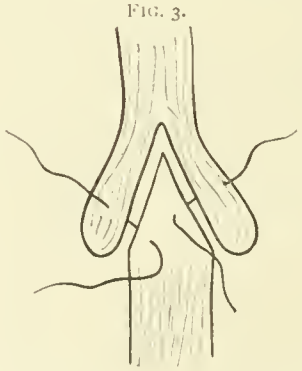

The most serious obstacle to successful nerve-suturing is the loss of nerve-substance, occasioned either by a wound or by the extirpation of a neuroma or other tumor. Frequently an inch can be gained by clearing the nerve for a considerable distance, but when this fails the gap must be bridged either by flaps cut from the nerve by longitudinal splitting and turned over from either end or by the device of Bruns (see Figs. 1, 2, and 3), or by grafting.

[1] One of the Mütter Course of Lectures delivered before the College of Physicians of Philadelphia.

Gleiss[1] reports thirteen instances of nerve-suturing in eleven patients in Bruns' clinic at Tübingen from 1882 to 1891. Four were primary operations, seven secondary. Union was secured in all but one case. The median nerve was sutured five times, the ulnar three, the radial four, and the peroneal once. The most rigid asepsis was adopted.

Bruns does not freshen the nerve-ends in primary wounds, but in secondary ones the ends are cut off and the intermediate cicatricial tissue is removed. He gives two new plans for approximation in old cases in which there is union by a connective-tissue bridge. While these are ingenious they do not seem to offer a good end-to-end approximation; not so good as is secured by cutting off the ends and simply suturing them, Figs. 1, 2, 3.

In a case of tearing of a radial nerve complicated with fracture there was no restoration of function at the end of five months. The nerve was thoroughly liberated from compression and from the connective tissue, and was enveloped in a graft of skin, after the method of Thiersch, to prevent restrangulation. Without having given this latter method a practical trial, it strikes me that the squamous epithelial skin-cells would more probably produce compression than would the connective-tissue cells.

The limb should be fixed after the operation, to prevent motion and tension. Massage and electricity should be subsequently used.

Etzold reports six cases ot nerve-injury in the region of the axilla in which restoration of function did not occur, even though the nerves were sutured. He attributes this result to the fact that in high injuries like these it is difficult to restore the nerves. This was, perhaps, not so much due to the height of the injury as to the complications that existed in the axillæ, as the brachial veins had to be ligated; and this, in addition to the injury of the surrounding soft parts, must have interfered with nutrition. Etzold found, as have other observers, that cerebral impulses are conducted along the nerve at an earlier period than those arising from electric impulses. Motion was established in one case fourteen months after suturing, yet there was no electric response.

That sensation seems to require a lower degree of conducting-power in the nerve than does motion is demonstrated in another instance in which return of sensibility was much more rapid than that of motion.

Wolberg[2] has made a number of experiments to decide whether a nerve can heal without degeneration of the peripheral segment. In all of his cases degeneration did take place, and in all of my experiments undoubted degeneration has occurred. In Bruns' four cases of primary suture there was immediate restoration of function.[3]

NERVE-GRAFTING AND NEUROPLASTY.

The suturing of one end of a widely separated nerve-trunk to the freshened surface of a neighboring nerve or muscle is sometimes advantageous. Splitting the nerve and turning down the fragments endangers the vitality of the nerve. Fig. 4.[4] I have practised this method in cases in which the ends could not be brought together by other means, but the results have been only partially satisfactory. Splitting a nerve interferes very seriously with its transmitting-power and subjects it to the risk of inflammation. Microscopic examination, however, in a number of my experiments, shows that even though the injured flap degenerates, it forms a skeleton or basis for regeneration of nerve-filaments.[1] The split halves can, however, sometimes be brought into close end-to-end union; but if torn loose from its attachments the flap becomes a transplanted nerve. If its sources of supply are gone, this procedure possesses but slight advantage over the transplantation of an entirely new piece of nerve from an individual or an animal. The best possible insertion for a fresh graft is a nerve taken from an amputated human limb and immediately introduced into the gap. (Fig. 5.)

Fig. 4.

Fig. 5.

To freshen a neighboring trunk and apply the cut end to its side may be helpful, but this is attended with the risk arising from irritation of the trunk, which may result in pain and other trophic symptoms.

Numerous operations for transplantation of nerves have been described. One of these is by Tillemanns,[2] in which a section four and one-half centimeters long, from a nerve of a rabbit, was inserted in the median and ulnar nerves. Sensation returned in four weeks and motion in nine. Another case is Kaufmann's,[3] in which after an injury to the musculo-spiral nerve a gap of four centimeters was filled with the transplanted sciatic of a dog. The result was doubtful three months later.

Robson[4] inserted two-and-a-quarter inches of a human posterior tibial nerve (secured from a fresh amputation) into a gap in the median, forty-eight hours after an injury. Four months later sensation was almost entirely restored, and although trophic changes were present, the case was very hopeful.

Hoffmann inserted the sciatic of a dog into the radial without benefit; and White, replacing the musculo-spiral by the sciatic of a dog, met with a like result. Albert grafted a section of human nerve into the median and the ulnar in separate cases, but without benefit. Gunn attached the ulnar to the uninjured median, and one month later reported the finger as strong.

Ward inserted two and a half inches of median nerve, just amputated, into a median injured four months before. Seventeen months later there was slight sensation of touch and a fair amount of power, an improvement upon the previous condition.

In another case two inches of a sciatic nerve from a rabbit were placed between the split ends of an ulnar. Sensation returned upon the eighteenth and motion upon the twenty-fifth day. The use of the hand, with marked grasping-power, completely returned.

[2] Berliner klinische Wochenschrift, June, 1883.

[3] Revue de Sci. Méd., 1884, vol. xxiv, p. 305.

[4] Clinical Society, London, 1889.

It will be noticed that sensation antedates motion, and in all these cases it was proved that atrophy of the peripheral end certainly was marked.

Atkinson sutured the median nerve and inserted the sciatic of a rabbit between the extremities of the ulnar. Sensation returned before motion.

Harrison[1] reports eight cases of nerve-grafting. In one case he inserted two-and-one-quarter inches of the sciatic nerve of a freshly killed kitten into a median nerve, two inches of which had been destroyed, suturing with catgut. The wound healed by first intention, and sensibility returned in forty-eight hours; nutrition improved. After five months motion returned in the fingers. In another case four inches of the sacral nerve of a dog were inserted into an ulnar, with a return of sensation in thirty-six hours.

Primary grafting is, of course, much more certain than secondary, as trophic changes naturally interfere greatly with the success, although nerve-function is not impossible after a long period of time.

A ferrule of decalcified bone stitched in the gap after invaginating the ends, is recommended by Vaulair,[2] but such isolation of a nerve from surrounding supporting tissues may result in sloughing. In my experience the bone tube disappears so quickly that it is of no use either in guiding the two ends in reaching each other, or in protecting them from subsequent cicatricial contractions.[3]

Another method of splicing consists in splitting longitudinally the nerve through its center for the necessary length, say, one inch, then cutting out one side and reflecting the flap upon its base. The opposing end is then treated in the same way, the flap being made upon the opposite side so as to fit against the corresponding flap. The two can then be sutured.

MacCormac exposed a nerve and attached it by two loops of kangaroo tendon to the inner edge of the triceps, and sutured the fascia with catgut. Decided improvement took place. By the same method Pearce reduced a dislocation forward of an ulnar nerve.

Croft exposed and sutured a nerve to its sheath. Gould also performed a similar operation.

Bergmann adopted another course, viz., resection of the humerus, in order to shorten the arm so that the divided nerve-ends could be brought together, but this seems an unnecessary procedure.

Dittel reports a case in which the ulnar nerve was split for seven centimeters. Flaps were turned up and united end to end, with the result of a restoration of sensation and of movement under prolonged electric treatment.

Vucetic reports an injury to the ulnar nerve attended with loss of substance. Flaps were cut from each end, and catgut sutures employed. Suppuration took place, but the final results were good.

In all cases of nerve-grafting it is vitally important that the animal furnishing the nerve should be young, as the regenerative power is much greater at an early period of life, and in cases of nerve-suture it has been noted that young patients are more hopeful than older ones. The direct method of suturing is usually employed, although the indirect plan has been used in a number of instances.

Pain and stiffness may follow either primary or secondary suturing, but the functions return to a remarkable degree. Sometimes the first evidence of returning sensation is a feeling of tingling or of numbness, followed by a recognition of the fact that certain sensations are being received. This increases until finally restoration more or less complete takes place. There is at first a sense of confusion in regard to sensations, as it is impossible to join filament to filament. A filament of a nerve that primarily brought intelligence from a toe may have been united with a filament presiding over a leg-area; hence, reëducation is necessary, and this is entirely a question of time. It is well known that after an amputation many years are not sufficient for the reëducation of the brain in regard to the area from which new impressions are received.

Although at the time of secondary suturing, degeneration has progressed, yet the speedy restoration of nerver function after injury shows that by some method transmission of nerve-force is brought about; the prognosis, therefore, is very favorable, and no case should be allowed to suffer for want of the attempt to secure union. We may give this class of patients a large degree of hope as to prognosis, as even without operation great improvement has been found to take place, showing that we may have return of sensation in a divided nerve without actual reunion. The functions of motion and sensation both return if continuity of the axis-cylinder has been restored. The symptoms of nerve-regeneration to be expected then will be active muscular contractions, improvement of atrophy and faradic irritability of muscles that have been previously paralyzed.[1]

The question of age materially affects the rapidity of regeneration; this I have proved personally by experimentation, and find that union takes place much more quickly in the pup than in the older dog. Bowlby thinks that the musculo-spiral particularly presents great energy of union, even more than other nerves.

In one case reported at St. Bartholomew's Hospital, in which the ulnar was operated upon by Mr. Marsh, twelve years after the injury, there was decided gain of motion and sensation. No patient, therefore, should despair, but it is well to warn against the expectation of too immediate results. Improvement is sometimes decided only two years after an operation. Of course, the cases operated upon years after an accident are not as hopeful as early ones, yet they are worth the attempt. Whenever improvement fails to take place it is probable that a change has occurred not only in the nerve but also in the central cells. When there has been sloughing and suppuration the amount of dense cicatrix will have much to do not only with preventing union but also with secondary results. If, however, each nerve is freed from surrounding compression this danger is lessened, although a wide line of reunion will certainly interfere with nerve-transmission.

The fact that degeneration occurs in the motor cells of the spinal cord, which are the trophic centers of the muscles, probably explains why in some cases motor

[3] Internat. Med. Magazine, April, 1894, Experiment No. XII.

[1] A most satisfactory study of nerve-regeneration is contained in Howell and Huber's admirable article in the Journal of Physiology, 1892, vol. xiii, No. 5.

power cannot be restored. Sensation may return when operations are done years after the nerve has been severed, but motion may not so often be restored. Within a year good results may be looked for; the difference of a few weeks or a few months is not believed to affect materially the chances of success. After this time there is a smaller ratio of cures.

I had recently an opportunity of observing a lad upon whom I operated nearly ten years ago for a glass division of the ulnar, which was united and sutured almost immediately after the accident. While able to use the little finger, and while the ring-finger has slight sensation, there is atrophy of all the muscles of the small digit, and that portion of the hand, while useful, is feeble.

In many cases in which no improvement has at first occurred, gradual gain for some months has taken place at a later period.

As regards the errors in reporting various nerve-results after operation the observations of Zander[1] are interesting. His reports tend to show that surface-manifestations are unreliable even as regards such distinct tracts as the divisions of the median into the ulnar and radial. The facts of the case probably are that divisions are uncertain, and that irregularity of distribution and free anastomoses are frequent. Arloing and Tripier have shown that in order to secure absolute loss of sensibility in the foot of a dog, it is necessary to divide every nerve leading to the part.

It is possible that some of the immediate excellent results may have been due to the fact that a region (for instance, the hand) is supplied with nerves from a number of sources, and other vicarious or substitutive nerves may have been brought into play, thus deceiving the surgeon, who may unwittingly report a return of sensation early. A number of these cases are cited by Weir Mitchell,[2] showing that sources of error are common, and Létiévant has forcibly called attention to the same subject.

In many cases of rapid return of function, especially in primary suture, it should be remembered that the supplementary activity of other nerves may give rise to a series of remarkable results, not because a nerve has been sutured, but because the patient has recovered from the shock of the injury, which previous to the operation may have temporarily annulled both sensation and motion. This vicarious action of nerves has been well demonstrated by Mitchell, Savory and others, and errors in observation have been carefully depicted. Errors may occur, as in the case of Pirogoff, quoted by Weir Mitchell, in which case it is possible that the surgeon labored under the same mistake that happened to myself in one of the experiments already alluded to.[3] In this case I was probably as certain as Pirogoff that the nerve had been completely divided, as it was distinctly before my eyes, and yet subsequent examination proved that a large bundle of fibers had escaped section. Naudorfer and Schuh had a similar experience. In Pirogoff's case sensation was normal, but he had *not* sutured the nerve.

Howell and Huber's[4] tables on secondary suturing show that, as a rule, secondary suturing is more hopeful soon after an injury, although results have been excellent even after a long period of time; the average time for the return of motor power is about six months, and for the return of sensation three months—a peculiar fact that shows itself in all nerve-experiments.

Their summary includes 80 cases of nerve-suturing secondarily, with 38 per cent. of successes and 50 per cent. of improvements, making 88 per cent., with only 12 per cent. of failures.

They have presented the profession with most valuable deductions from the recorded cases of suture, and conclude that in primary nerve-suture the nerve-function will in all probability be restored either completely or partially, that young patients are more hopeful than older ones, and that clinical as well as physiologic evidence is against the possibility of immediate union.

In primary suturing the prognosis is exceedingly good, and improvement may be expected in nearly all cases.

Rapid return of motion, and more particularly of sensation, has been frequently noted, but the errors of interpretation have been already noted, and it seems to be definitely proved that the transmission of a nerve-impulse requires a continuous axis-cylinder. Nerve force is a vital force, and though resembling electricity is entirely distinct.

The natural inference from cases of the kind related is obviously that in all cases in which nerves are accidentally divided union should be aided by suturing; and in the majority of cases their function will be restored if the attempt is made within a reasonable period of time.

The prognosis of recovery of function after primary and secondary suture of nerves is very much better now than formerly. Even in secondary suture great improvement is almost certain to follow, and complete success is to be expected in the majority of instances.

Primary suture. Of 117 cases of primary suture collected for me by Dr. John H. Rhein the following summary is made:

The median nerve was sutured 41 times; the ulnar, 38; the median and ulnar, 30; the median, ulnar, and radial, 3; the radial, 4; the musculo-spiral, 3; the sciatic, 1; the external popliteal, 1; the posterior tibial, 1; the anterior tibial, 1.

It will thus be seen that the nerves of the upper extremity have been subjected to this operation in 113 cases, and also that the nerves of the forearm suffer injury more frequently than those of the upper arm. This may be accounted for by the fact that many of the wounds were due to glass, and caused by the effort of the individual to save himself by extending his hand. Knife-cuts are also much more frequent in this region.

The *nature of the injury* was as follows:

From sharp instruments in 62 among 81 cases; from dull instruments in 8; from nerve-injury during operation, 14.

Sex. As might be expected, males are in excess of females, as accidents are much more frequent in men than in women. In the cases recorded, 86 males were injured and 20 females.

Age. Under ten years (the youngest being two years) there were 8 cases; from ten to twenty, 34; from twenty

[1] Berliner klinische Wochenschrift, 1891, Feb. 24.

[2] Injuries of the Nerves. Mitchell, Morehouse, and Keen.

[3] International Medical Magazine, April, 1894.

[4] Journal of Physiology, 1893, vol. xiv, No. 1.

to thirty, 31; from thirty to forty, 15; from forty to fifty, 18; from fifty to sixty, 3.

The exact time after injury is recorded in only a few instances, but it is fair to assume that the majority of operations were performed on the first or second day, and that these were all primary sutures.

Material used. Catgut was employed in 72 cases; silver wire in 5; silk in 7; kangaroo-tendon in 1.

Distance of separation of ends. This unfortunately is recorded in only a few instances. The smallest distance given is 1 cm., and occurred six times; 2 cm., three times; 3 cm., once; 4 cm., once; 2 inches, once.

Return of sensation. The record covers only 39 cases. Sensibility returned on the same day as the causative accident in 7; on the next day in 2; within a few days in 17; after one week in 13; after two weeks in 6; after four weeks in 7; after six weeks in 2; after two months in 3; after six months in 4; after one year in 1; after one and one-half years in 1.

Return of motion. This occurred on the day of the injury in 1; on the next day in 1; after several days in 4; after one week in 6; after two weeks in 2; after three weeks in 5; after four weeks in 3; after two months in 5; after three months in 1; after six months in 1; after one year in 4. One "cure" was reported in seventeen days.

Results. Among 123 cases, one death is reported a few weeks afterward (the cause was not stated), and another took place from gangrene sixty-five days after operation. Improvement in one day is reported in 6 cases; complete return of motion and sensation, one year later, in 10 cases; slight improvement at the end of this time in 10 cases; partial improvement at the end of one year in 3 cases. Slight improvement is also noted in several cases at the end of two and three months, and in other cases complete return of motion and sensation is recorded at the end of one week, eighteen days, two months, three months, six months, ten months, and one year respectively.

Negative results are given in 2 cases.

Sensation is reported normal at the end of two years in 3 cases; in 1 case at the end of four months. Four cases are reported as well in two years, 5 at the end of five years, and 5 at the end of three years. In 14 cases motion and sensation are noted as good.

Secondary suture. A review of the extensive and valuable tables made for me by the indefatigable efforts of Dr. John H. Rhein shows that of 130 cases of secondary suture the median nerve was involved 35 times; the ulnar, 34; the median and ulnar, 20; the musculospiral, 10; the brachial plexus, 1; the fifth cervical, 1; the radial, 29; the sciatic, 6; the popliteal, 1; the external popliteal, 2; the posterior tibial, 1; the perineal, 1; the posterior inter-osseous, 1.

As might be expected, there is a preponderance of males, as they are much more subject to accident. There are noted of males 98, of females 31.

The character of the accidents is as follows: from sharp instruments, 96; from dull ones, 5; from gunshot-wounds, 6; as a result of nerve-injury during operation, 3.

The character of the suturing material used was catgut in 47 cases; kangaroo-tendon in 14; silk in 10; horsehair in 6; silver wire in 2; decalcified bone in 1.

The time of operation after injury was fifteen days in 12; one month in 15; two months in 19; three months in 14; six months in 19; nine months in 20; two years in 10; six years in 1; nine years in 1.

The return of sensation is definitely recorded only in a few cases. This was noted on the next day after operation in 12; several days afterward in 17; within the first two weeks in 21; after one month in 19; after three months in 2; within six months in 12; after one year in 1; after two years in 1.

Motion returned on the next day in 1 case; after several days in 3; within the next two weeks in 9; within a month in 18; after six weeks in 1; within six months in 13; after one year in 3; after two years in 1; after three years in 2. In 1 case it was reported that motion had not returned at the end of a year.

The amount of separation was one-half cm. in 18 cases; one cm. in 9; two cm. in 4; three cm. in 7; four cm. in 9; seven cm. in 1; ten cm. in 2; one inch in 1; two inches in 8.

The results are given as follows: One death from hydatids. Improvement within the first month was noted in 6 cases; "motion and sensation improved in six months in 11 cases." Complete return of motion and sensation took place in from one week to six months in 17 cases. A similar result is reported as having occurred in one month in 7; in six months in 14; in one year in 25; in two years in 18; in four years in 2. Fourteen cases are reported as cured; 3 as completely cured in five years. Other cases are reported as showing a slight improvement in one, two, and three years respectively. These should be put down as unsuccessful cases. The total number of cases slightly improved is 10; either greatly improved in motion and sensation or absolutely cured, 102; very slightly improved, or not improved at the end of a year, 15; 1 death resulted from hydatids; thus giving 80 per cent. improved by operation, with practically no risk to life.

CONCLUSIONS.

1. Immediate suturing of a divided nerve should never be neglected, as the result is eminently successful as regards restoration both of sensation and of motion.

2. Clean end-to-end suture should be secured if possible. In wounds inflicted by a sharp instrument this is easily attained; in torn wounds it is wiser not to remove more of the nerve than is imperative, as a nerve continuously stretched unites less readily than one which lies loosely. Whenever a portion is necessarily sacrificed better union will be secured by clearing the nerve for a considerable distance, stretching it thoroughly so as to obtain end-to-end suture if possible, and then stitching. When it is impossible to join the ends other material may be grafted into the gap, or the nerve may be spliced by flaps cut from its own substance.

3. The best suturing-material is fine chromicized catgut inserted by means of a small, round needle directly through the sheath and body of the nerve. Two sutures are usually advisable, crossing each other at right angles.

4. Secondary suturing offers good hope of success, and should be attempted even if years have elapsed since the accident. Repeated operations may ultimately succeed if the nerve is thoroughly cleared, stretched, and brought together.

5. When the loss of nerve-substance has been large,

a nerve-graft, or a section taken preferably from a freshly amputated limb or from an animal, should be inserted in the gap. This usually gives better results than the splicing-operation of splitting the nerve and turning the flaps into the gap.

6. Decalcified bone-tube, which has been employed for guiding the ends toward each other, is so rapidly absorbed that it is of but little service.

7. Restoration of function often takes place many months after the operation.

8. My own experiments agree with those of other operators and prove that the distal portion of a severed nerve rapidly degenerates, as does also an interposed graft; yet that transmission of function is possible and that subsequent regeneration may take place as regards both sensation and motion.

9. During the healing-process the part should be placed absolutely at rest, and the nerve slightly relaxed if possible.

CLINICAL MEMORANDUM.

AN UNUSUAL CASE OF SYPHILIS.

By J. ABBOTT CANTRELL, M.D.,
PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; DERMATOLOGIST TO THE PHILADELPHIA AND ST. AGNES' HOSPITALS.

The following record of a case of syphilis is more than usually interesting, as the symptoms and course of the disease presented very decided irregular conditions during a period covering eighteen months, during a portion of which time the patient was under my care. I wish to emphasize the extreme malignancy of the disease, the persistent cutaneous manifestations, the therapeutic difficulties encountered, and the thorough carelessness of the man in following directions as to treatment.

W. W., a male, forty-three years old, has been under observation for a period covering twelve years. During that time he has been in the habit of taking periodic "sprees," and while each of these would last only one, two, or three days, he nevertheless kept more or less under the influence of liquor for several months consecutively; and although a married man and one of the best of husbands in the interim, he would often, during these sprees, have a lapse of sexual virtue, which in a number of instances resulted in attacks of gonorrhea. This condition generally responded to proper treatment and was cured in a few days. Unfortunately for him, the last of these sprees occurred about the 15th of November, 1892, while he was away from home, at which time there appeared the initial lesions of syphilis. He permitted himself to go untreated for about five weeks, at the end of which time he presented himself at my office. On December 24, 1892, the man stated that he had always been in the best of health, with the exception of the preceding troubles. He was five feet seven inches in height, and weighed one-hundred-and-seventy-five pounds.

Upon examination I found an initial lesion just behind the corona glandis and on the superior surface of the penis. I advised the use of the official mercurial ointment, and upon his return one week later the lesion was found to be entirely healed. As he was weak and not at work, I ordered one-sixteenth grain of mercuric chlorid, to be taken every six hours, for its tonic effect only; but it was found, after he had taken five doses, that he became salivated, and the drug was discontinued. After this (January 3, 1893) the patient was lost sight of until April 9th, when he again called, stating that he had had no treatment since last seeing me.

At this visit I found that the man had been suffering from lesions upon the skin for the previous three weeks. Upon removing his clothing I noticed that these lesions were scattered here and there over the body-surface. Upon the face the lesions were situated directly above and between both eyes—"corona veneris;" another was found occupying a position directly above the left eye; another covered the right ala of the nose; there was one immediately below the angle of the jaw on the left side, and one was situated in the median line of the neck below the chin. Each shoulder was the site of a lesion; the left arm upon the outer side contributed four similar lesions, and there were three upon the internal surface. There were also three surrounding the right wrist; nine lesions were encountered upon the chest and abdomen, while only five were seen upon the posterior portion of the trunk. I also found twenty-five lesions upon the left leg, the right contributing ten more. Upon close examination I found that all were examples of the large, flat, pustular syphiloderm, and that each lesion (all lesions were circinate) ranged in diameter from one-fourth of an inch to two inches, and all were covered with a rupia-like crust, in some instances raised about one-half inch. There was apparently no discharge from any of them, but upon removing one of the crusts I found a decided exudation of pus. I advised mercury protiodid in doses of one-fourth grain to be taken three times a day, and after the man had taken three or four pills I was again confronted with the constitutional effects of the drug. I changed the remedy and gave potassium iodid in small doses, with the understanding that the dose was to be increased.

On June 1st the man complained of severe pain in the head, which, in fact, was only a sign of a cerebral neuralgia; but the pains resembled very much those found in connection with a gumma of the brain. These pains, peculiarly, were more noticeable at night, and only in the daytime when he was alone. Thinking to assist the potassium iodid, of which he was taking fifteen grains three times a day, I advised inunctions of half-strength mercurial ointment. Salivation again occurred after three or four applications, and, of course, these were discontinued, and after a week, all signs of the former characteristic effect of the drug having disappeared, I again gave him the bichlorid, but in doses of $\frac{1}{200}$ of a grain three times a day; but the same effect was produced after a few doses.

On June 10th, at my request, the man was admitted into the wards of St. Agnes' Hospital, under my care. The pains in the head seemed to be very much worse, and in fact so much so that I was sure that a gumma was present. At this time he was given hypodermics of morphin before sleep was induced, and the potassium salt was increased to twenty grains three times a day. These means were continued for two weeks, when he was again removed to his home. On June 24th the pains had entirely left the head, but

at this time he complained of general neuralgia (more properly a myalgia), the pains extending over the entire body, there being no one portion that was exempt. From this time he began to lose power in every muscle, and consequently was confined to bed, and simply remained in the position in which he was placed by the attendant. At times, while lying in one position, the pains would become severe in a portion of his body, and then he would be changed in bed, with relief for possibly a half-hour, when another change would be demanded. During all this time his appetite remained of the best.

On July 6th entire disappearance of the myalgia was noted, but the man was still confined to his bed and unable as yet to move any portion of his body—the head, the trunk, or the extremities. I noticed at this time that he was losing flesh (present weight 125 pounds) so rapidly that I thought that death would surely occur. His voice began to fail. He was taking thirty grains of potassium iodid three times a day. On July 10th he had lost his voice entirely, and on July 14th he had several chills, for which I advised large doses of quinin.

On July 16th the chills were entirely relieved, and I gave cod-liver oil, ʒij, three times a day. On July 23d the man used the right hand slightly and the voice had returned. He had no pain whatsoever. I noticed that the crusts which, up to that time, had remainded as described, had fallen off, leaving a spot having the color of raw ham. On July 27th he was able, with the assistance of the nurse, to sit up in bed for an hour. On August 3d the potassium iodid was increased to forty grains three times a day. The man was able to stand on his right foot, but had no power in the left leg whatever. On August 10th he was able to walk about five steps, with slight assistance, but there was still no power in the left leg. On August 20th, by supporting himself, and without other assistance, he could walk five or six feet, and on September 1st, with assistance, he could walk about twenty feet. On September 25th, without other assistance than crutches, he was able to walk twenty-five feet. The iodid was now increased to fifty grains three times a day. On October 20th, with one crutch and one cane, the man could walk about thirty yards; although he still had very slight power in the left leg, he could stand upon the right foot without other support. The lesions showed a very dark pigmentation. On November 1st he walked one hundred yards with the assistance of his crutch and cane. By December 1st he walked one-half mile, having his crutch with him, and on January 1st he walked three miles, still having his crutch with him, because he was afraid to go without it, as he was somewhat unsteady as yet on his feet.

The man was again lost sight of until about the 9th of March, when I saw him on his doorstep, and he stated that he had been wearing some electric apparatus. He was unable to walk, or even to stand on his feet. Since that date I have not seen him.

An Anti-Corset League has been formed in England, and it is to be represented at the coming Health Exhibition at Liverpool. We very much fear it will be another of the many failures to try to make women sensible in matters of dress. A young schoolgirl thinks she must have a corset before she is in long dresses. Great is Fashion and it will prevail!

THERAPEUTIC NOTES.

PAPAIN AS A REMEDY FOR TENIÆ.

By ROBERTS BARTHOLOW, M.D.,
OF PHILADELPHIA.

THE apparently successful use of papain in a case of *tænia solium* is the occasion of this letter. The remedies most successful in the expulsion of this parasite are so disagreeable and so difficult to take, for the most part, that it is desirable to have some agent free from these objectionable features. I have happened lately to know of a case in which an immense *tænia solium* was expelled during a course—it at least may be said—of papain, when various effective remedies had been taken in vain. The unfortunate host had been passing segments for several weeks when the first efforts were made by his physician to procure the expulsion of the worm. There were tried successively the "Gardner Extract of Pine Needles," a terebinthinate preparation having some reputation as a teniafuge; naphthalin; pumpkin seeds; decoction of pomegranate root, and Tanret's pelletierin; croton oil, etc.; but they all failed to expel the parasite or indeed any considerable number of segments. The harsh remedies irritated the mucous membrane, and the repeated failures discouraged the patient. Under these circumstances, by my advice, he began the use of papain, taking ten grains three times a day after meals. This ferment, although of vegetable origin, has properties similar to those possessed by pepsin and pancreatin, and it has, also, been employed successfully as a remedy for tapeworm, especially in children. The theory of its action entertained was that, having a solvent action on albumin, it must destroy the worm, which is an albuminous substance. The result in this case is clearly adverse to this theory, for in a few days after it was begun segments passed in considerable numbers—so many as twenty-three in one day—when the patient, finding the parasites much affected, without further delay, on his own account, took a dose of the pine-needle extract and followed it with two ounces of castor oil. Apparently this experiment was, also, a failure, for the day passed without any result, and in the evening the contents of the stomach were evacuated. At 8 P.M. some abdominal pain was suddenly felt, and in a few minutes an immense *tænia solium* was passed complete. This formidable parasite was found by actual measure to be twenty-five feet in length. It seems in a high degree probable that the papain exerted a toxic action on the worm, causing it to relax its hold on the mucous membrane, for, as is usual under such circumstances, it was discharged in a mass, coiled up and motionless, but when hot water was poured over it the motion of uncoiling began, showing that it was stupefied.

I need hardly observe to the readers of THE NEWS that papain is a principle—a ferment—contained in the juice of the *Carica papaya*, and is employed as a substitute for pepsin and as a solvent of the membrane of croup or diphtheria. As it is not a poison or an irritant, it can be used freely in the conditions for which it has been prescribed.

1527 LOCUST STREET.

Dr. Charles A. Power, formerly of New York, has removed to Denver, Col.

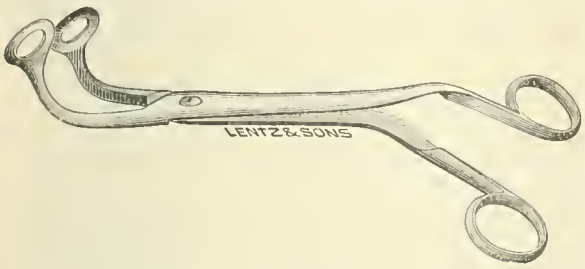
NEW DEVICE.

A NEW POST-NASAL FORCEPS.

By ARTHUR W. WATSON, M.D.,
PROFESSOR OF DISEASES OF THE THROAT AND NOSE IN THE PHILADELPHIA POLYCLINIC.

As there are so many forms of post-nasal forceps already before the profession, I have felt some hesitation in adding another to the list. But I have used the instrument here described for the last two years in a large number of cases, and it has proved so satisfactory that I think it may be found of advantage by others.

In nearly all the forceps for the removal of post-nasal adenoids with which I am acquainted, either the blades are too small, or their cutting-edge is too short, and when working anteriorly the cutting is done with the side instead of the end of the blades. To overcome these defects I have had made the instrument shown in the accompanying illustration. It is of the kind known as



gouge-forceps; and is of the usual length, about eight inches, with a post-nasal bend of an inch and a half. The blades, which are the important feature of the instrument, are oval in shape, with the long diameter transverse to the shaft, making the upper or cutting-edge long—five-eighths of an inch. This edge is set at an angle to correspond, when in position, with the slope of the vault of the pharynx. The anterior projection enables the operator to reach the anterior part of the naso-pharynx without having to depress the handles sufficiently to alter the relation of the cutting-edge to the pharyngeal vault. As the blades are fenestrated, they present no obstacle to the forceps taking a large bite and cutting deeply into the tissue. The instrument is made by Charles Lentz & Sons, of Philadelphia.

MEDICAL PROGRESS.

Abscess of the Right Cerebellar Hemisphere, with Paralysis and Fits Limited to the Same Side.—DRUMMOND (*Lancet*, No. 3700, p. 190) has reported the case of a girl, nine years old, who for three years had had a purulent discharge from the right ear, with the development, a few days before coming under observation, of headache, vomiting, paralysis of the right arm, and right-sided convulsions. The child lay in bed on the left side. The right arm was helplessly paralyzed, the right angle of the mouth was weak, and the leg on the same side showed evidence of paralysis, although a certain degree of voluntary power remained. Convulsions recurred at intervals of an hour, and sometimes more frequently. The spasm began in the face, and almost immediately extended to the arm and occasionally to the leg, but remained limited to the right side. In the intervals the child seemed to regain consciousness, and then it was observed that she was unable to utter a syllable, although to a certain extent she understood spoken language. There was early optic neuritis. No obvious discharge was to be detected from either ear, though cotton introduced in the right meatus was soon moistened with offensive purulent material. A perforation of the left tympanic membrane was discoverd, with some fetid discharge. It was decided to explore the temporo-sphenoidal lobe on the left side, but an abscess was not found. The left arm-center was then exposed, and also the left lobe of the cerebellum, but without disclosing a purulent focus. For a few days succeeding the operation the patient seemed to be somewhat better, the fits becoming less numerous and consciousness returning, but the arm remained paralyzed, and the speech-defect was unaltered. Death took place a week later, and on post-mortem examination a large abscess-cavity, containing about an ounce of pus, was found in the left lobe of the cerebellum, located near the surface and about three-quarters of an inch from the medulla. Careful exploration failed to disclose a lesion of the left side of the brain.

The Staining and Mounting of Tube casts and other Organic Urinary Deposits.—BRAMWELL (*British Medical Journal*, No. 1749, p. 8) makes the following useful suggestions for the study of urinary sediments. An ordinary conical urine-glass is filled with equal parts of urine and an aqueous solution of boric acid, and set aside until the deposit settles. This is then removed by means of a pipet and transferred to an ordinary test-tube containing about half a dram of a solution of picrocarmin, and the two are thoroughly mixed and set aside for twenty-four hours. Some of the sediment is then removed, by means of a fine-mouthed pipet, and mounted. If there is reason to suspect the existence of amyloid disease of the kidney a solution of methyl-violet may be used instead of that of picrocarmin. In order to bring out the fine details of the tube-casts stained in the manner described, and in order to preserve them as permanent preparations, they may be mounted in Farrant's solution, consisting of gum arabic and distilled water, each four parts, and glycerin, two parts, with a little camphor. A small test-tube is filled three-quarters with this solution, and in it is placed, by means of a fine-mouthed pipet, the stained deposit from the test-tube containing the mixture of urine and solution of picrocarmin. The smaller tube is then securely corked, inverted two or three times in order to facilitate thorough mixture, and put aside until the sediment has had time to settle. In the course of three or four days a minute drop of the deposit is removed from the bottom of the tube by means of a fine-mouthed pipet and placed upon a slide and covered. The preparation may in the course of a few days be sealed in the ordinary manner. If the preparation thus mounted is overstained with the solution of picrocarmin the deposit should be transferred to fresh Farrant's solution. Any organic urinary deposits may, of course, be stained, mounted, and preserved in the same manner.

The Thyreoid Gland and its Relation to Myxedema.—LANZ (*Zur Schilddrüsenfrage; Sammlung klinischer Vorträge*, 1894, No. 98) in an elaborate treatise upon the thyreoid

gland and its relations to myxedema, reports the results obtained from a series of experiments made by him upon cold-blooded animals from which he removed the thyreoids. He assumes that the symptoms in cold-blooded animals are much less acute because of the slowness of their metabolism. Fishes, amphibians, and reptiles were employed in the course of his experiments. The removal of the thyreoid from fifty sharks gave an almost completely negative result, all recovering quickly from the operation; the lives of the sharks thus treated, however, were notably shortened. Bony fishes do not survive the operation of thyreoidectomy, but reptiles bear the operation well. In none of his operations did he find a subsequent enlargement of the spleen. He was unable to determine the existence of any relationship between the pituitary body and the thyreoid gland. As regards the influence of food upon thyreoid cachexia Lanz claims that poorly-nourished animals withstand the cachexia better than those that are well fed. Animals without thyreoids do not stand narcosis so well as normal animals, and do not respond to efforts at artificial respiration. Among the symptoms following removal of the gland are pronounced diminution of the blood-pressure, leukocytosis, and great increase in the number of blood-plaques, marked disturbance of respiration, and various digestive disorders—dysphagia, anorexia, vomiting. The experiments of Lanz upon himself do not confirm the experiences of the English experimenters. He has not observed any quickening of the heart's action after the ingestion of fresh thyreoid glands. He suggests the treatment of akromegaly with pituitary gland.

Electric Illumination in Abdominal Surgery.—KELLY (*American Journal of Obstetrics*, September, 1894, p. 348) has adopted the electric light as a perfect means of artificial illumination in abdominal surgery, viewing it as an indispensable part of his armamentarium. In hospital-work he uses a portable drop-light consisting of a sixteen-candle power lamp attached to a short, wooden handle, and connected with the source of supply by insulated wire cords. The light was at first used to secure independence of sunlight, but it was soon found that in many cases it is superior to even the brightest sunlight. By means of such a light, held in the hand and reflected according to will in any direction, every accessible part of the pelvis appears with vivid distinctness, and the smallest oozing vessels can be picked up and torn surfaces accurately united by delicate sutures under direct inspection. Half of the lamp may be surrounded by a reflector, painted black and covered with flannel on its convex surface, in order to protect the eyes and face of the operator from light and heat. The light is to be held steadily and properly directed, about six inches above the patient's body and a short distance below the operator's face. When a street-current or house-current cannot be tapped, a good light may be secured by means of a portable storage-battery. Under some conditions a head-light may be employed, the light being condensed by a reflector behind and a lens in front, the lamp being attached to a flexible steel band which fits the head.

Trephining of the Skull for Spastic Paralysis.—SMITH (*Lancet*, No. 3700, p. 193) has reported the case of a boy, five and one-half years old, whose arms were contracted upon his chest, the legs crossed and partly flexed at the thighs, and unable to stand. Although quite intelligent, he was able to articulate but a few monosyllables. The symptoms had been present from birth, and no material improvement had been hoped for. A transverse depression was found in the occipital bone, two and one-fourth inches wide and about an inch from above downward, just below the occipital protuberance. The uncertainty of the results of operation having been explained to the parents, and they having agreed to assume all risks, two openings were made in the depressed bone by means of a trephine an inch in diameter and united into one. The meninges projected forcibly upward through the opening, but there was no pulsation of the brain when first exposed, but before the completion of the operation pulsation was quite natural. The wound healed by first intention. There was at once a marked improvement in the child's general condition, and the limbs became gradually more relaxed and the legs less drawn up, and the little patient became able to extend the right hand to be shaken, as he had not been able to do before. The improvement was continuous, and the child slept more quietly than before the operation.

THERAPEUTIC NOTES.

A Case of Medicamentous Lipuria.—SCHLOSSMANN (*Archiv f. Kinderheilk.*, B. xvii, H. iii, iv.; *Wiener med. Presse*, 1894, p. 1347) has reported the case of a child, a year-and-a-half old, presenting dyspeptic symptoms, but otherwise healthy, to whom was administered a prescription containing a half-ounce each of castor-oil and olive-oil, with one drop of peppermint-oil, a teaspoonful at night and half a teaspoonful in the morning. The child began to improve, but it was observed that it was passing a smaller amount of urine than normal. The first passed was quite opaque, of whitish-gray appearance, somewhat resembling dirty milk, and contained many fine particles in suspension. On permitting the urine to settle in a conical glass it was found that the turbidity was due in part to the presence of alkaline urates and in part to the presence of fat. The filtered urine did not respond to tests for albumin, and the sediment contained no cellular elements. The little patient soon recovered from her gastro-intestinal derangement, and the urine and micturition became normal in the course of two days. From a diagnostic point of view it is pointed out that a condition of pathologic lipuria is not to be assumed until the ingestion of a readily absorbable fatty substance is excluded.

Two Cases of Nitro-benzol Intoxication have been reported by GRIECHOW (*Virchow*, 1893, p. 13; *Schmidt's Jahrbücher*, 1894, No. 8, p. 139) following the ingestion of one or two drops, and five or six drops respectively, of oil of mirbane in brandy. The symptoms presented were weakness, vertigo, dyspnea, with increased frequency of respiration, cyanotic discoloration of the skin, dilatation of the pupils, and a characteristic odor of the breath and vomited matters. In the course of three days both patients were practically well, though for a considerable length of time there was complaint of headache and nausea. Forty-two additional cases of poisoning with nitro-benzol have been reported. The drug is a nervous poison, acting on the central nervous system.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 6, 1894.

RECENT RESEARCH CONCERNING THE STRUCTURE AND FUNCTIONS OF THE ADRENAL GLANDS.

WHETHER it has been the successful issue of the experimental researches in connection with the thyroid gland which has acted as an incentive, or merely economy demanding that from an excess of workmen in fields already well tilled, some should be delegated to certain neglected and more or less out-of-the-way corners of the domain of inquiry, or whatever may have been the cause, certain it is that during the last two years a remarkable amount of attention and thought has been directed toward those small and as yet comparatively little understood structures in the body—the so-called ductless glands. And when we ransack the literature and estimate the progress made and the results obtained by the workers in these byways, we must admit that while many of the researches have been incomplete and fragmentary, yet, when the fragments are pieced together, outlines of conceptions of function and structure quite new and unsuspected begin to appear, very indistinct as yet, it is true, and broken by many gaps and spaces which have still to be filled up, but nevertheless outlines—surprising, promising and stimulating.

As an example of what may be found out almost for the looking, we wish to call attention at this time to some new points in connection with the supra-renal capsules, which have some bearing not only upon the anatomy, but also, it would seem, upon the physiology of these bodies. Without entering at all into a review of the normal histology of the adrenals, it is of importance, in connection with what is to follow, to refer to one or two of the microscopic features of these organs which have been before noted by a few observers. Of these we shall mention three, viz: (1) occasionally single adrenal cells are present in the suprarenal vein; (2) red blood-corpuscles have been seen included within the protoplasm of adrenal cells; and (3) groups of red blood-corpuscles apparently not within bloodvessels have been observed among the gland-cells, giving the impression of small hemorrhages into the parenchyma of the gland.

MANASSE,[1] working recently, in Von Recklinghausen's laboratory, on the hyperplastic tumors of the adrenals, noticed certain peculiar buds and processes of adrenal cells projecting into the veins, and immediately set about studying normal adrenals to find out whether or not similar structures existed in them. That they did exist in the healthy glands he was able to establish beyond doubt. Besides adrenal cells, occurring singly and in small heaps, mixed with the blood in the veins, he could demonstrate, especially in the medulla, processes of adrenal cells varying in size from small buttons to long strings of cells pressing through the walls of the veins. These were sometimes found floating without any covering within the lumina of the vessels, and sometimes spread out, with bases of considerable width, on the inner surfaces of the venous walls. The free floating processes too could be made out in transverse section, when they had the appearance of small discs of adrenal cells situated within the veins and surrounded on all sides by red blood-corpuscles.

This relation of the adrenal cells to the veins was so striking that MANASSE determined to carry his investigations further. He therefore collected at slaughter-houses the adrenals of horses, oxen, calves, pigs and sheep, removing them with the least possible disturbance from the body and laying them unopened into hardening reagents—alcohol, Müller's fluid, and a 2 per cent. solution of potassium bichromate. The medulla of the supra-renal bodies, with its granular, polygonal cells arranged in cords

[1] Virchow's Archiv, Bd. 135, Heft 2, p. 263.

and irregular networks imbedded in a connective tissue framework, has been especially studied by EBERTH, by v. BRUNN, and by ARNOLD. One of the most interesting characters of the medullary cells described is the deep-brown tint which they assume on treatment with solutions of the salts of chromic acid. MANASSE in his comparative studies found that the substance giving this reaction varied much in amount in different cells—the difference being referable, he thinks, to different stages of physiologic activity rather than to the presence of distinct varieties of cells.

But MANASSE found—and this is to us as interesting as any of his observations—in the veins of the medulla, and occasionally also in the arteries, masses of a substance which, although observable at first glance, were so striking that he thought he must be dealing with an artefact or with a pathologic condition. He saw in these vessels brown, glassy, homogeneous masses intimately mixed with the red corpuscles, and completely filling the lumina so as to form veritable casts. Along with these masses in the veins he could also often make out spherules apparently of the same material as the former, although of a darker-brown color This hyaline substance could be seen in the veins of the adrenals of all the animals examined, when the tissues were fixed in chromate-solutions immediately after death; adrenal glands, however, which had been hardened in alcohol showed no trace of its presence. This fact led MANASSE to think of a connection between the brown hyaline in the vessels and the brownish pigment of the medullary cells, as VON BRUNN had before pointed out that in tissues hardened in alcohol the pigment in these cells was extracted.

His experiments on the supra-renal bodies of animals not only completely confirmed his earlier observations on human adrenals, as far as the projection of columns and masses of adrenal cells directly into the veins was concerned, but also yielded additional results. In some of the smaller veins he could make out a distinct relation between the brown hyaline masses and the contents of the brown cells, of which the intravenous processes of adrenal substance consisted. The membraneless cells of the processes were seen to communicate directly with the homogeneous masses; a portion of the latter still remained within the cells, while part was already within the lumina of the veins, so that cell-contents and venous contents formed a continuous whole. In other places small slit-like vessels could be seen, lined on one side by endothelium and on the other by a row of brown cells, the latter apparently pouring out their contents into the lumina. Following these smallest vessels still further, he came finally to structures which gave an appearance as though the brown masses represented a direct secretion from the brown cells. At these points the canals had a striking resemblance to gland-tubes, being lined completely by brown cells; the lumina were filled with the refractive brown masses mixed with red-blood corpuscles, and occasionally blood-capillaries could be demonstrated communicating directly with the tubes.

The brown hyaline is quite different from what we have been accustomed to understand by hyaline, especially in its chemic reactions. It is easily soluble in alcohol, and is not affected by sulphuric, nitric, or acetic acid, by solutions of magnesium sulphate, ammonium or magnesium phosphate, or by silver nitrate.

To satisfy himself that this brown hyaline was not an artefact due directly to the chemic action of the chromates, MANASSE attempted to find the substance in living animals, and succeeded in making out in the blood of the supra-renal vein obtained from an etherized dog large numbers of small hyaline, glistening, colorless spherules, each about half the size of a red blood-corpuscle. These spherules occurred usually in clumps, bore no relation to the red or white corpuscles of the blood, and were entirely unaffected on treatment with osmic acid. In view of the fact that GOTTSCHAU had described similar findings in the blood from the supra-renal veins of the rabbit, MANASSE apparently regards the hyaline substance seen in the blood as the same as that seen in the veins in his sections.

His paper is carefully written and is extremely conservative in its claims. In closing his article he lays stress on the fact that the question as to whether or not the brown hyaline in the ves els represents a condition existing *intra vitam* must still remain an open one. Neither does he consider it proved that the brown masses represent a secretion of the medullary cells which is carried through the veins into the circulating blood. He remains, for the present, satisfied in his demonstration of the near relation of the adrenals to the veins and to the venous circulation.

We had also intended to refer somewhat at length to the interesting researches of OLIVER, referred to

by Prof. Shäfer in his admirable address to the Physiological Section of the British Medical Association at its recent meeting, but for want of space must dismiss them in a few words. Oliver, working with an extract of suprarenal capsules, found that in certain cases in human beings it was capable of producing an increase of vascular tone and a diminution in the size of the arteries. In other words, its effects were quite contrary to those of thyroid extract. Turning to animal experiments, he also proved that both alcoholic and aqueous extracts of the adrenals contained a most potent physiologic substance, which, on injection in extremely minute doses, produced a remarkable effect upon certain parts of the nervous, muscular, and vascular systems. When the vagi were intact after the injection, the heart beat slowly and weakly; when they were divided, these inhibitory influences disappeared, and the heart was very differently affected, the beat gaining enormously in force and frequency; at the same time the peripheral arterioles became much contracted, and there thus resulted an enormous increase in the arterial pressure. Whether this extraordinarily powerful substance is to be looked upon as a useful product manufactured by the adrenals from the blood, and "subsequently gradually used up in the economy for the virtue of its action upon the circulatory system, or whether it is to be regarded as a poison formed by the tissues during their activity, and carried by the blood to the suprarenals, there to be rendered innocuous, we do not as yet certainly know."

When these facts are added to those already known in connection with Addison's disease, with the interesting spectroscopic examinations of the pigment in the suprarenals made by McMunn, and with the ablation-experiments of Brown Séquard, Tizzoni, Abelous and Langlois, and others, the significance and the importance of the adrenal glands, small as they are, cannot fail to be better appreciated. It is to be expected that further investigations will in the near future be rewarded with results fully as interesting as those to which we have just referred.

EDITORIAL COMMENTS.

The Foot-ball Craze is again manifesting itself. The daily papers contain interesting accounts of the friendly practice games of the various teams. Of one college crew we read the following report:

They practise with a desperate fierceness, and quite a hospital list is swelling out. Trainer —— has ordered a number of men to stop practice until they recover their full vigor. As a result two elevens could not be gotten out to-day, so general work in catching, punting, stealing, tackling, blocking, following, and interfering was done.

——'s knee is growing worse instead of better, and he is laid off just as he was beginning to round out nicely and show signs of becoming a valuable man.

Trainer —— is seriously worried about him, and is afraid he will not come about until too late in the year to be of any use. Captain —— received another serious wrench in his knee, and has been compelled to cease practice, although he daily appears in a suit. ——'s foot remains no better, and another abscess is forming. —— has badly bruised his thigh, while a number of the other men have sustained minor injuries.

These, be it observed, are only the playful results of practice-games, and with the brothers of one's own team. What a charming and inspiring picture! This is the end of intellectual and educational training!

Like another disgusted traveller, we might place at the entrance of this wretched road the warning sign:

This road is impassable;
Not even jackassable!

At a dinner of the alumni some time ago the President of Princeton University said in reference to athletics: *I appreciate scholarship as much as any one, but I realize the fact that all of those who go to college do not desire to become fine scholars.*

Could strabismic ethics be more sly or cunning? Could catering to a vulgar fashion be more abject?

But does squint-morality finally pay? Not always. The present freshman class at Princeton is smaller than that of last year, a result to be charged up to foot-ball and hazing, two amusements that logically go well together. It seems that parents and guardians do not quite agree with some of their wiser (?) but weaker educators. Such a result, our readers will remember, has more than once been prophesied in these columns.

The Need of Negro Physicians.—It is said that the average length of life of the New Orleans negro is only 24.2 years. This frightful mortality is also ascribed to the lack of medical attendance and the wretched sanitary conditions in which the colored population of large Southern cities live. It is asserted that probably not one-half of the negroes receive any medical attention during illness. Here is certainly a field for home missionary work. If the foregoing assertions are to any great extent true, it is a disgrace to our civilization and to our common humanity. Forty million dollars have been given since the war toward the literary education of the colored race, but how much more pressing is the problem of their medical care and sanitation! It may be doubted if forty cents have been given toward the education of negro physicians. Much has been done in educating foreign medical missionaries; why not do the more needed duty of medically educating young colored men, thus avoiding a crying public disgrace by enabling them to work among their suffering brethren?

The Anti shaking-hands Society.—Science is a great destroyer of sentiment. Much has been printed in both lay and medical journals concerning the dangers of kissing. Children may no longer buy a cent's worth of ice-cream

in the street, fine ladies will no longer handle money, except in bills never before put in circulation, gloves must be worn whenever touching a door-knob, nurses must never allow children to be kissed by anybody, and so forth. A humorous correspondent of a London journal, taking advantage of this bacteriomania, has perpetrated a joke not only on his own serious-minded journal, but upon many others who have solemnly reproduced it and added great warnings to their readers. This excellent correspondent tells how in the ancient and semi-barbaric city of Baku, in Russia, there has been formed a society of the leading citizens, each member paying a subscription of six rubles; the object of the society is the prevention of handshaking. Any lapse into handshaking is punished with a fine of three rubles. The correspondent tells how a delegation consulted a scientific specialist, who warned them that the hands of their dearest friend might be covered with horrid germs of all kinds, but especially with those of cholera. The Anti-shaking-hands Society was speedily formed.

Prof. R. Matas, of New Orleans—as we shall henceforth be glad to call him—is not so much to be congratulated upon his appointment to fill the Chair of Surgery in the Medical Department of Tulane University as is the University itself in securing such a man. The departmental vacancy had been caused by the untimely death of Dr. A. B. Miles, and a strange tendency was shown to seek elsewhere for a surgeon to fill it. Indeed, the position, we believe, was offered to Dr. L. McLane Tiffany, of Baltimore. Certainly the University has honored itself in choosing Dr. Matas, whose remarkable abilities have long been most widely recognized.

Dr. Matas has now one imperative duty to perform—to work with his characteristic energy and high-mindedness to stop the disgrace of graduating students into the profession after only two years of medical study.

We congratulate The Journal of the American Medical Association upon the enlargement of its mechanical and editorial facilities, and wish it increased and ever-increasing success. The *Journal* is in one sense beyond competition. It has a unique place to fill and unique opportunities to advance the science, art, and ethics of medicine. When it shall have been brought to a realizing sense of what it owes to the profession it will become a power for good second to none in the world. Meanwhile THE AMERICAN MEDICAL ASSOCIATION should receive the earnest and thorough and hearty support of every physician in America.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Abstract of the Proceedings of the Seventh Annual Meeting, Held in Toronto, Ontario, September 19, 20, and 21, 1894.

FIRST DAY—SEPTEMBER 19TH.

THE Association met in the Council chamber of the College of Physicians and Surgeons at 10.15 A.M., and was called to order by the Second Vice-President, DR. GEO. F. HULBERT, of St. Louis, Mo.

An Address of Welcome on behalf of the local medical profession was delivered by DR. JAMES THORBURN, which was responded to by Dr. Hulbert.

The reading of papers was proceeded with, the first being by DR. J. HENRY CARSTENS, of Detroit, entitled "The Incision in Abdominal Surgery—Methods and Results." The author summarized his results as follows:

1. With a small, narrow-bladed, sharp knife, make a clean incision of the necessary length through the skin, and with another sweep or two cut through the linea alba, muscle, etc. Lift the peritoneum with the fingers, open it, and enlarge the incision. The use of the forceps or the grooved director to lift the tissues is unnecessary.

2. In closing the abdominal incision use animal ligature, kangaroo tendon, and catgut. First, carefully bring together the peritoneum in a running stitch, then the transversalis fascia, and the rectus, if the incision is through this muscle. Then carefully bring together, edge-to-edge, the tendinous insertion of the oblique muscles. The fat and loose cellular tissue above can be brought together in one or two tiers, according to thickness. Bring the skin together carefully with Marcy's cobbler-stitch, thus burying all sutures.

3. Then seal with collodion, and if everything connected with the operation has been carefully aseptic, absolute primary union will take place, and the different layers of the abdominal wall will have been brought together as near as possible as they were in the first place, and no hernia will result.

4. In cases of extensive umbilical, ventral, or other hernia, it is best to bring the peritoneum together with an over-and-over stitch of kangaroo tendon or catgut; to make a flap-splitting operation of the ring, bring together with silkworm-gut or silver wire, buried, and then the fat and skin are united with the buried animal suture.

DR. JOSEPH PRICE, of Philadelphia, read a paper on "Plastic Surgery in Gynecology," in which he said that the practice of surgery in all its branches required a mechanical turn of mind and an ability to devise means to accomplish a given end. In order to mend a perineum intelligently the mechanism of labor must be understood and the lines of fracture appreciated. In cases of serious pelvic invasion with accompanying lacerated cervix, it is often better or imperative, first to do the pelvic operation, and to follow this at another time with the cervical repair. The author condemns the plan advised by some, to perform internal and external operations at one sitting. Perineal tears always occur at certain parts of the perineal structure. These tears are either lateral, under the ramus of the pubes, or central, extending from the vagina toward the rectum. The tears toward the rectum tend to run round it rather than through it, owing to the differentiation of structure in these two tubes. The tears of the vagina are always from within outward, and from above downward, and therefore the external, or skin operations, for perineal lacerations are essentially unscientific procedures. All operations for the restoring of the integrity of these parts should be done in the lines of their destruction, and therefore from within outward and from above downward. When the skin of the perineum is involved, mending is merely a cosmetic procedure. The cosmetic element too often predominates in many of the so-called perineal devices. The silkworm-gut with shot is by far the most preferable

material to be used for sutures. As little tissue as possible is to be included within the ligature, and strangulation is to be avoided.

Dr. W. B. Dewees, of Salina, Kansas, next read a paper entitled "The Care of Pregnant Women." The paramount duties of the obstetrician in the study and care of pregnant women may be classified as follows: 1. To discover if the patient be actually pregnant. 2. To determine positively if the impregnation be uterine, or normal, as contradistinguished from tubal, abdominal, or abnormal. 3. To carefully note the pregnant woman's history, including her age, primiparity or multiparity, environments, station in life, general condition of health, period of gestation, as well as her dress, food, drink, and habits of life. To make repeated examinations of the urine, and ascertain the temperature from the time pregnancy is established to the termination of gestation. 4. To make a physical examination for the purpose of accurately determining the diameter of the pelvic straits; the symmetry and size of the bony outlet; the integrity, condition, and position of the vagina, uterus, and other intra-pelvic viscera and adjacent structures; the state of the abdominal muscles; the presence or absence of hernia, varicose veins, tumors, etc.; the shape, size, and condition of the breasts and nipples; the condition of the heart, lungs, mind, stomach, bowels, etc. 5. To observe the state of the fetus, its strength and viability, as well as the implantation of the placenta. The thoughtful obstetrician will advise his patient as to the requisite *régime*. The consciousness of his full duty will impel him to insist upon: 1. Absolutely regular hours and wholesome environments. 2. Plain but nutritious and wholesome food and drink, being principally composed of fresh lean meats, fresh fruits, pure milk, and distilled water. 3. A proper amount of exercise, by walking or light labor on foot, and maintaining the correct erect posture. 4. An open condition of the bowels and skin, which is to be chiefly maintained by proper diet, exercise, and bathing, the wearing of flannels, warm low-heeled shoes, and loose garments, and in rare cases the proper use of laxatives and hot-water enemas.

Dr. George S. Peck, of Youngstown, Ohio, read a paper on "Appendicitis, with Report of Cases."

Case 1. Operation on July 6th, during intervals of attacks; obstruction; a second operation was performed, recovery following. The operation was on July 27, 1894. The appendix was buried in a mass of strong adhesions between the ileum and cecum, and contained large fecal concretions. The appendix was removed in segments. The ileum was returned to the abdominal cavity. During the first six days the highest temperature was 100°; the pulse was 100. On the fifth day there were four attacks of vomiting, the fourth containing fecal matter. On August 4th the incision was reopened and there was found about three feet from the ileo-cecal valve a complete obstruction by a band of dense adhesions. The obstruction was liberated, the ileum brought out in the incision and the abdominal cavity packed with gauze. During the entire day of August 1st the pulse ranged from 140 to 160; vomiting of fecal matter continued at frequent intervals, and tympanites was increasing. At 7 P.M. symptoms of obstruction continued, becoming worse every hour. As a temporary expedient a small opening was made in the ileum, and fecal matter and flatus came away in large quantities; the vomiting then ceased and tympanites disappeared. From the thirteenth day to the present time the patient has had from one to three daily passages per rectum; she sat up for the first time on the thirty-third day. She was discharged from the hospital on the fifty-fifth day after the first operation.

Case 2. The operation was during the fourth day of the first attack. The large appendix was removed, containing two drams of pus and fecal concretions. The adhesions were broken up and the incision packed with iodoform gauze. Uninterrupted recovery followed. The woman was discharged from the hospital the twenty-eighth day after operation.

Case 3. Operation was on the third day of the third attack. The peritoneal cavity was opened and the adhesions broken up; the large appendix was removed; uninterrupted recovery ensued.

Case 4. Operation was during the tenth day. Death from septic peritonitis in sixty-five hours followed. A large abscess cavity was evacuated; the appendix, gangrenous and detached, was washed out by irrigation. Autopsy revealed general septic peritonitis.

Case 5 was one of perforating appendicitis. Operation was during the third day of the attack. Death followed from septic peritonitis twenty-seven hours or more after operation.

Case 6, similar to the previous one, died from general septic peritonitis.

Dr. W. G. McDonald, of Albany, contributed a paper on "Appendicitis: Observations Based on a Clinical Study of Eighty-four Cases." Out of the great amount of literature, controversial and otherwise, three important landmarks are established: (1) That for all practical purposes all inflammatory processes in the right iliac fossa arise from the appendix. (2) That practically the appendix is always intra-peritoneal, and that any operation undertaken for appendicitis that does not involve the entering of the peritoneum is false in its surgical conception. (3) That idiopathic peritonitis does not occur. That many cases diagnosticated as such are really cases of perforating appendicitis. The author classified the varieties as (1) Acute perforating, fulminating appendicitis with general peritonitis. (2) Acute suppurating appendicitis with local plastic peritonitis and abscess. (3) Subacute appendicitis, variously termed catarrhal, chronic, relapsing, or obliterating appendicitis, or appendicular colic. The perforation occurs very much earlier than is commonly believed. Acute suppurative appendicitis with local peritonitis presents the most favorable field for operation during the attack. The removal of the appendix is to be undertaken with great circumspection when it lies in the walls of an abscess-cavity. The third group of cases does not require operation during the first attack, but if repeated attacks occur, operation during quiescence is demanded. Operative results in these cases are most favorable.

Dr. Joseph Hoffman, of Philadelphia, followed with a paper on "Surgical Appendicitis."

Second Day—September 20th.

Dr. W. B. Dorsett, of St. Louis, read a paper entitled "Ligation of the Uterine Arteries for the Cure of Fibroid Tumors and Checking Hemorrhage." The

object of this paper was to establish the author's priority as well as the originality of ligation of the uterine arteries for the cure of fibroids. He made observations during December, 1889, and January and February, 1890, and reported a case of atrophy of the genitalia and described the technique of the operation of ligation of the uterine arteries for the cure of fibromatous growths in a paper read before the St. Louis Medical Society, May 17, 1890, and which was published in the *St. Louis Courier of Medicine*.

Dr. Henry Howitt, of Guelph, Ont., read a paper entitled "Remarks on the Surgical Treatment of Intussusception in the Infant, Based on Two Successful Cases." In it he recommends early abdominal section as being the best method of treatment to reduce the high mortality rate of intussusception in early infancy. Of the two cases cited, one child was at the time of operation under three and the other under six months of age. In regard to the steps of the operation, among other things he advises a small median incision, evisceration, reduction by pressure on the apex of intussusceptium, while the intussuscipiens is drawn in the opposite direction, and forcing the contents of the ileum into the colon before returning the intestines to the abdomen.

Dr. Robert T. Morris, of New York, demonstrated a method of intussusception in rabbits.

The next paper was on the "Treatment of Distention of the Fallopian Tubes without Laparotomy and Removal," by Dr. Frank A. Glasgow, of St. Louis. The paper was intended to bring before the profession a method of curing tubal distention by means of intra-uterine treatment in contradistinction to celiotomy and removal. By this means the uterine ends of the tubes are made more patulous, and a discharge takes place from the tube through the uterus. The author called attention to the fact that the tubes, so far as his observation goes, are always pervious at the outer extremity of the cornu, hence, when removing them, we must always clamp them before cutting. The obstruction must be within the uterine wall, probably in the endometrium, and hence gonorrheal inflammation is not an adhesive inflammation, and therefore it does not follow that the tubes have a true atresia following this inflammation. His opinion was that the closure is due to a swelling of the endometrium, and hence a closure at the uterine end takes place. When this inflammation and swelling are overcome by pressure and antisepsis, the tubes become patulous again. The intra-abdominal pressure will cause fluid in any pendant portion of the tube to ascend into the uterus. The foregoing procedure can be carried out in three different ways: First, by gradually packing with gauze without anesthesia. Second, by rapid dilatation of the cervix and packing with gauze after curetting. This is done under anesthesia. Third, his own method of dilating by means of antiseptic or sterilized elm-bark tents. These tents are small strips of elm-bark made just long enough to enter the cervix completely and not press on the fundus. They should be kept in an alcoholic solution or mercuric chlorid, 1 to 4000, and have a short string attached by means of which they may be withdrawn. They are partially broken in a number of places for the purpose of making them more pliable. They may be dipped into glycerin or water just before introduction. These tents may be used when it would be impossible to pack with gauze. He had treated twenty or more cases during the past year, and did not recall one in which he did not get some discharge from the tent. All of the cases were either cured or very much benefited.

Introductory remarks by Dr. William W. Potter, of Buffalo, were made upon "Inflammatory Disease of the Uterus and Appendages and of the Pelvic Peritoneum." Dr. Potter began by recalling the well-known fact that the pathology of pelvic disease had been entirely reconstructed since 1860, and that now we had come to regard inflammation of the pelvic peritoneum as generally symptomatic of disease of the ovaries or Fallopian tubes, or both. Mr. Tait within the last ten or twelve years, together with men who have worked abreast of him (some of whom are members of this Association) have driven out the theory of pelvic cellulitis that for so long held sway, and now perimetritis and parametritis have been dropped from the gynecological vocabulary. The struggle has been a long one, but abdominal surgeons have demonstrated the truth of this proposition, that pus originating outside of the tubes or ovaries in the non-puerperal state is a very rare condition, and that speaking generally, pelvic abscesses are pus tubes. The largest number of women in the consulting-rooms of gynecologists are those suffering from pelvic inflammation or its residues, hence the importance of the subject under discussion cannot be overestimated. But, he asserted, it is only within the past seven or eight years that anything like uniformity of opinion as to the causes and proper treatment of pelvic inflammation have been adopted. Now, just as we are beginning to agree as to the essentials governing these cases, we are told by a number of agreeable gentlemen who call themselves conservatives, that these diseases do not demand operation, but that they can be cured in most instances by tentative measures, such as diet, rest, electricity, and the like. By denouncing the work of abdominal surgeons as unnecessary mutilation, and stigmatizing it as castration or unsexing women, they have created a panic among the medical journals that is reaching far into the ranks of the profession. The effect of this is to turn back the wheels of time and stay the advance of progress, with harmful results to suffering women. It must be admitted that these so-called conservative men are clever, which makes their subtle and dangerous doctrine all the more damaging in its results.

Dr. C. A. L. Reed, of Cincinnati, discussed the "Clinical History of Inflammatory Disease of the Uterus and Appendages and of the Pelvic Peritoneum"; Dr. L. S. McMurtry, of Louisville, the "Causation and Pathology"; Dr. James F. W. Ross, of Toronto, the "Diagnosis and Prognosis"; Drs. M. Rosenwasser, A. Vander Veer, J. Henry Carstens, and Dr. Joseph Price, "The Treatment."

Dr. Joseph Hoffman, of Philadelphia, read a paper entitled "Pus in the Pelvis and Abdomen, its Diagnosis and Treatment." He said that pus in the abdominal and pelvic cavities had been treated and considered with far more leniency than pus anywhere else in the human economy. It was the tramp manifestation of all disease. He considered briefly the various organs in which pus makes its appearance, and in the order of frequency he

mentioned the kidneys, the appendix vermiformis, tubes and ovaries, the liver, the pancreas, and the spleen. Each case should be treated according to the demands it makes and according to its complications. There is no good in doing an ideal operation and have the patient die when it is over. Ideal work was that which gives the best result in the line for which it was done. Surgery of the abdomen was a work of self-denial, of trial, of unexpected complication, and lurking disaster. He best can rise to it who has for his motto "my patient." Self-seeking carelessness of lives has its place in the carnage of internecine strife, not in the shadowy sorrows of dying women.

Dr. E. W. Cushing, of Boston, made some remarks on hysterectomy for cancer of the uterus.

Dr. James F. W. Ross, of Toronto, read a paper entitled "Personal Experience with Pus Tubes, when to Operate, how to Operate, and the Results of Operation."

Dr. H. T. Machell, of Toronto, contributed a paper on "Congenital Diaphragmatic Hernia," in which he reported two interesting cases.

"A New Operation for the Radical Cure of Inguinal and Femoral Hernia," was a paper read by Dr. C. A. L. Reed, of Cincinnati. The operation which the author devised is as follows: The incision in inguinal hernia is made from a point two inches above Poupart's ligament midway between the anterior-superior spinous process of the ilium and the spine of the pubis, obliquely downward and inward as nearly as possible consistent with the access of the inguinal canal to a point at the base of the scrotum. The dissection is then carried into both scrotal and pelvic cavities. The protruding viscus is then reduced and carefully inspected after being brought out above. The sac is then carefully dissected from its scrotal connections and reversed by invagination. It is then opened by two incisions, one toward the pubes, the other toward the ileum, being thus converted into an anterior and a posterior flap. The cord is now dissected loose and placed in the canal, denuded of its peritoneum at its outer angle. The internal ring is closed by several interrupted sutures of animal or buried silk, these sutures being applied beneath the peritoneal flaps formed by splitting the sac, care being taken that in the closure of the ring undue pressure shall not be brought to bear upon the cord. The posterior peritoneal flap is now excised, the stump being ligated, should there be any necessity for doing so. The anterior flap is carried across the now obliterated internal ring and stitched by interrupted sutures to the posterior parietal peritoneum. The external ring is now closed by passing a number of sutures through its pillars externally to the cord, which is now fixed in the internal (pubic) angle of the outlet of the canal. The incision into the abdomen is closed by interrupted figure-of-eight sutures, the internal loop embracing the peritoneum, the aponeurosis of the transversalis and of both oblique muscles, and the external loop embracing the superficial fasciæ, fat, and skin. These sutures should not be more than three-quarters of an inch apart. The incision into the scrotum may be closed in the ordinary way. Drainage should not be employed except in the presence of marked oozing or obvious infection.

Dr. A. Vander Veer, of Albany, presented a report of one hundred and forty-five operations done for removal of ovarian tumors and pathological conditions associated with the ovaries and uterine appendages only. He gave a careful review of the subject of the preparation of patient, embodying all the strong points pertaining to the technique of such work, placing great stress upon the importance of the room in which the operation was to be done being put in a thoroughly aseptic condition, and thorough cleanliness of the patient herself. The operations comprise all the varieties of pathological conditions met with in connection with the ovaries and tubes. The histories of the cases were somewhat interesting. Thirty-nine gave a history of phthisis, fifteen of carcinoma, fifty-seven of irregularity of menstruation. The mortality amounted to 11 per cent. While not criticising adversely the methods of other operators in closing the wound by means of different rows of sutures, kangaroo tendon, and other forms of sutures, yet he has no reason to give up his usual method of closing the wound by deep sutures of silkworm-gut, placing them three or four to the inch, taking in carefully only a margin of the skin, a portion of the fascia and muscles, and not to exceed one-quarter of an inch in width of the peritoneum itself, placing much stress upon the importance of careful, thorough, complete apposition. The causes of death in the seventeen cases were as follows: Obstruction of the bowels due to a coil of small intestines becoming attached to the stump of the pedicle, causing death on the fourth and fifth day, two cases. Septic peritonitis, two cases. Immediate hemorrhage from the pedicle, slipping of the knot within six hours after the operation, though the wound was reopened, the vessels secured, abdomen flushed, and hemorrhage controlled, one case. Undoubted hemorrhage from the pedicle, causing general peritonitis, although no distention of the bowels was present, death on fourteenth day, one case. Shock within twelve hours after operation, one case. Shock within twenty-hours after operation, one case. Autopsy in both cases revealed everything in good condition. Pulmonary infarction on sixth day, one case. Aggravated diabetes, one case. Exhaustion on the sixth day, no other apparent cause found, one case. Another case of exhaustion on the third day, the symptoms in the last two cases, including an autopsy, not revealing any other cause. Multilocular ovarian cyst, tapped twice, operation complicated with four months' pregnancy, one case. Puerperal septicemia, one case. Intestinal obstruction on twenty-first day, one case. Advanced age, complicated with the recent effect of an attack of la grippe, one case. Delayed operation in a case of extra-uterine pregnancy possibly four months, one case.

Dr. A. H. Cordier, of Kansas City, read a paper on "Hydrosalpinx." He said that articles had appeared in medical journals by the so-called conservative writers in the last few months in which aspiration or catheterization of the Fallopian tubes filled with liquid had been advocated as a procedure of relief and cure. Such articles had engendered a retrograde tendency on the part of many, and it is sure to be at the expense of an increased mortality from subsequent operative procedures to cure these cases after abandoning the unsurgical and uncertain tinkering. Hydrosalpinx had been looked upon as the least hazardous of all inflammatory results to the Fallopian tubes. The writer claimed that hydrosalpinx was a sequel of some old inflammatory diseases of the

tubes, an offspring of a virulent process that had wrought permanent and irreparable injury to the delicate structures of the tubes. The writer did not consider hydrosalpinx as a retention-cyst. Cases were rarely diagnosticated prior to operation. A digital examination of one of these cases causes less pain than is produced in examining a case of pyosalpinx. In one case occurring in the essayist's practice the uterine extremity of the tube was largely dilated and filled with a clear fluid, while in the ampulla there existed a collection of pus separated from the clear fluid by a closed stricture.

"Inflammatory Disease of the Uterus and Appendages under Various Modes of Treatment" was the title of a paper by Dr. Joseph Price, of Philadelphia. The methods of treatment of pelvic disease may be broadly classed as those that are proved and those that are experimental. Many of the operations now successful were formerly failures, because of the insufficient knowledge of how to deal with a wounded gut, how to make an anastomosis, or how to do a bowel-resection. Hence, it is to be put down as a postulate in pelvic surgery that no man has a right to attempt it who does not know how to deal with all the complexities of intestinal surgery. To know when to stitch and when not to stitch the intestine is as necessary as to know when and when not to operate. The leaving of pus tubes to recover of themselves is just one step removed from stuffing them with gauze and trusting to Providence. To puncture and evacuate and stitch a suppurating cyst—say a real ovarian cyst—would be derided, and yet, said the essayist, we have operators who do not hesitate to do this with the smaller pus tube.

Dr. George H. Rohé, of Catonsville, Md., said that conservative surgeons were very much shocked at first by the proposition to remove the uterus together with the adnexa in cases of inflammatory disease in the pelvis. The operation has, however, won its way against opposition, and must now be considered as an elective procedure in cases of extensive suppuration with adhesion, and especially in those cases, so numerous, in which the endometrium is likewise the seat of purulent inflammation. Gonorrheal, puerperal, or tubercular inflammations and dense adhesions with displacement of the uterus demand removal of this organ, as well as of the appendages, if permanent good results are expected. Total extirpation of the uterus and appendages by the vaginal method for pelvic suppuration was first done by Péan, in 1886. Péan, Segond, Doyen, Jacobs, and Landau have performed the operation upward of five hundred times, with an average mortality of less than 5 per cent. The operation by the vagina is easier than abdominal extirpation, and, in the hands of most surgeons who have performed it, is attended by less shock. It leaves the parts in condition for perfect drainage. The after-treatment is simple. Patients may sit up in a week or ten days. Forceps are preferred to the ligature for hemostasis.

The next paper was on "The Present Status of the Treatment of Pelvic Inflammation, or How Shall We Deal with Pelvic Inflammatory Troubles? By Dr. W. B. Dorsett, of St. Louis, Mo.

The author drew the following deductions:

1. Pus in quantities is hard to deal with down in the pelvis in laparotomy cases, and, if possible, should be evacuated prior to taking out the tubes and ovaries, either through the cul-de-sac of Douglas, or, if between the layers of the broad ligament at the side of the uterus, laparotomy should be done at some future time.

2. Pus-sacs in the tube near the uterine end of the tube can be evacuated through the uterus by packing the horn.

3. Parametritis or cellulitis of the ancients is, except under rare instances, a secondary trouble due to a foul uterine cavity. Clean out the cavity and stop the source of poison, and you do the best thing possible to be done.

(To be concluded.)

AMERICAN PUBLIC HEALTH ASSOCIATION.

Abstract of the Proceedings of the Twenty-second Annual Meeting, held in Montreal, P.Q., September 25, 26, 27, and 28, 1894.

First Day—Morning Session.

The Association convened in the Hall of the Y. M. C. A., and was called to order at 10 A. M. by the President, Dr. E. P. Lachapelle, of Montreal.

Dr. Robert Craik, of Montreal, reported on behalf of the Local Committee of Arrangements.

Dr. H. F. Nuttall, of Baltimore, contributed a paper entitled "Hygienic Notes Made on a Short Journey Through Italy in 1894," which was read by Dr. A. L. Gihon, of Washington, D. C. The notes referred principally to the sanitary condition of Naples, where poverty and ignorance provided an easy prey to every epidemic until 1884. But after the cholera epidemic of 1884 the government resolved to spend one million francs for sanitation. New sources of water-supply were secured, new sewers built, and whole blocks of tenements were torn down and replaced by modern houses. The result has been to impart habits of cleanliness to the people and to greatly reduce the death rate.

"The Cart Before the Horse," was the title of the next paper, by Dr. Benjamin Lee, of Philadelphia. The object of the paper may be briefly embodied in the two following propositions:

1. Copious water supplies with the aid of what is known as modern plumbing, constitute a means of distributing fecal pollution over immense areas, through the soil, through subterranean water-courses, and in surface streams, and cannot, therefore be regarded with unmixed approbation by the sanitarian.

2. The question of drainage and sewerage, whether for individual residences or for communities should always precede that of water-supply; and no water-closet should ever be allowed to be constructed until provision has been made for the disposition of its effluent in such a manner that it shall not constitute a nuisance prejudicial to the public health.

Dr. Wyatt Johnston, of Montreal, followed with a paper on "Observations upon Sedimentation in Water," in which he said that the amount of settling which takes place in the settling basin of the Montreal Water Works is too small to be seriously considered, the capacity of the basin being only twenty-three million gallons, and the daily consumption about eighteen million, the water really only passes in and out of the basin. Analysis proves that bacteria are far less numerous in the reser-

voir water than in the settling basin. The melting of snow in the spring has a tendency to increase the number of bacteria in the reservoir water. As to the value of sedimentation from a hygienic point of view, it is much below that of a sand filter.

Dr. A. N. Bell, of Brooklyn, described very completely the Long Island Water Basin, or Brooklyn's Reservoir.

Prof. F. T. Shutt, of Ottawa, Canada, read a paper entitled "Water of Our Farm Homesteads." The speaker had examined hundreds of samples of water from wells from Canadian farms, and very frequently had found it polluted. No doubt many cases of disease could be traced to this source. Water containing the drainage of barnyards could not but be a source of danger and the cause of internal disorders. Too much care cannot be taken in selecting the site of the farm-well and in keeping the surroundings free from filth.

"Sand Filtration of Water, with Especial Reference to Recent Results Obtained at Lawrence, Mass," was the next paper, by Mr. Geo. W. Fuller, of Lawrence. The author entered a strong plea in favor of sand filtration of water. During the five years preceding the use of the filter at Lawrence the average annual death-rate from typhoid fever was 1.27 per 1000 inhabitants, the population of Lawrence being 50,000, and this average is equivalent to 63 actual deaths per annum. During the past year there have been 26 deaths from typhoid fever, a reduction of 60 per cent. Of the 26 who died, 12 were operatives in the mills, each of whom was known to have drunk unfiltered and polluted canal water, which is used in the factories at the sinks for washing.

Mr. E. B. Shuttleworth, of Toronto, contributed a paper entitled "Some Deductions from Bacteriological Work on the Water of Lake Ontario," dealing with the bacteriological character of lake water. With regard to the depth of water as affecting the number of bacteria, the author is inclined to think that bacteria are directly influenced by season. He is convinced that certain microörganisms multiply most readily at certain seasons of the year. He threw out the suggestion that this may have an important bearing in explaining the prevalence of typhoid fever at certain times during the year. This seasonal peculiarity was marked in Toronto, where every September shows a sudden increase in the typhoid rate, with a corresponding decrease after October.

First Day—Afternoon Session.

On reassembling the first paper read was by Dr. Charles Smart, of Washington, it being the "Report of the Committee on the Pollution of Water-Supplies," of which Dr. Smart is chairman.

The report reviewed at length the influence which a polluted water-supply may have had in the recent cholera epidemic in Europe, and upon the spread of typhoid fever on both continents. The efforts to purify water by sand-filtration were also reviewed, the committee hesitating to reaffirm its former positive language with regard to the sufficiency of filtration as protection against typhoid fever; nor, on the other hand, does the committee regard the testimony as authorizing a formal declaration of opinion in favor of the efficiency of filtration. It is hoped that the success achieved at Lawrence will lead to the filtration of other surface waters, each of which will probably teach an important lesson in connection with bacteriologic experiments and with the mortality from typhoid fever before and after the construction of the filter-beds.

Dr. Gardner, of London, Ont., moved that, in view of the danger to the public health by the sewage contamination of our fresh water lakes, rivers, and streams, this Association memorialize the different Federal Governments, as well as the State and Provincial Governments, to pass laws prohibiting the contamination of water-supplies by sewage from cities, towns, and villages, and compel them to provide some means for the treatment and oxidization of this sewage before emptying it into these places. Carried.

Dr. Charles A. Hodgetts, of Toronto, read a paper on the "Management of Diphtheria Epidemics in Rural Districts." The medical officer in these cases must exercise a personal supervision, not only over his patients, but personally superintend the carrying out of all orders, for upon the thoroughness of the work depends to a very large extent the prevention of further outbreaks in the district. The inhabitants of the rural districts should receive more attention from the sanitary authorities than they have in the past, and some inexpensive system should be adopted for the more efficient and prompt management of epidemics in those portions of our country. The schools should be closed in the district until such time as the inspector has satisfied himself in the manner indicated that the households of the individual scholars thereof are free from diphtheria.

Dr. P. H. Bryce, of Toronto, followed with a paper on "Practical Difficulties by Medical Health Officers and Physicians in Dealing with Inspected Cases of Diphtheria." One of the difficulties consisted in differentiating between simple sore-throat and diphtheria, but in order to be on the safe side the author recommends and urges isolation of all cases.

Dr. J. Ed. Laberge, of Montreal, read a paper on "Vaccination as a Preventive of Contagious Diseases," in which he dwelt largely upon the investigations of Pasteur and others.

Dr. J. D. Griffith, of Kansas City, contributed a paper entitled "Innocuous Transportation of the Dead." He opened by quoting instances in which epidemics were renewed by the exhumation of bodies after years had elapsed, and concluded that the danger of one having died from an infectious disease must be great. He cited as an instance of the virulence of a dead body that in a Normandy village twenty-three years after an epidemic of diphtheria some of the bodies of those who had died of the disease were exhumed, and an epidemic at once broke out, first among those who had opened the grave, and spread from those to many others. Other examples were cited. Until we educate the public to the point of thorough sanitation of cremation the transportation of dead bodies by the railways is and always will be a source of very great danger. He urged that attention be directed by the Association to the different legislative bodies of the land to a subject of such vital importance. He urged, furthermore, that all railways set off a small portion of their baggage cars for the transportation of dead bodies, placing the body in a box lined with zinc with a door very much after the fashion

of a large ice-chest. This done, the lives of employés would not be endangered. No broken or open box could become infected, and no odor would escape from the car.

FIRST DAY—EVENING SESSION.

At this session addresses of welcome were delivered by Dr. Robert Craik, of Toronto, His Honor the Lieutenant-Governor of Quebec, Mayor Villeneuve, of Montreal, and Hon. L. P. Pelletier, of Montreal. The President's Address followed, in which he reviewed the progress of the Association during the twenty-two years of its existence.

(To be concluded.)

CORRESPONDENCE.

VITAL STATISTICS OF THE NEGRO.

To the Editor of THE MEDICAL NEWS,

SIR: Mr. Frederick L. Hoffman, in an article in THE MEDICAL NEWS (September 22, 1894, page 320) entitled "Vital Statistics of the Negro," refers to a communication made by me on the same subject, April 7, 1894, page 389, in which a plea is made for the consideration of sociologic factors in the study of this question.

The whole subject of statistics is involved, and the negro is merely used as an illustration. Figures in themselves mean nothing; they must be carefully analyzed and studied in connection with social conditions. To say that one city has a larger death-rate than another may be a statistical truth, but it is not a truth from which alone we can draw conclusions. We must know what influences exert themselves in each city; what is the occupation and the nationality of its population; the percentage of children to adults; the geographic position of the city; whether its inhabitants live in tenements or separate dwellings; whether they are in affluence or in poverty; whether ignorant of hygienic laws or cultivated in them; and a host of other matters must be taken into consideration before we can say that one city is *healthier* than another. There are three kinds of lies, some one has said, "white lies, black lies, and statistics."

Mr. Hoffman, from the strength of facts presented, concludes that "the differences are physical and permanent," and yet a few lines before he says that "under better social and sanitary conditions the death-rate (among the negroes) will diminish, but it will still be in excess of the neighboring whites." Certainly, because the neighboring whites in the better districts are usually the wealthy classes who employ these very blacks, who live in the alleys back of their mansions.

And again, he says, "what else but a high rate of mortality and a low degree of morality can be the result of such tendencies," namely, the crowding together in the worst districts of the large cities. But if the "differences are physical and permanent," of what use "the genuine education in laws of hygiene and principles of morality" which Mr. Hoffman recommends? If an all-wise Providence has ordained the black man to be the servant of the white man, and to be unable ever to cope with him in the social struggle, why try to oppose the "hidden wisdom?"

Mr. Hoffman raises the question that "if the high rate of mortality among the colored population be due largely to unfortunate social conditions, why should not also the foreign element be affected in a similar manner?" And he partly answers this question by stating that the Irish population shows a mortality similar to the negro, and in my communication I stated that the Italians gave as large a death-rate in the slums as the negroes.

I will here quote from the compendium of the Eleventh Census, Part II, in which returns are given from registration bureaus covering a population of about 13,400,000 persons. Of this number, 7,200,000 live in cities and the balance in country or rural districts. Arranged according to nativity and color are:

Colored	1,000,000
Native-born whites	6,000,000
Native born of foreign parentage	3,250,000
Foreign born	3,000,000

A sufficiently large number from which to draw conclusions.

	Per 1000.
The death-rate on the total number was	19.64
" " " city population was	23.58
" " " rural population was	14.99
" " among the colored was	19.57
" " " foreign born was	19.85
" " " native whites was	17.00
" " " native born of foreign parentage was	24.32
Colored death-rate in cities was	34.52
" " in rural districts was	19.00
White " in cities was	23.32
" " in rural districts was	16.00

This shows that the foreign-born whites and the children born of foreigners have the same death-rate as the colored, because they often dwell in the same surroundings and are under the same economic conditions.

This summer I had opportunity of studying the mortality of some of the so-called "slum" districts of our city. A tenement-house owned by a philanthropist and conducted on sanitary principles, occupied by 25 colored adults and 25 colored children, gave an annual mortality for the past three years of 10 per 1000 (2 deaths in four years), while in the rear of this tenement a court, in which several colored and white families resided, returned a mortality of 40 per 1000. Two squares away—in Baker Street—(the rag-pickers' district) occupied almost exclusively by Italians, and where the children are less numerous in proportion to the adults than among the Russians and negroes, the mortality rate was 45 per 1000.

Now, to show how little statistics in themselves are worth, we find the Russian Jews living in the same house with Italians and colored returning a much smaller percentage of deaths than either, and yet much larger than is obtained from the farm colonies of New Jersey, where the same class of individuals are settled, because the Jew, no matter how filthy he may appear, has some knowledge of hygienic laws and takes care of his children; the more ignorant he is, the more orthodox in his observances of these Mosaic laws.

Thus, social conditions and hygienic surroundings largely influence the death-rate, and the negro usually lives in the most unsanitary and wretched portions of the large cities.

We ought not to classify the mulatto with the full-

blooded negro any more than with the pure white. They should be considered in a class by themselves, and yet all the deaths occurring among this mixed breed are credited to the negro. The death-rate among mulattoes is, I believe, much in excess of that of the pure negro, and this may be due to the illegitimacy of birth, which plays some rôle here. Leffingwell, in his study on "Illegitimacy," states that among the illegitimate children of Great Britain and other countries the death-rate is twice as great as among the legitimate. This fact may also have some bearing on the death-rate among the colored generally, as illegitimacy is quite common among them. Children without a father are more apt to be neglected, the mother, obliged to make her living, leaving the child to care for itself.

Mr. Hoffman brings forward statistics from the army and insurance actuary, and he could use the figures presented in my communication in relation to deaths in prisons. We do not dispute the fact that the *adult negro* furnishes a greater mortality than the *adult* white under similar conditions; but, as the majority of these deaths are due to tuberculosis, and as this disease can be acquired in infancy and remain latent for a long period, and that nowhere can we find better conditions for the spread of this infectious disease than in the miserable and overcrowded dwellings of the great majority of negroes, a reasonable claim might be made for the statement that because of this *previous environment* the colored adult is not the equal of his white brother, and must react differently to the same stimulus, and not because "of a race proclivity to disease and death."

The moral question must be treated in the same special manner. All law-breakers are not sent to prison, and the more influential the criminal, the less likelihood of conviction. The police-court investigation in New York City shows us that morals cannot be determined by the number of arrests, and that the most disorderly element in New York City was most exempt from police interference.

We should compare this mass of poverty and ignorance with that mass of poverty and ignorance; but we cannot take a class as socially distinct as the negro and stand him up against the whole white race with its four or five social divisions; it is not scientific. As stated before, this is not a race question; it is simply a plea for the sociologic analysis of statistics.

In the same number of the Medical News (p. 316) Dr. Irving M. Snow has a paper on "Rickets among Italian Children," and in it he shows how, under bad surroundings in this country, the children of Neapolitan parents are more likely to be afflicted with rachitis than in their native clime, "because in their own land the misery, ignorance, and neglect of hygiene amid which the children are reared are in some degree offset by the bright, warm sunshine," and in which they constantly live. He further states: "This cannot be accomplished with the children of the city poor, and it is to *this lack of pure air* and *sunlight* that we may attribute the spread of rickets in densely populated urban communities." . . . All the causes of rickets—improper food, bad air, depression caused by infantile maladies—are intensified, and the presence of rachitis in seven-tenths of the Neapolitan babies in Buffalo indicates a constitutional deterioration from a great and sudden change in environment."

The very same causes are active in the negro, and rickets is likewise a common disease among the colored children.

Thus, before we can call characteristics racial and dependent upon distinct organic differences, we must eliminate the sociologic factor, and to understand this requires a thorough knowledge of the environment and how it influences the element of society in question; and most important, from a physical as well as moral point of view, is the environment of infancy and childhood. Improper nourishment, neglect, exposure to disease, all leave lasting effects on impressionable material, causing deep physical changes, as might be illustrated by many well-known examples.

Respectfully yours, M. V. Ball.

Philadelphia, Pa.

NEWS ITEMS.

The New York State Medical Association.—The eleventh meeting of the New York State Medical Association will be held Tuesday, Wednesday, and Thursday, October 9, 10, and 11, 1894, at the Mott Memorial Hall, 64 Madison avenue, near Twenty-seventh street, New York City. The following papers have been announced: (1) A Case of Lateral Lithotomy for the Removal of a Wire-nail, Alleged to Have Been in the Bladder for Years; Recovery; (2) Report of a Case of Traumatic Epilepsy; Recovery, Zera J. Lusk, M.D., Wyoming Co.; (3) A Case of Anesthesia with Death, and Attempted Extortion Successfully Resisted; (4) A New Non-conducting Speculum for Post-partum and Post-abortum Intra-uterine Douching, Eden V. Delphey, M.D., New York Co.; (5) Interesting Cases from General Practice, Illustrating Special Points of Treatment, Charles E. Lockwood, M.D., New York Co.; (6) Brief Comments on the Materia Medica, Pharmacy, and Therapeutics of the year ending October 1, 1894, E. H. Squibb, M.D., Kings Co.; (7) Some Interesting Cases of Appendicitis, Joseph D. Bryant, M.D., New York Co.; (8) Typhlenteritis Versus Appendicitis, J. W. S. Gouley, M.D., New York Co.; (9) The Differential Diagnosis of Intra-cranial Lesions, Charles Phelps, M.D., New York Co.; (10) Recent Studies on Diphtheria and Pseudo-diphtheria, William H. Park, M.D., New York Co.; (11) Diphtheria, John Cronyn, M.D., Erie Co.; (12) The International Sanitary Conference of Paris in 1894, Stephen Smith, M.D., New York Co.; (13) Can Herpes Cause Dangerous Edema or Spasm of the Glottis? John S. Jamison, M.D., Steuben Co.; (14) The Technique of Cesarean Section, with Exhibition of Cases, A. Palmer Dudley, M.D., New York Co.; (15) Hysterectomy for Uterine Fibroma by Baer's Method, with Report of Nine Successful Cases, Joseph Taber Johnson, M.D., Washington, D.C.; (16) Hysterectomy in Pus Cases, William R. Pryor, M.D., New York Co.; (17) The Anatomy and Surgical Treatment of Inguinal Hernia in the Male, Illustrated by the Stereopticon, Henry O. Marcy, M. D., Boston, Mass.; (18) Fractures at the Elbow-joint, E. M. Moore, M.D., Monroe Co.; (19) Fractures of the Inferior Extremity of the Humerus, Involving the Articulating Surface; with Report of two Cases Occurring in Chil-

dren, Douglas Ayres, M.D., Montgomery Co.; (20) The Stearate of Zinc Compounds in Atrophic Rhinitis, Joseph S. Gibb, M.D., Philadelphia, Pa.; (21) Suppurative Cellulitis Following an Injury to the Hand, William H. Robb, M.D., Montgomery Co.; (22) Diet and Regimen for the Diminution of Fat, T. J. McGillicudy, M.D., New York Co.; (23) Discussion on the Prevention of Tuberculosis, Hermann M. Biggs, M.D., New York Co.; (1. The Importance of Tuberculosis from a Sanitary Standpoint, as shown by its Prevalence. 2. The Factors in the Causation of Tuberculosis. 3. The Communicability of Tuberculosis and the Manner of its Transmission. 4. The Early Recognition of Pulmonary Tuberculosis through Bacteriological Examination and its Influence on Prevention. 5. The Influence and Value of Special Hospitals for the Treatment of Tuberculosis in the Prevention of the Disease. 6. The Influence of the Doctrine of Communicability upon the Diminished Prevalence of Tuberculosis. 7. The Importance of Measures to be taken at Health Resorts for Tubercular Patients for the Prevention of this Disease. 8. The Dangers of Infection in the Various Means of Transportation, *i. e.*, Steamboats, Surface and Elevated Cars, Day-coaches and Sleeping-cars. 9. The Proper Attitude of State, Municipal, and Sanitary Authorities Toward Tuberculosis, and the Specific Measures to be Taken for the Prevention of this Disease.) These propositions will be discusses by: (24) Lawrence Flick, M.D., Philadelphia, Pa.; (25) W. T. Councilman, M.D., Baltimore, Md.; (26) Edward G. Janeway, M.D., New York Co.; (27) E. K. Dunham, M.D., New York Co.; (28) William H. Park, M.D., New York Co.; (29) Henry D. Didama, M.D., Onondaga Co.; (30) The Diagnosis and Treatment of Pleurisy, J. Blake White, M.D., New York Co.; (31) The Treatment of Retinitis Albuminuria from an Ethical Standpoint, Frank Van Vleet, M.D., New York Co.; (32) Address: The Germs of Some Discoveries, John Shrady, M.D., New York Co.; (33) R: A Few Therapeutic Hints, Henry D. Didama, M.D., Onondaga Co.; (34) The Removal by Trephining of Fluid the Result of Acute Cerebral Meningitis, with Report of a Case, and Experiments Upon the Lower Animals, B. M. Ricketts, M.D., Cincinnati, Ohio; (35) Reminiscences of a Country Doctor During the Past Fifty Years, Including the Crude Condition of American Medical Literature at the Beginning of that Period, Darwin Colvin, M. D., Wayne Co.; (36) A Practical Study of Grave Abdominal Contusions, with a Clinical Report of Twenty Other Cases, Thomas H. Manley, M.D., New York Co.; (37) Some Facts About the Treatment of Typhoid Fever, John G. Truax, M.D., New York Co.; (38) Intestinal Anastomosis, Frederick H. Wiggin, M.D., New York Co.; (39) The Arthropathies of Locomotor Ataxia, Parker Syms, M.D., New York Co.; (40) A Case of Ectopic Pregnancy at the Utero-tubal Junction, E. D. Ferguson, M.D., of Rensselaer Co.; (41) Primary Laparotomy in Tubal Pregnancy, J. E. Janvrin, M.D., New York Co.; (42) Direct Arterial Transfusion, John G. Orton, M.D., Broome Co.; (43) Restoration of Function of the Lung and Pleura after Thoracentesis, Charles A. Leale, M.D., New York Co.; (44) Uretero intestinal Fistula as a Result of Abdominal Abscess Not Due to Appendicitis, A. J. Van Vraken, M.D., Albany Co.: (45) Remarks on Strangulated Inguinal Hernia, Robert Selden, M.D., Greene Co.; (46) What is Fever and How is it Best Managed? Henry F. W. Risch, M.D., Kings Co.; (47) Tetanus; its Etiology, Pathology, and Treatment, J. Lewis Smith, M.D., New York Co.; (48) Cases of Death of Fetus at an Early Stage of Gestation, and Retained in Uterus to full Period, H. O. Jewett, M. D., Cortland Co.; (45) Title to be announced, C. G. Stockton, M.D., Erie Co.

The Medical Society of Virginia will hold its twenty-fifth annual session at Richmond, October 23, 1894. In addition to the annual address of the President, Dr. William P. McGuire, of Winchester, the subject of "Appendicitis" will be discussed by Dr. William L. Robinson, of Danville. Dr. J. W. Long, of Richmond, will follow with a paper on "The Indications for Celiotomy in Appendicitis." Dr. Edwin A. Down, of Hartford, Conn., will read a paper on "The Psychic Factor in Appendicitis." Drs. A. M. Phelps and Robert T. Morris, of New York City, and Dr. Joseph Taber Johnson, of Washington, D. C., will discuss the subject.

The following additional papers are announced: "Currettage of the Uterus," by Dr. John W. Dillard, of Lynchburg; "Care of the Insane," by Dr. James D. Moncure, of Williamsburg; "Trephining for Epilesy," by Dr. J. T. Boutelle, of Hampton; "Dysentery," by Dr. William F. Cooper, of Woodville; "Preventive Medicine," by Dr. William A. Thom, Jr., of Norfolk; "Some Old Remidies in the Treatment of Diphtheria," by Dr. George W. LeCato, of Wachapreague; "The General Practitioner's Knowledge and Responsibility in Gynecological Troubles," by Dr. Joseph Price, of Philadelphia; "Preventive Treatment of Pulmonary Phthisis (Tuberculosis)," by Dr. J. Edgar Chancellor, of Charlottesville, Va.; "Sepsis: its Early Diagnosis by the Pulse," by Dr. J. Allison Hodges, of Richmond, Va.; "Sporadic Cretinism and its Treatment by Thyroid Extract," by Dr. Wharton Sinkler, of Philadelphia; "Cesarean Section—Report of a Case," by Dr. Alfred B. Tucker, of New York; "Glycerin Suppository as a Substitute for the Glycerin Tampon," by Dr. J. T. Graham, of Wytheville, Va.; "Psychical Epilepsy," by Dr. Samuel J. Fort, of Ellicott City, Md.; "Report of a Case of Dislocation of the Hip-joint, with Fracture of the Femur," by Dr. George W. Larrick, of Middletown, Va.

Dr. Oertel, Assistant Superintendent of the Hygienic Institute of Hamburg, died on October 2d. His death is said to have been caused by infected water ingested for the sake of experiment and which was followed by an attack of cholera.

TREPHINING IN THREE CASES OF EPILEPSY: TWO OF THE JACKSONIAN VARIETY; ONE DUE TO OLD MENINGEAL HEMORRHAGE; IMPROVEMENT.

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

THE resources of the pharmacopeias have been exhausted in endeavoring to cure epilepsy, but as yet no drug has been found upon which we can rely. The bromids, either alone or in connection with other agents, such as antipyrin, chloral and borax, still rank first; but these often fail in giving more than temporary relief. All cases of epilepsy treated successfully or unsuccessfully by surgical measures should be reported in detail, so that, from a knowledge of the causes of the successes and failures, we may ultimately be able to determine the conditions favorable for operative procedure. In the hope of adding something of value to this important subject, I submit the following cases:

CASE I. *Epilepsy of eighteen years' standing, in a woman thirty-three years of age, following a blow upon the left side of the head at the age of five years; seizures beginning in the right hand; excision of cortical center for right index-finger and thumb, followed by complete paralysis, but no disturbance in sensation until six days after operation; great improvement.*—Miss M., thirty-three years of age, single, a domestic, was born in Missouri, but has lived in Colorado twenty-six years. So far as she knows there have been no cases of epilepsy, or mental or nervous trouble in the family.

Her health in childhood was good, and remained so up to her fifth year, when she received a blow on the left parieto-frontal region of the head from a fall. She was sick for some time after this, but knows nothing of the particulars. After this her health was fair until her fifteenth year, when, while sitting one morning tying her little nephew's shoestrings, she has a distinct memory of falling over in a faint and being aroused by her people throwing cold water in her face. She was told that there were no convulsive movements in this seizure. She does not know if this attack was followed by sleep, nor of any direct cause which precipitated it.

One year later she had her second seizure, which she remembers began in the right hand, but she remembers nothing more than a contraction of the finger and thumb of this hand, as she lost consciousness after this occurred. After her second attack she thinks the seizures occurred almost daily, certainly weekly, for the next three or four years. The fits up to the present time have usually occurred daily or weekly, but the woman has had a few periods of two or three months' freedom from the seizures. She states that as far as she remembers all her convulsions have begun on the right side, and, with the exception of a few attacks, they have begun in the right hand. Occasionally a drawing sensation has been first felt in the right foot. The seizure commonly occurs in the morning, occasionally in the afternoon, and very infrequently at night.

There have been no attacks of *petit mal*. The fits are never preceded by headache, but each is followed by headache and a confused condition of the mind, lasting from one to several hours. She has been treated for prolonged periods by the bromids, without any apparent result.

She was admitted to the Arapahoe County Hospital in the latter part of November, 1893. The examination on December 4th, 1893, showed the patient to be rather undersized, poorly nourished, and presenting almost an imbecile appearance. Her memory seemed to be fairly good for past events, but she stated that she had considerable difficulty in remembering things of recent occurrence.

The left side of the head over the parieto-frontal region was not so well developed as the corresponding region on the right side. There was no ataxia. The knee-jerks were both normal. Ankle-clonus was absent, and the other deep reflexes presented nothing abnormal.

The plantar and the superficial reflexes of the abdomen were absent. The dynamometer registered, R., 70; L., 58. Sensory phenomena, including the special senses, were normal. The ophthalmoscope showed no change in the optic nerves or fundi except a slight paleness of the discs. She was placed on thirty grains of sodium bromid and ten grains of borax, thrice daily, but the convulsions continued to recur two or three times daily. Several of these were witnessed by an intelligent trained nurse. A description of one will suffice for all, as there was but little apparent variety in the character of the convulsive seizures.

According to the patient's account, the first sensation she experiences is a sensation of tingling and numbness in the fingers and thumb of the right hand, and immediately this hand begins to close and her arm to flex at the elbow. She remembers that always, if she is standing at the time this sensation comes on, she has presence of mind enough to sit or lie down before she loses consciousness. She remembers

[1] Read before the meeting of the Colorado State Medical Society, held in Denver, June 19, 20, and 21, 1894.

nothing of any of the attacks after the arm begins to flex at the elbow. She remembers telling other patients in the ward when the attack is beginning.

According to the nurse's description, the patient was standing by the window; she caught hold of her right hand with the left, saying: "I am going to have an attack," walked across the room, and lay down upon her bed. The fingers and thumb of the right hand were beginning to flex and the right arm to bend at the elbow, when clonic convulsive movements began in the right hand and arm, followed by convulsive movements in the right foot and leg and right side of the face, and a few seconds later by convulsive movements in both arms and legs and in both sides of the face. The seizure lasted about two minutes, and was followed by sleep of an hour's duration; later by a dazed condition lasting several hours, during which headache was bitterly complained of. Several convulsions were witnessed from first to last, but they all began in the fingers and thumb of the right hand, the index-finger and thumb always being flexed before the adjacent fingers. After faithfully trying sodium bromid and borax for about thirteen weeks, but obtaining no beneficial results, I explained to her that an operation offered some hope, not in curing the disease entirely, but in mitigating the severity of the convulsions and improving the mental condition. She gladly accepted, and said she would rather die than go through life in her condition. On March 30th, 1894, Dr. Rogers, after strict observance of aseptic precautions, trephined over the middle third of the left fissure of Rolando. The bone was found thickened, but there was no appearance of fracture or abnormal adhesion of dura to the bone. The internal surface of the bone presented nothing abnormal. On applying the Keen double electrode, attached to a Fleming faradic battery, to the dura, points were reached where stimulation induced flexion of the thumb, then of the index-finger, followed by flexion of the other fingers of the hand. By a slight movement of the electrode the muscles of the right arm and right side of the face were made to contract. As the external surface of the dura seemed healthy it was decided to open this membrane.

On exposing the pia and convolutions of the brain everything seemed in a normal condition. On again applying the electrodes I found the centers, irritation of which caused contraction of the thumb and index-finger of the right hand. Dr. Rogers excised a portion of the cortex, about one-half of an inch in diameter and a fourth of an inch in thickness, which included these centers. The wound was dressed, and the patient reacted from the operation fairly well; but the temperature remained rather low until the morning of March 31st, when it was normal. At noon of March 31st she said she was feeling well and free from headache. The right thumb could be extended, but she was unable to bend it except to a very slight extent. The lateral movements of the thumb were completely lost. All movements in the index-finger were lost. The little finger could be extended and flexed to a normal degree, but the movements were weak. The ring-finger was much more limited in flexion and extension than the little finger. The middle finger could be extended and flexed only to a very slight degree.

The extensors of the wrist were strong, the flexors quite weak. All the interossei muscles of the right hand except those that move the little finger were paralyzed. The right side of the face around the mouth was almost completely paralyzed. The upper portion was unaffected. The dynamometer registered R., 2; L., 60. The right elbow and shoulder were apparently normal in power.

Great care was observed in testing the tactile sense the temperature sense, and the posture-sense of the fingers of the right hand, and these were all found to be normal. No loss of tactile sense was observed in the paralyzed portion of the face.

On April 1st the patient was still doing well, with a normal temperature. The entire right hand and the elbow-muscles were now paralyzed. The shoulder-muscles of this arm were weak. The lower portion of the right side of the face was completely paralyzed for voluntary motion, but emotional mobility was still present. Sensory phenomena were again tested and found normal.

On April 2d the temperature was 97.2° F. The woman seemed stupid, and complained of considerable headache. As Dr. Rogers and I were unable to account for the low temperature, severe headache, and evidences of depression which she presented, and the absolute paralysis of the entire right arm, which now included all the shoulder-muscles, paralysis of the right side of the face, protrusion of the tongue to the right and thickness of speech, we were fearful that meningeal hemorrhage had occurred and that the effused blood was exerting pressure on the brain.

We decided to wait until the next day, April 3d. At this time, finding the temperature still depressed and the other symptoms the same as on the previous day, Dr. Rogers, on opening the wound, found everything in a normal condition, with the parts healing by first intention, and not a drop of pus. In a few days the woman rallied from this depressed condition and went on to uninterrupted recovery.

On April 5th the paralysis was still complete; the tactile sense was apparently preserved in the paralyzed parts, except on the tip of the ring-finger, where two points of the esthesiometer were perceived as one, even when held apart twice the normal distance, but even on this finger the contact of a substance was recognized at once. On the tip of the little finger the contact of the blunt points of the esthesiometer was not recognized, but when they were moved slightly the two points gave the impression of one. The temperature-sense and the posture-sense were perfect.

On April 6th the motor and sensory phenomena were the same. On April 7th tactile sense was normal. The paralysis remained the same, that is, absolute in the right hand and arm, including the shoulder. The lower portion of the right side of the face was still paralyzed.

On April 12th she was first able to move the right arm at the shoulder, and by the 15th she had gained almost normal power in the shoulder and

elbow muscles. The sensory phenomena had been investigated daily and found normal. On the 16th: She had had no convulsion since the operation, but during this afternoon, after Dr. Rogers removed the stitches and rubbed the scalp over the cicatrix briskly for a while, she remarked: "I feel that my arm is going to be cramped," and almost instantly the flexors of the right hand began to contract. The movements began in the right thumb and index-finger, and the spasm was tonic in character. It was followed by contraction in the flexors of the wrist and elbow and adductors of the right shoulder. The movements passed to the right leg, left arm, left side of the face, but just in what order the muscles were affected was not observed. At this point the head turned to the left, she uttered a cry, and went into a general convulsion, which lasted about two minutes, and was followed by a few minutes' sleep. After the convulsion she remembered that the doctor was rubbing her head and that she told him her arm was going to be cramped. This was the last thing she remembered before the convulsion. The first thing she remembered after the convulsion was being in bed several hours after the fit. The convulsion was followed by headache as usual.

On the 18th she had another convulsion, at 9 A.M., similar in every respect to the one of two days before. She was now placed on the solution of borax and bromid which she was taking before the operation.

On the 22d she was able to move the little finger of the right hand and extend and flex the wrist. On the 26th the little finger, the ring and middle fingers had regained some power, and the index-finger and thumb could just be moved, but the interossei were paralyzed. The dynamometer showed R., 2; L., 60. The sensory phenomena still remained normal.

On May 18th she had her third convulsion, which began in the thumb and index-finger of the right hand. On May 22d the dynamometer registered R., 44; L., 60. She was unable to completely extend the index-finger of the right hand, and in closing the fingers of this hand the index-finger moved more slowly than the other fingers. The power in the index-finger was fairly good, but the movements were awkward. Flexor movements in the right thumb were about normal in strength, but slow. She was unable to extend the thumb to any extent unless the fingers were extended at the same time. The extensor muscles of the thumb were very weak. She was unable to use the thumb and fingers for such movements as sewing or buttoning her clothes without experiencing considerable difficulty. She was unable to use the thimble on the fingers of the right hand. All sensory phenomena were still normal. The pupils were rather large, the left slightly larger than the right. The most marked improvement at this time was in her appearance and mental condition. She was now hopeful, bright, and cheerful, and said her memory was better; she did not seem confused. Her face had lost, to a considerable extent, the melancholy and imbecile appearance. On June 3d her condition remained about the same as on May 22d. No convulsion had occurred since May 18th.

The convulsions in this patient occurred several times in each week, and sometimes daily, before the operation, although she was taking thirty grains of sodium bromid and ten grains of borax thrice daily. Since the operation only one convulsion has occurred since she has been placed on the same treatment, during a period of two months and a half. While the operation has not removed the entire cause of the epilepsy, it has so modified it that with appropriate treatment sufficient relief can be obtained to enable the patient to earn her own living. The mental improvement is decided. One of the most interesting points in connection with this case is a physiologic one, and consists in the tactile sense remaining perfectly normal in the index-finger and thumb of the right hand, although the cortical centers that seem to preside over the muscles that move these members were completely excised, and the muscles themselves left absolutely paralyzed. The only disturbance of sensation that occurred at all was a slight blunting found on the end of the ring-finger on the sixth and seventh days after the operation, and an inability to recognize a substance on simple contact with the tip of the little finger during these two days.

It seems to me that if tactile sense is governed by the same cortical centers that regulate muscular movements it would be impossible for excision of these centers to leave sensation perfectly normal. In all cases of cortical injury of the motor region coming under my observation, in which tactile sense has been affected, the injury has been attended with a blow or shock, and in this way the interference with tactile sense may be accounted for without attributing to the cortical motor centers sensory function.

The subjective sensory phenomena often experienced in the parts which are the seat of the initial spasm in Jacksonian epilepsy are interpreted as indicating that the motor cortical centers also contain sensory centers. It seems to me that in the absence of sensory change in excision of a motor center we are justified in looking for another explanation of these subjective sensations. All voluntary or reflex muscular movement is the result of centripetal impressions, and it is probable that sensory impressions that excite the activity of a motor cortical center go to the sensory center with which the motor cortical center is connected before reaching the latter. If this be the case it does not seem strange that irritation of a motor cortical center causing muscular movement should give rise to subjective sensations in that portion of the brain through which all impressions must pass to reach the motor center in question. I do not wish to convey the impression that I believe the sensory centers are as definitely located in certain portions of the brain as we have

reason for thinking the motor centers are, nor that the latter have no sensory function, but I do desire to call attention to the fact that such phenomena as were observed in the case just reported seem to prove that the alleged motor-sensory function of the Rolandic region of the cortex needs further investigation and careful study before we can accept the dual function of the Rolandic region as settled.

Case II.—Thomas N., twenty-nine years old, married, born in England, by occupation a miner, came to Colorado sixteen years ago, and has lived at an altitude varying from eight-thousand to nine-thousand feet.

His family history is negative. He denies syphilis and excess in alcoholic indulgence, but admits gonorrhea and excess in venery. He says that he enjoyed good health up to the time of the receipt of an injury to his head which has given rise to his present trouble. He was injured in April, 1890, by a falling rock, while engaged in blasting. He received injuries to the right shoulder, right eye, and right side of the head, and was rendered unconscious for several days. After this he was in a semi-conscious condition for one or two weeks longer. The physicians told him that the right parietal bone was fractured, with considerable depression of the bone at this point, and that they took out a small button of bone and elevated the depressed area.

During the three weeks that he was confined to bed he suffered but little with headache. With the exception of occasional dizziness, he remained comparatively well until August, 1890, a period of four months, when he felt very dizzy, but did not lose consciousness, was sick at the stomach, and vomited for one or two days afterward. In September, 1890, while in California for his health, he had a sick and dizzy spell, in every respect similar to the one he experienced in August. In November, 1890, while walking along a street in San Francisco he began to feel very sick at his stomach, and attempted to seek a retreat, but a minute or two later he fell in a convulsion and became unconscious. His wife, who was with him at the time, says the convulsion affected all the limbs, but she did not observe whether it began in one limb or in all at the same time. He remained unconscious an hour after the convulsion. No headache preceded the attack, but a severe headache followed it, and lasted for a day or so. Twelve days later he had a second convulsion, and one month after the second a third occurred. After this the attacks began to be more frequent, and occurred once or twice each week. They were held in check at first by the bromids, but later these seemed to lose their effect. All the attacks were preceded for a few seconds by a sick stomach, attended by general convulsive movements, and followed by unconsciousness, or disturbed consciousness and sleep, lasting for a few hours, and headache lasting for a day or more. There had been no constant headache. Between the attacks he felt fairly well. On an average he had about two convulsions each week.

On August 27, 1891, the existing conditions were noted as follows: He is a healthy, well-built young man, decidedly muscular, but is irritable, and his memory is uncertain and poor.

On the right side of the head, just back of the middle third of the Rolandic fissure there is an old scar, and the bone seems considerably depressed for an area of one or two inches in diameter. Over the center of this depression there is a space of a half-inch in diameter where the bone is absent, indicating the site where he was trephined at the time of his injury. The gait is perfect. There is no ataxia. Knee-jerk of the right is increased, of the left greatly exaggerated, and by measurement twice as great as the right. Ankle-clonus is present on each side, but much more marked on the left than on the right. Plantar reflexes are absent on each side. All the sensory phenomena, including the special senses, are nearly normal. The dynamometer registered R., 180; L., 200. The old injury to the right shoulder probably accounts for the deficient strength in the right arm and hand, as he is right-handed. The fundi, discs, and fields are normal. There is no paralysis of any kind of the ocular muscles. There is no affection of the face or tongue muscles.

He was admitted to the Arapahoe County Hospital, August 31, 1891. On September 2d, at 9 A.M., three days after entering the hospital, he had a convulsion which was witnessed by two trained nurses and the resident physician of the hospital. The first sensation experienced by the patient was a dizziness and the sensation of specks floating before the eyes, but he did not feel sick at the stomach. He called to the nurses and informed them that he was going to have an attack, but lost consciousness before muscular contraction began. He was standing at the time, and fell; and almost simultaneously with the fall the muscles of the left thumb began to contract and pull the thumb across the palm of the hand; immediately following this the flexor muscles of the left hand, wrist, and elbow were contracted, and next in succession the left foot began to jerk. Then the muscles of the right side of the face and the entire right side of the body were affected, but just in what order the nurse was unable to observe. He was deathly pale on falling, but the pallor was soon succeeded by congestion and lividity of face. The muscular contraction lasted about one or two minutes, and he was more or less unconscious for fifteen minutes, and was drowsy for a short time afterward, but did not sleep.

On September 5, 1891, at 12.30 P.M., the temperature of the ward being 70° F., the temperature of the mouth was 99.5°, of the right axilla, 98.9°, of the left 99°. The pulse was 84, the respirations 18. The head-temperature, in the right Rolandic region, was 97.2°, left 97.4°, frontal 96.6°, occipital 97°. The head-temperature showed considerable elevation above the normal, but afforded no means of localizing the seat of irritation.

An operation was advised for the relief of his convulsions, to which he readily consented. He was told that the operation would probably not cure his convulsions, but might greatly relieve them. As the site of the injury to the head was nearly over

that portion of the Rolandic region which controls the left hand, the seat of the initial spasm, it was decided on consultation with Dr. Parkhill, the attending surgeon, to trephine over the depressed bone. On September 6, 1891, the bone was exposed by Dr. Parkhill by means of a large flap, base downward, and it was found that the old fracture was quite extensive, with a depression of bone having an area, quadrangular in shape, two inches long by one and three-quarters in width. The depression of bone seemed to be about one-eighth of an inch greater at the lower than at the upper portion of the fracture. The Rolandic fissure bordered the anterior line of the depression, leaving the greater portion of the depression posterior to the fissure; the portion of greatest depression, however, was in the lower portion of the middle third of the fissure of Rolando. The depressed area in its longest diameter was parallel with the fissure of Rolando.

At the lower portion of the depressed bone a small trephine opening was found about one-half inch in diameter. Here the dura was exposed, and slight pulsation of the brain could be felt through it. Both upward and downward, from the area of the depressed bone, lines of fracture could be traced. A circular piece of bone one-and-a-half inches in diameter was removed by means of a trephine. The center of this was at the lower and anterior margin of the depressed area of bone. The under surface of this button of bone was comparatively smooth, showing less depression of the internal than of the external table. The dura beneath seemed comparatively healthy. The edges of the old trephine-opening were depressed, as were portions of the bone around the trephine opening just made, and to these edges and other portions of the depressed bone the dura was firmly adherent. By means of the rongeur forceps the trephine-opening was enlarged to two-and-a-half inches in diameter, thus removing all the bone that seemed to be depressed. The dura everywhere in this area seemed normal in appearance, and it was decided not to open it. The brain pulsations could be seen and felt. It was thought best not to open the dura at present, but wait and see the effect of removal of the depressed bone, so that more time could be allowed to study the convulsions, if any should occur, in which case, if the initial convulsive seizure should affect the same muscles each time, it was proposed at the second operation to remove the cortical centers for the muscles in which the convulsive movements first appeared.

The first week after the operation the patient had a convulsion, but it was light in character, and it is not known whether it began in the left hand or not. About a month later he had his second convulsion. Following the second, he had a convulsion every two or three months, but each one seemed much lighter than those that occurred before the operation. His mental condition has much improved, and he has now returned to work as a miner, and is able to earn a living for his family and himself. On May 21, 1894, Dr. John P. Kelly, of Golden, writes me: "Thomas N. is now working in a mine in the mountains. He had a convulsion two weeks ago, which was the first that he has had for six months. Until this occurred I had thought he was permanently cured."

This case, while not entirely cured, is greatly relieved, and the results fully justify the operation.

Case III.—L. A., four years of age, in February, 1891, began, when two days old, having spasms, which continued in rapid succession for two days.

One year ago he commenced failing and developed epileptic attacks. After the spasmodic seizures he would be unable to get up for a week. These attacks occurred one or two weeks apart. Six months ago they became very severe and increased in frequency, often occurring two or three times a day. He would fall on the right side of the face, and the mother thinks the right leg was affected. The head is small, and the child presents an idiotic appearance. Vision is exceedingly poor; and both eyes are affected with horizontal nystagmus. Dr. Parkhill, on October 9th, 1891, performed linear craniectomy on the right side of the head of this boy (see the report, The Medical News, February 27th, 1892). The convulsions were lessened in frequency and severity. Some months later the same surgeon performed a similar operation on the left side of the head. This still further lessened the convulsions and improved the mental condition of the child. After the second operation his convulsions were much less frequent and severe for nearly a year; after this they again recurred with considerable frequency, and affected the right arm and leg more than the left.

About a year ago, as the left parietal region was less prominent than the right, Parkhill removed a strip of bone about one-half inch in width and two inches in length which covered as nearly as could be determined the left fissure of Rolando. After the last operation the convulsions ceased for some time, but they have since recurred. They are now less frequent than formerly, and it is only very occasionally that he has a severe convulsion.

As the injury to the brain of this patient occurred when the child was only two days old, and was bilateral and quite extensive, it is evidently permanent, so that nothing more than slight amelioration of the convulsions could be expected by an operation.

ELECTRICITY AS A COSMETIC.

By JOHN V. SHOEMAKER, A.M., M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND CLINICAL PROFESSOR OF DISEASES OF THE SKIN, IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; PHYSICIAN TO THE MEDICO-CHIRURGICAL HOSPITAL.

The skin is frequently subject to morbid conditions, to depression or perversion of nutrition, which impair or destroy whatever advantages of person may have originally existed. Many of these conditions can scarcely lay claim to the title of actually developed disease, but are, so to speak, on the border-line. They undoubtedly depend upon faulty nutrition. The defect may be purely local,

or it may be associated with a more or less perceptible deviation from the normal standard of general health. As a rule, some systemic disorder underlies a faulty action of the skin. Although the failure may be scarcely perceptible, it is, nevertheless, present.

The blemishes of which we shall treat in this paper often prove very unyielding to treatment by means of drugs. We possess, however, in electricity an agent much more powerful than medicinal substances. Electricity is peculiarly qualified to improve the nutrition and promote the functions of the skin, because it acts directly upon the part affected, and also indirectly through the system at large. The topical application of electricity stimulates the capillary circulation through the integument, and overcomes any engorgement that may exist. It awakens the activity of the absorbent vessels, and enables them to remove morbid deposits. It acts favorably upon the nerve-fibers and their peripheral terminations, and exerts a beneficial influence upon the cells. By its tonic influence upon the heart, bloodvessels, and general circulation, electricity tends to maintain the normal type of nutrition in the skin as well as in other tissues. These properties enable us, by means of electricity, to relieve certain aberrations from the standard, trivial in themselves, and yet capable of causing much annoyance.

There is a dull, discolored, as it is often aptly termed, muddy, hue of the skin that nullifies the effect of regular features, and is not infrequently associated with a dejected or peevish expression. Some disorder of the digestive system is usually the foundation of this appearance of the skin. It is especially prone to occur in persons of dark complexion. Individuals thus affected require a total change in habits of life. It will often be found that they are of sedentary occupation, are overworked, and anxious. All the rules of hygiene must be strictly enforced, but there is no measure capable of so rapidly, so surely, and so effectually improving the complexion as electricity. In these cases there is undoubtedly some failure of general health, yet the subjects may scarcely be conscious of the fact. They are able to attend to their duties, and mingle in society, yet the dingy skin is a source of mortification, particularly in the case of females. If the discoloration is uniform, or nearly so, upon the surface, it must depend upon the action of a general cause, and the electricity should be applied to wide areas by means of rollers or sponge electrodes. As it is upon the face that the individuals especially desire improvement, it is well to make the applications, above all, to that part of the body. The neck and shoulders, the hands and forearms, likewise require attention. In such cases the use of the metal cylinder constitutes a good means of affording the benefits of electricity. Galvanism is the preferable form in which to employ this agent. A somewhat similar discoloration may be relieved by the same procedure. I allude to the sallow or slightly icterode tinge so often manifested by persons of deficient hepatic activity, with a tendency to depression of spirits and symptoms of lithemia. The subjects are generally brunets, and the blending of yellow and brown gives them a distinct physiognomy. The employment of the galvanic current, the anode or positive pole being placed over the region of the liver, and the kathode or negative pole over the discolored surface, is followed usually by the best results. Cases of this kind often occur in families in which hepatic difficulties are common. The diet, and habits as regards eating, need to be rigidly supervised. This regulation, in conjunction with galvanism, causes the sallowness to disappear.

The direct effect of the galvanic current is beneficial in another slight, but common condition, and the source of much mental disquiet. This is a greasy and shining appearance of the face, particularly the forehead and the tip and sides of the nose. Unfortunately, it is most common in women, and, above all, in young women. It occurs most often in those of dark complexion. This blemish denotes the existence of a slight degree of *seborrhœa oleosa*. Although restricted to but a small portion of the body, it is, in most instances, connected with some deviation from health, and not seldom such patients are anemic or chlorotic. Another annoyance connected with the presence of oily matter upon the face is the disposition of particles of dust to readily adhere to it, so that a dirty as well as greasy aspect is the result. Comedones are very liable to form under these conditions. The gaping orifices of the sebaceous ducts are often prominent, and from this appearance alone one is almost justified in diagnosticating impaired health. The stimulating influence of galvanism corrects the relaxation of the ducts, improves the nutrition of the glands, and restrains their secretion within the normal limits as to quantity and quality.

A sluggish peripheral circulation, dependent upon an atonic state of the vessels and a flabby condition of the heart-muscle, finds expression in a red-tipped nose, which, upon exposure to the cold, becomes purple. This, again, is an affliction most common in women, who are often themselves responsible for the trouble by their neglect of exercise. The red nose is most common in thin, anemic, or strumous blonds. The local and general application of galvanism is the most powerful means at our command for restoring the strength of the circulation and causing the habitual congestion to disappear.

An eruption of red papules is often seen in young women of from eighteen to twenty-two years of age. The patients are, for the most part, blonds, of a fair and delicate skin and blooming complexion. Their beauty is marred by the development, from time to time, of red spots upon the face, neck, and shoulders. The lesions are usually small and seldom suppurate. The spots are not numerous, are of a rose color, and are all the more conspicuous on account of the contrast with the white surface upon which they are seated. They cause extreme annoyance to their possessors. The patients are of a susceptible, nervous organization, frequently commit dietetic errors, and sometimes suffer from ovarian congestion or neuralgia. These cases receive more benefit from the direct employment of the faradic current than from any other method of treatment.

In the different forms of acne much good is accomplished by the use of electricity. The papules and tubercles undergo retrogression, suppuration is arrested, and itching and smarting are relieved. The faradic current, applied both centrally and locally, may be advantageously employed under these conditions. In some cases I derive better results from the alternate use of the faradic and galvanic currents.

One sometimes encounters cases of *rosacea* in the first or second stage in young women. Occasionally they complain that the rash is accompanied, in the afternoon and evening, by a sense of burning. Dilated and varicose capillaries may often be detected and small acne-pustules develop, from time to time, upon the affected surface. The irritable condition of the sebaceous glands may give rise to a greasy, shining appearance of the skin. In such cases no treatment is equal to galvanism, the anode being placed upon the back of the neck and the kathode upon the seat of disease. If the congestion is great and is disposed to linger, I am in the habit of also incising the skin with the needle knife, encouraging local depletion by sponging with hot water. The distended bloodvessels can be obliterated by passing into them a fine needle which is connected with the kathode of a galvanic battery of from six to ten cells.

Static electricity is of value in relieving the dryness and roughness of the skin so often found in scrofulous subjects. The application, moreover, exerts a decidedly beneficial systemic influence. Small growths, like warts and localized thickening of the integument, can be removed by the alternate use of the static and galvanic currents. Corns upon the toes, and corns or callosities upon the soles are amenable to the same treatment. Sparks are applied daily to the affected regions, and the *séance* is terminated by the passage of the galvanic current. Callosities form upon the fingers as the result of habitual irritation due to occupation. This result is seen, for instance, in professional performers upon stringed instruments, as the banjo, guitar, violin, and harp. Seamstresses and tailors, also, acquire a similar condition from the constant use of the needle. The epiderm is sometimes thickened in consequence of the continued friction between adjacent folds of the skin, as beneath the breasts, in the groins and armpits, between the nates, and upon the perineum. Cases presenting this condition may be treated successfully in the manner indicated. Galvano-puncture affords likewise an effectual means of dealing with warts. The alternate use of franklinism and galvanism is an effectual mode of treating scars, those that are indurated and hypertrophied being especially appropriate to this treatment, inasmuch as they usually prove unyielding to other measures.

Pigmented spots or patches upon the skin seriously detract from or even destroy personal comeliness. The simplest and most common form of pigmentation we see in the familiar freckle. The disfigurement produced by freckles depends much upon their number and size. A few freckles upon the fair face of a young girl may not be unsightly, but when they are sprinkled copiously over the face and upon the backs of the hands, they must undoubtedly be regarded as serious blemishes. In extreme cases, neighboring spots may run together, form blotches of considerable size, and communicate a dingy appearance to the skin. Freckles may be removed, it is true, by the action of mild caustics, but they are very likely to be reproduced, and, indeed, some of the methods that have been employed encourage a subsequent deposit of pigment. The spots are most effectually and permanently removed by the use of galvanism, applied in a manner to be presently described.

Chloasma is, as regards pathologic histology, an enlarged freckle or an aggregation of freckles. In respect to its etiology it differs from the latter in being often associated with disordered health. Both affections result from a deposit in excess of the normal pigment in the cells of the *rete mucosum*.

The application of the galvanic current will, in the majority of cases, be followed by the permanent disappearance of the discolored spots or patches. In these cases I usually employ galvanism by means of a nickel plate, or by what is even better, a nickel-plated cylinder attached to the kathode. I rotate the cylinder to and fro over the large spots in order to avoid giving the patient pain from concentrating the current upon the integument. Occasionally the metal is left in contact with the pigmentation long enough to give the impression of warmth to the skin. To freckles I am in the habit of applying a strength of from 10 to 15 milliampères every day

or two, the sitting lasting from three to five minutes. In chloasma the strength may be increased to 15 or 20 milliampères, applied in the same way, with the same frequency and for the same period as in the treatment of freckles.

Another form of pigmentation is sunburn, or a "coat of tan," so common a result of a summer's outing, especially if much time has been spent upon the water. A sun-browned skin may be justly preferred to a chalky or a pasty complexion. Nevertheless, the "nut-brown maid" will presently begin to inquire whether some means does not exist by which the disappearance of the sunburn may be accelerated. The sharp contrast, especially in the blond, between the hue of the face and that of the neck, shoulders, and arms, is an additional argument for the removal of the brown color. The same procedures found successful in the treatment of freckles and chloasma will generally prove equally efficacious in removing the effects of exposure to the sun.

Pigmented and hairy moles are sufficiently common defects. A small, smooth mole, destitute of hair, and situated upon the back of the hand, may almost escape notice. If seated upon the face, however, and if covered with hair, they constitute a serious blemish. They are often met with in brunets, and a young lady who possesses regular features, sparkling black eyes and luxuriant tresses, with a brilliant complexion, may have her charms diminished by a large, dark, and hairy spot located upon the chin. Hairy moles may be removed *in toto* by the knife, but many will object to surgical intervention, which has, moreover, the disadvantage of sometimes leaving a scar. In such cases we may usually succeed in bringing about the gradual disappearance of the objectionable spot by the use of the galvanic current or the galvano-cautery.

That variety of birth-mark known as port-wine stain or claret-stain, as well as the more formidable tumor composed of dilated bloodvessels or lymphatic vessels, sadly disfigures the face. Surgical interference often proves ineffectual or only partially successful, is accompanied by profuse hemorrhage, and is followed by cicatrices. In galvanism we possess a treatment for these lesions to which no objection can be urged and which may be relied upon to correct the defect. The current may, according to the circumstances of the case, be applied by means of the sponge electrode or by galvano-puncture.

Excessive activity of the sudoriferous glands constitutes a cosmetic defect. In well-marked cases an abundance of fluid is poured out upon the skin in certain favorite locations. The face, axillæ, genitalia, hands, and feet are particularly prone to be affected. The streaming surface becomes pale and wrinkled, and in some regions an offensive odor is generated, forming an additional affliction. Another form of annoyance is that the sweating is limited to one side of the face. This affection of the sudoriparous glands is often linked with anemia or some other constitutional disease. The systemic and local effects of electricity are therefore to be commended in the treatment of this troublesome and often rebellious condition. I have in many instances witnessed the most decided improvement in consequence of the persistent use of electricity in the form of galvanism or an alternation of galvanism and faradism Static electricity is also a valuable therapeutic resource in hyperidrosis of the hands or feet.

Electricity is no less potent in affections of the hair. With comparatively little alteration of the scalp, the nutrition of the hair will often fail and the individual will begin to dread the development of premature baldness. The scales of dry seborrhea will fall upon the shoulders, the hair will lose its luster, will become dry and dead-looking, will look rough and ragged, will break or split at the ends, and will be plucked from its roots in the simple act of combing. If this condition be neglected premature alopecia will be the result. In other cases the loss of hair will be limited to certain spots, and the peculiarly unsightly patches of *alopecia circumscripta* will be the outcome. No method of treatment is so successful in checking the progress of baldness as the application of electricity, which increases the nutrition of the scalp and the hair-follicles. No case need be regarded as hopeless in which atrophic destruction of the follicles has not occurred. Nevertheless it is advisable that treatment should be begun at an early stage in order to avoid unnecessary loss. Falling of the hair is regarded as a grievous misfortune by women, who are thus threatened with the loss of one of Nature's ornaments. In men the process may attack not only the head but also the beard. Both faradism and galvanism are admirable tonics to the hair-follicles. In beginning treatment it is my custom to use only mild currents. A galvanic current of the strength of not more than from 10 to 20 millampéres may be applied by means of moistened sponge electrodes, or what is, perhaps, a better method, through a brush having metallic bristles. Faradic currents may likewise be conveyed in the same way through a wire brush, the moistened sponge electrode being held in the hand of the patient or on the back of the neck. The brush is slowly passed over the scalp until the skin is reddened.

Used in the same manner electricity serves to arrest the approach of premature grayness. As the loss of color is feared by women almost as much as baldness, they can very readily avail themselves of the advantages of electric treatment. This method prevents early grayness by a tonic influence upon the entire hair-forming apparatus.

ICE-COLD APPLICATIONS IN ACUTE PNEUMONIA.[1]

By THOMAS J. MAYS, A.M., M.D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO RUSH HOSPITAL FOR CONSUMPTION.

While cold applications in the treatment of pneumonia are by no means a new procedure, I am of the opinion that this has not yet received the consideration and extensive introduction which it merits, and in saying what I have to say to-night I trust that I am loyal to that spirit which prompts one to conservatism in the commendation of any curative measure until it has stood the test of experience; when, however, one has observed the magic changes which follow in the pneumonic condition under the beneficent influence of cold locally applied, as has been done by others as well as by myself on numerous occasions, I feel that this method has passed the experimental stage of clinical medicine, and I therefore hope that you will pardon me for appearing obtrusive when I again direct your attention to this subject.

Cold has been employed in the treatment of pneumonia for various purposes and in various ways. Jürgensen believes that the chief danger in this disease arises from the high fever, and which finally leads to cardiac failure. He appeals to the experiments of Zenker and others to show that high fever is detrimental to the fibers of the heart-muscle and to those of the voluntary muscles. He, therefore, recommends cold principally with a view of reducing the pyrexia. It is a question, however, whether a high temperature of itself is more fatal in pneumonia than a low one, but this is a point which will be referred to later on. So far as I know Niemeyer was the first to apply cold immediately to the chest for the purpose of reducing the activity of the local inflammatory process in the lungs.

It must be seen that these different views govern the practitioner in the mode of applying this remedy. If he believes in the constitutional nature of the disease, and especially if he thinks that the high fever endangers the integrity of the heart-muscle, his principal aim is to reduce the fever at large, and to accomplish this he immerses his patient periodically in a cold bath, which is done by Jürgensen and others. If he holds that the local trouble in the lung is responsible for the high fever, and that this constitutes the vulnerable point in the disease, he will pay less attention to the general condition and make his cold applications directly over the inflamed lung.

I believe that much of the ill-success which has followed the use of cold in pneumonia is attributable to the fact that it was employed according to the first method. The pyrexia of pneumonia is not the same as that of typhoid fever, or at least it does not yield to cold in the same way as that of the latter does. The former is best subdued by cold being applied directly over the affected lung, as well as to the head, and general baths or spongings do not seem to be essentially indicated, and if the latter are applied they do not keep the fever down for any long period. If the fever and a great deal of the constitutional disturbance of pneumonia depends on the inflammatory process in the lung, then an abatement of the pulmonary disorder will strike at the very root of the difficulty, and it is clear too that the measure which accomplishes this must be applied continuously and persistently, and not, as in typhoid fever, at stated intervals. Moreover, it is a hazardous procedure to subject a pneumonic patient to the bodily changes and cardiac strain which are incidental to the giving of a general bath. It must be remembered that the heart is always implicated in pneumonia, and is therefore a weak and easily assailed organ.

How, then, is the cold to be applied, and how long must it be continued? The affected area must be surrounded with ice contained in bags which are wrapped in towels. If the disease is confined to the front base on one side, one good-sized bag will suffice; but if the exudation extends to the side and back, then at least one more bag must be applied laterally and as far back as possible. If the affection is extensive, put on as many ice-bags as are necessary to cover the whole area. Watch the morbid process, for it is very apt to migrate from one spot in the chest to another, and if it does so, follow it up with the ice-bag.

The length of time for which cold is to be used must, in most cases, be decided by the amount of fever which is present. If this falls to or near the normal point, and shows a tendency to remain there, then the ice may be gradually removed. It is best, however, not to be in too much haste in withdrawing the cold, for frequently before this is off very long the temperature suddenly flies up again. If this takes place, and the temperature remains high after the ice is reapplied for some time, it is a possible indication that the inflammation has invaded a new field, and is not active in the old one. This has happened several times in my experience.

It must always be borne in mind, however, that the ice is not employed solely for the purpose of reducing the fever, but rather with the object of circumventing the exudative process and of hastening resolution in the affected part. There may be very little fever present in some cases of pneumonia, as in the aged, yet the destructive changes are

[1] Read before the Philadelphia County Medical Society, September 26, 1894.

going on in the lungs at a rapid rate. In senile and latent pneumonia the activity with which the ice is employed must be governed entirely by the impression which is made on the pulmonary disintegration. This must be the objective point, and not the temperature.

This brings me to say something on the fever in pneumonia as a prognostic sign. Although a temperature of 105° Fahr. is generally regarded more dangerous in the adult than one of 102°, I really believe that this is an error. When the fever is excessive, as when it rises to 107° or 108°, every one admits that this is almost necessarily fatal; but it must also be granted that a markedly low pneumonic temperature, as for example 95° or 96°, is equally fatal. The safety-point, if such there be, lies somewhere between these extremes; and within a certain range I think we can look upon this fever as an indication of the degree of vital resistance which is present in the body. If it remains between 104° or 105°, the prognosis is good, provided other conditions are equal; but if it is either very high or very low it is evidence of serious exhaustion and of vital inadequacy to cope with the destructive forces.

This opinion is partly confirmed by the high authority of Dr. Wilson Fox, when he says (*Diseases of the Lungs and Pleura*, page 352): "The extent of the pyrexia has a less unfavorable influence on the prognosis than might be expected." Out of a total of 353 cases he shows, on the same page, that the mortality from 107° to 110° was 100 per cent.; from 106° to 107°, 42.8 per cent.; from 105° to 106°, 18 per cent.; from 104° to 105°, 7.4 per cent.; from 103° to 104°, 17.6 per cent.; and under 103°, 36.9 per cent.

What, now, is the local action of cold on the pneumonic process? This, I believe, consists in its powerful influence on the pulmonary capillaries and in its ability to resolve the exudate and infiltrate. It is well known that the most apparent lesion in acute pneumonia is an enormous distention of the pulmonary capillaries, with partial or complete stasis of the blood in these vessels, exudation of fluid constituents of the blood, and proliferation and accumulation of epithelial cells, and diapedesis of white and red blood-cells in the alveoli and bronchioles. Now, it is well known that cold has the power of contracting bloodvessels, and from this action it can be understood why it should be of benefit in pneumonia. But how it can dissolve an exudate or an infiltration is not so clear to me. That it accomplishes this I am firmly convinced. For example, there is a pneumonic area which is wholly devoid of vesicular sounds, and has a flat percussion note and bronchial breathing, indicating beyond doubt that the process has passed beyond the stage of engorgement and into that of exudation or of infiltration, yet the application of ice to this spot will in a remarkably short time develop a new group of physical signs, such as crepitation, reappearance of the vesicular murmur, diminution of flatness, etc. This has not only been observed by myself over and over again, but is also dwelt on by Dr. Lees, who had an extensive experience in the use of ice in this disease, when he says (*Lancet*, November 9, 1889, page 894): "In many cases I noticed a striking arrest in the development of the physical signs," and that the ice-bag "distinctly tends to repress the inflammatory process in the lung."

Is the ice-treatment applicable in croupous or in acute catarrhal pneumonia, or in both forms of the disease? In my earlier experience I inclined to believe that it was only adapted to the treatment of the croupous variety, but further familiarity with the measure taught me its use in the acute catarrhal form. I have also given it a trial in chronic broncho-pneumonia and in pulmonary phthisis, but with rather indifferent results, if not with positive harm in some cases. I must admit, however, that in several cases of this kind it seemed to do exceedingly well. It must be borne in mind, too, that the ice-bag is strongly recommended by the late Dr. Brehmer, and by Dr. Detwiler and others, in the treatment of chronic lung trouble, and with such excellent testimony in its favor it is very probable that many of us do not yet understand the specific indications for its use.

Besides being useful in croupous pneumonia, and in acute catarrhal pneumonia, it also has excellent effects in the capillary bronchitis of infants, and in the catarrhal pneumonia which follows measles, diphtheria, and scarlet-fever.

It is also desirable in this connection to say something regarding the heart in this disease. From the tenor of much that is said and written on pneumonia at the present time, one receives the impression that more is to be feared from cardiac than from pulmonary failure. That the heart's function is impaired no one will, I think, deny. Indeed, this could not be otherwise, for the heart and lungs have a common nerve-supply, are bound closely together by the pulmonary blood-current, and whatever invalidates one must also affect the other; but I believe that the doctrine that pneumonia becomes fatal because the heart is unequal to the work of forcing the blood through the engorged lungs, and all that we are required to do is to stimulate and to goad this organ, unmindful of what is going on in the lungs, is as imaginary in its conception as it is fatal in its practice.

The pulmonary circulation is undoubtedly obstructed, and there is no question but that the heart

chafes, frets, and becomes seriously embarrassed. Dr. Wilson Fox (op. cit., page 285) says: "One of the most important consequences of pneumonia on the circulation is the occasional occurrence of thrombosis in the pulmonary vessels leading to the affected part. This event, caused in all probability by the retarded circulation in the lung, is not uncommon, and may, by extending to the larger branches of the pulmonary artery, be a source of immediate danger from sudden death, and may also in great probability retard the process of resolution and the subsequent convalescence." But is this any reason why we should whip up this organ in the hope that it may perform an impossible task, and stand by and do nothing to alleviate the blockade in front? Is this sound sense or physiologic reasoning? No. We must discard this cart-before-the-horse theory, and make strenuous efforts to remove the difficulty in the lung, and in this way liberate the heart from its entangled situation. To accomplish this very end there is no agent more efficacious than ice; and besides removing the engorgement and even the exudation in the affected lung, it also acts as a powerful stimulant to the heart's function. Indeed it is chiefly for its serviceable influence on the heart that the ice-bag is recommended in chronic lung-diseases by Dr. Brehmer and others.

In conclusion, I beg to say that the external application of cold in typhoid fever has reduced the death-rate from this disease to almost nothing, and I am sure it is not too much to presume that the same remedy, although differently applied, will do the same in the case of pneumonia. My opinion is based on what I have seen in my own practice and in that of others. In my collective report of fifty cases from various sources (see Medical News, June 24, 1893) there were two deaths. Since the publication of this list I have received abstracts of seventeen other cases treated by Dr. Jackson, of Brockville, Ontario, and have myself collected seven cases without a death, neither the histories of which, nor those of Dr. Jackson, had I time to write out since receiving the kind invitation from your Board of Directors to prepare a paper for this evening—making in all seventy-four cases of pneumonia treated with cold applications, and two deaths; or a death-rate of 2.70 per cent.

Now, the death-rate from pneumonia when treated according to current methods is variously estimated from 20 to 30 per cent., hence the results from the cold-water treatment are at least ten times better than those which are obtained by other methods.[1]

[1] In addition to the ice, most of the patients received quinin, a mixture of ammonium acetate, strychnin, digitalis, morphin occasionally, a nutritious diet, etc.

HYPERMETROPIA AND HETEROTROPIA.[1]

By HOWARD F. HANSELL, M.D.,
of Philadelphia

The subject of this communication has been in part presented to the profession in two papers, "The Treatment of Internal Squint," *Annals of Ophthalmology*, January, 1894, and "A Cause of Failure in the Surgical Treatment of Internal Squint," read by title before the Pennsylvania State Society, May 16, 1894. I desire now to bring it, modified and strengthened by added experience, before this Society, with the hope that a discussion may be elicited by which its value as a statement of actual existing conditions and as an explanation of those conditions may be determined. I submit the following two propositions:

1. In constant, or monocular squint, due to hypermetropia, when one and the same eye is always used in fixation, the second eye is invariably turned upward as well as inward.

2. In concomitant, or alternating squint, due to hypermetropia, when either eye is used indifferently for fixation, the squinting eye is invariably turned upward as well as inward, and, with alternation of fixation, the upper deviation is transferred simultaneously with the inward deviation.

Both propositions may be included in one statement; namely, that functional esotropia, or purely lateral deviation of the visual axes, is never found alone, but is always associated with hypertropia.

I make these assertions with a certain amount of diffidence and hesitation, for, while I have been unable to find their equivalents in my reading, it seems improbable that these facts have escaped the observation of the many careful investigators who, following Donders' lead, have so thoroughly studied the etiology of functional strabismus, and I fear that my own researches into literature have been too limited.

I have found allusions to an upward squint complicating convergence, and in Stevens' studies, published in the *Archives*, attention has been called to the same condition; but in no text-book or monograph with which I am familiar is it positively stated that the two must be invariably associated, nor has any author, so far as I know, who has mentioned the upward squint as complicating the internal, suggested an explanation.

If we accept Donders' theory of hypermetropic squint, which is, I believe, universally admitted as correct, and we pursue his line of reasoning to its logical and physiologic conclusion, we shall have a satisfactory explanation not only for the existence of the hypertropia, but also a sufficiently convincing

[1] Read before the American Ophthalmological Society at Washington, May, 1894.

reason for the clinical fact that esotropia cannot be caused by hypermetropia unless hypermetropia also cotemporaneously develops hypertropia.

Pathologic convergence is induced through excessive action of the ciliary muscles, by reason of the anatomic and physiologic relation of the nuclei of the ciliary and interni, when the bounds of relative convergence and accommodation have been overstepped. But the nuclei of other branches of the third nerve participate with the convergent nuclei in this excitation, as is shown in the pupillary contraction.

Now, the elevators of the cornea are the superior rectus and the inferior oblique, and both are supplied with motor force from the third nerve. The depressors of the cornea are the inferior rectus and the superior oblique, only one of which receives impulse from the third. Therefore, excessive stimulation, or hypermetropic stimulation, if I may be allowed to use the expression, must induce not only overaction of the interni, but also of all the muscles supplied by the motor oculi. As the external recti cannot maintain lateral equilibrium, the elevators are for the same reason only in part antagonized by the depressors, and the cornea is rolled inward and upward. Hence, when the visual axis of one eye crosses that of the other within infinity, it must be on a higher plane.

These propositions have been verified by clinical observation. In every case, without exception, that has come under my care during the past few months, in which I have been able to induce the patient to become cognizant of the image which falls on the retina of the squinting eye, perhaps twenty-five or thirty in number, he has described its position as homonymous and on a lower level than that of the fixing eye.

No insurmountable difficulty has been encountered in discovering the false image. It has demanded, however, patience and perseverance, and the use of glasses of different colors—the true image blurred by a dark blue, and the false changed by a bright-red glass. It has occasionally been necessary in the early efforts to bring the false image nearer to the true by prisms, bases out, or to place the light nearer to the patient than twenty feet.

The final and determining tests have always been made without artificial deflection of the false image, so that no doubt as to its horizontal plane could arise from a possible oblique turning of the prism thus used. Rarely, cases may be found in which the projection is false, when, for instance, in convergence the images are heteronymous and no deduction can be drawn from the patient's answers. Here the observer must rely upon objective examination of the deviation of the squinting eye, and close inspection will reveal both esotropia and hypertropia.

Further, I believe the application of the same principle can be extended to an elucidation of the etiology of hyperphoria as well as hypertropia, and help us to a clearer comprehension than we now have of the origin of this perplexing condition. The bases of argument must again rest upon Donders' theory of hypermetropic squint. If hypermetropia in its higher grades can produce a positive deviation of the visual axes, it follows that, in the lower grades, it is responsible for tendencies to deviation, or "phorias," and, logically, the tendency cannot be limited to esophoria, but must include hyperphoria.

The influence of the ciliary muscle in overcoming the low grades of hypermetropia and astigmatism in the young is not sufficiently great to destroy the extra-ocular balance, and the visual axes are maintained in their binocular relation at a cost of nerve-energy that, in patients of neurotic disposition, is followed or accompanied by severe reflex disturbances. But it manifestly produces a corresponding overaction of the other muscles under the control of the third nerve, or a tendency to deviate from equilibrium. In persons of middle age, when presbyopia is commencing and the range of relative accommodation and convergence is limited by loss of accommodation through stiffening of the lens, the effort at contraction of the ciliary muscle, or the nerve-power, is, however, unchanged from that of earlier life, and thus the other branches of the third are stimulated in their accustomed degree. Since, as has been shown, this action includes other than the internal muscles, we have every reason to believe that the asthenopia is muscular and not accommodative, because better vision or less error of refraction in one eye will determine esohyperphoria of the other.

This hypothesis, more rational than any that has been proposed in explanation of the muscular anomalies so frequently associated with hypermetropia, receives confirmation in the effect of paralysis of accommodation and the optic correction of the error of refraction, both in heterotropia and heterophoria. In the former, the cure of the disjointed muscular action by these means alone has been perhaps the most persuasive argument to the universal acceptance of the truth of Donders' theory; and in the latter, correction of hypermetropia and astigmatism has been amply demonstrated to be quite sufficient treatment in the great majority of cases not only for the accommodative, but for the muscular asthenopia, as is so frequently demonstrated by the gradual, and in some cases immediate, disappearance of the symptoms, and by the restoration of equilibrium according to the tests commonly employed.

Before advising operation in hyperphoria, we must

therefore be convinced that it is a permanent and real condition, independent of and uninfluenced by the use of the accommodation, and cannot be transferred from one eye to the other. We may be led into error of diagnosis, even in hyperphoria, by the fact that the hypermetropic patient under the test by artificial horizontal diplopia involuntarily or unconsciously fixes at the moment with one eye, and having determined in our own mind that a right or left hyperphoria is present, all subsequent tests seem to confirm the impression. A constant hyperphoria, just as a constant hypertropia, is plainly consistent with the theory advanced, and it is only in such cases that operation on the superior rectus, either alone or in addition to operation on one or both internal, is admissible.

Recognition of the truth of the two propositions presented in the first part of this paper, and acceptance of the hypothesis offered in explanation, will necessarily modify the methods commonly employed in the surgical treatment of latent and manifest strabismus due to hypermetropia.

1. In so-called constant monocular squint, binocular fixation can be secured and maintained, unless prevented by amblyopia, only by full correction of the optic defect, tenotomy of the interni and tenotomy of the superior rectus of the squinting eye, and possibly of the inferior rectus of the fixing eye.

2. In alternating squint, vertical equilibrium will be restored by correction of the refraction and tenotomy of the interni, each muscle divided to the same extent. Direct surgical treatment of the hypertropia is not indicated under any circumstances.

The endeavor to secure a cosmetic success by confining the tenotomies to the squinting eye only, such as extensive section of the internus, conjoined with advancement of the externus, as recommended by most authorities, is greatly to be deplored.

3. In hyperphoria, operations to secure vertical equilibrium may be made only when it is clearly proved that relief from asthenopic symptoms cannot be secured by less radical measures. And the influence of hypermetropia in causing this condition, and the possibility of alternation of fixation transferring it from one to the other eye, must be borne in mind.

254 S. Sixteenth Street.

Prof. L. Mauthner has been made the successor of Stellwag as Professor of Ophthalmology and Director of the Ophthalmic Clinic in the University of Vienna.

A Monument to Villemin, who first demonstrated the infectiousness of tuberculosis, was unveiled at Bruyères, (Vosges) on September 30.

ORIGINAL ADDRESS.

CHARITY-ORGANIZATION AND MEDICINE.[1]

By GEO. M. GOULD, A.M., M.D.,
of Philadelphia.

No subject is more rich in suggestion and in acute demand than that of the relations of medicine to those dependent upon the community by reason of crime, of disease of body or mind, or of defect, congenital or acquired. Of these classes not one is devoid of medical relations, for as counsellor, as curer, or as preventer, the physician's voice should be heard. If we do not strike hands with Lombroso and say that all crime is due to abnormality of organism, certainly crime and disease have *some* most intimate relations. What are they? What likewise are the subtle bonds that link together disease, physiologic or neurologic, with mental abnormalism? We do not seek to escape from our responsibility for much of the world's blindness; the idiot is physiologically defective; otology and laryngology have not said their last words as to deaf-mutism; every United States pensioner holds a physician's certificate (more's the pity!); have the surgeons done all that is possible for the cripples? Have we no accountability for pauperism, no responsibility for the criminally high death-rates, and no guilt for the criminally low average length of life? In the mysterious tapestry of civilization disease is weaving a thousand miscolored and rotten fibers that mar its beauty, spoil its design, and weaken its strength. Shall we longer permit with careless consent such negligent and fateful weaving? Nay, shall we longer consent to be ourselves such weavers.

And when one faces these problems, how they grow! At first it seems as if the inter-relations of the profession, the dependent classes, and the lay community are few and comparatively unimportant, but with sharp observation we see long and strong bands of cause and effect subtly running out and in, like warp and woof, linking and locking one with another and each with all.

One of the strangest and most dazing truths that soon becomes manifest is that charity as commonly practised is sin. The word, like many another, bears witness to the sad history of mankind. The beautiful Greek word is almost untranslatable into English. Its gracious compassion or tender pity has become simply almsgiving—a thing usually a double curse, degrading both to the giver and to the receiver. To relieve suffering is the delight and the duty of all good hearts; but we must see to it, 1, that the suffering is real and not fictitious; 2, that, if real, it is not deserved; 3, and most important, that by our methods we do really relieve and do not increase the suffering. It is just here that we run across the first principle of the charity-organization societies, which is to make benevolence scientific. It only needs a few bitter experiences (and we have all had many such, I suppose) in relieving supposed suffering without investigation, in giving doles to street beggars, or in cashing checks for unfortunate acquaintances, to give us most convincing proofs that under existing circumstances and

[1] Abridged Presidential Address delivered before the American Academy of Medicine, at its meeting in Jefferson, N. H., August 29, 30, 1894.

as human beings are at present constructed, non-investigating relief increases the evil it thinks to lessen.

Last year at the Philadelphia Hospital I was puzzled at my vain attempts to cure what seemed a case of simple conjunctivitis. After weeks of varied therapeutic measures I suspected and demonstrated that the "tramp" anointed his eyes just prior to each of my visits with a strong solution of soap. In this way he avoided being turned out upon a cold world until springtime came. Another fellow, so long as he remained under treatment, was in receipt of $5.00 a week from the Cigarmakers' Union, and he could at pleasure induce a subacute attack of iritis, filling the anterior chamber of the eye with blood by a very energetic bit of ocular massage. The older surgeons at the Philadelphia Hospital were often puzzled by the unusual difficulty of healing chronic leg-ulcers, until it was found that the owners did not *desire* to have them healed, and prevented healing by tightly binding in the ulcers old-fashioned cents.

It has for years been my practice to give every street beggar a charity-organization card, with promise of relief if he should be found worthy by the agent of the society. Only one has ever returned, and he was set right without any almsgiving. In China the making of monstrosities was a regular business by putting children in pickling vats for years, by breaking and mending their bones, or by transplanting upon their bodies bits of the skin of animals. We are horrified at this, but are we not equally infamous with our dime museum glass-eaters, our foundling-asylums, and our patent-medicine beastliness?

Mendicity is mendacity. The crimes of tramps and street-beggars are only surpassed by crimes of those who give to them. Mendicancy in all its forms and masks is not the result of poverty, but is the cause of poverty. All indiscriminate almsgiving, all wholesale crowd-relief, or collective-relief of want or suffering, is either a forged, to-be-protested promise-to-pay note of sympathy, or it is the payment of wages for something done. Nine times out of ten it is selfish charity, or self-flattery. Foolish people love to flatter themselves that they are kind-hearted. Benevolence is fashionable, and fashionable people—are fashionable!

One of the most debauching and disgusting forms of selfishness is that of indiscriminate philanthropy. For downright diabolism witness the mutual hatreds of two rival professional philanthropists! Almsgiving, on the other hand, is wages: by giving to beggars and tramps we pay for the continuance and increase of beggary and trampism; by Sunday breakfasts we increase hunger on Sunday mornings, and we also secure listeners for our pseudo-religious after-performances; by indiscriminate out patient relief we stimulate the production of disease, hire patients to experiment on, increase our own reputation or that of our hospital, and at one fine stroke pauperize both the profession and the populace; by municipal workshops, State aid to the unemployed and socialistic demagogism we hire people to be unemployed, to strike, and to lessen the sum total of production; by institutionalism gone mad, we hire the people to get rid of their personal duties to their dependents, and hire those on the borderland of breakdown, physical or mental, to give up the last instinct of self-help. We pay for these things and many like them when we give alms and taxes and hire other people to be sympathetic for us. Of course, what we shirk doing ourselves, our hired agents will hardly do better. "Like master, like man."

Appalled by this condition we, perhaps, stumble upon the work of the charity-organization societies, and at once we have a clear statement, both of the etiology and the treatment of the disease. Of all things these societies beg that no living spark of compassion or good-will shall be quenched, and no hand reached out to help shall be permanently withdrawn. There is a profound danger that, chilled by ingratitude and fraud, the foolishly kind shall become the foolishly cruel. If so, it only proves that their former charity was as selfish as their present uncharity. They gave before to please themselves, and refuse help now for the same reason. Charity-organization, as I have said, aims at making kindness effective, benevolence scientific. The heart must inspire, the intellect carry out. The brain is an inhibitory organ whether we view it physiologically, scientifically, or sociologically. But inhibition is regulative, not destructive. In the amelioration of the afflictions of mankind, it is only the intellect that can guide to lasting results, but, like the governor of the engine, it cannot supply the living steam, and it would certainly not advise "no steam."

As stated on the title-page of the excellent little *Handbook for Friendly Visitors Among the Poor*, compiled and arranged by the Charity-Organization Society of the City of New York (published by G. P. Putnam's Sons), charity must do five things:

1. Act only upon knowledge got by thorough investigation.
2. Relieve worthy need promptly, fittingly, and tenderly.
3. Prevent giving unwise alms to the unworthy.
4. Raise into independence every needy person when this is possible.
5. Make sure that no children grow up paupers.

Or, we might say:

1. Don't help frauds.
2. Help so as to make future help unnecessary.
3. Don't hire people to be miserable.
4. Prevent dependency.

All of this, once more, seems to have little medical bearing; but it is only seemingly so. The booklet contains an important and excellent chapter on sanitary suggestions by Dr. Charles D. Scudder. It should be remembered that it is only an A B C book, so to speak, designed only to guide beginners, to interest, and to lead on to the deeper purposes of the organization. I hope every member of the Academy will get and read the book issued by the Johns Hopkins Press, and edited by President Gilman, entitled *The Organization of Charities*, being a report of the Sixth Section of the International Congress of Charities, Correction, and Philanthropy, Chicago, June, 1893. In the last twenty years at least ninety-two charity-organization associations have been formed and are now actively at work in our country, whilst many hundreds exist in Europe. The English Charity-Organization Society is also publishing a series of manuals, of which I mention as of especial interest to physicians, one on the feeble-minded child and adult, and one on the epileptic and crippled. Another volume

is devoted to insurance and saving (intimately bound up with disease and the medical profession), and there are others on food, on medical charities, on the training of the blind, on the dwellings of the poor, on idiots, imbeciles, etc. The most cursory glance at these works will show how deeply into the whole organization of society the seeds of this ideal are striking root, and how intimately blended are they or may they become with those of medicine.

But before we can be very consistent or whole-souled charity-organizers we must first clean house ourselves. We must practise what we preach. There are few more outrageous sinners against the principles of the organization than our profession itself. The London *Lancet* has recently been weeping very profusely over the failure of the public to respond with sufficient liberality in financial support of the hospitals of London. Curiously enough, the epiphora seems to be caused by a

Summary of Tables.

	Hospital Sunday fund award.	In-patients	Relieved.	Cured.	Convalescent-homes.	Remaining under treatment.	Died.	Out-patients visits.	Accidents and emergencies.
General Hospitals	£17,378	49,835	14,027	27,607	4,614	3,476	4,910	1,442,447	222,733

Dispensaries	1,873	.....	.....	.....	.....	.....	.....	1,213 039	
Total	£35,067	103,585	30,061	57,494	7,293	7,505	7,093	3,871,290	243,801

respectably-sized beam in its own professional eye. To justify the tears it cites the number of cases treated in the one hundred and eighty-one London hospitals during 1893. The figures are so huge that it is necessary to quote them in full.

Let us leave out of consideration the in-patients (over 100,000) and the accident cases (243,801), and fix our attention for a moment upon the (nearly) four-million visits of out-patients. It strikes me that if any hysterics are justified in reference to this appalling figure it would be the hysterics of indignation. Can any conscientious physician, can any sane man believe that this number of people have been adequately considered, and had careful diagnoses made, and discriminating scientific treatment instituted? Can he believe that a vast proportion of these patients were unable to pay some fee for the service rendered? The whole affair begins to become ludicrous. The sentimental grimace of the charity-tragedy is plainly broadening into the guffaw of opera bouffe. The cloven foot of selfishness on the part of those lucky or powerful enough to get in charge of these hospitals is all too plainly evident to allow us to be much grieved at the moans and wailings of the melodramatic artist. The competition for these hospital-positions among the physicians of London, and everywhere else, for that matter, is vicious and intolerable. It is a question of *sauve qui peut*, and *After us the deluge*.

But there are some 3000 medical men in London *not* connected with hospitals; what of them and of their professional interests? Go where one will the same astonishing hospital-abuse glares at us. We are debauching and pauperizing both the profession and the public by this gigantic nuisance. Money given for the endowment or support of hospitals is likely to become a curse instead of a blessing to humanity, unless certain provision is made against indiscriminate free treatment. Indiscriminate medical charity is just as pernicious as indiscriminate almsgiving. One is disposed to ask if it might not be well to save much labor by adopting the plan of Louis XIV and Louis XVI, and gratuitously sending out millions of bottles of medicine all over the country, with accurate directions "for the relative indication" for taking, etc. Perhaps, even better, we might farm the entire business out to the American patent-medicine syndicate!

We should also not forget that the absorption of medical energy in the free treatment of disease by those who could pay keeps the profession bound in the treadmill of drudgery and of piddling cures, whilst the nobler and infinitely more important sciences of public hygiene and preventive medicine are left unfurthered or are turned over to the non-medical world. Thus in this blind man's race we rush impetuously to a silly suicide.[1]

[1] Specifically, the chief defects of the hospital-craze are thus set forth by the Charity-Organization Society in a petition to the House of Lords:

1. The promiscuous congregation in out-patient departments of large crowds of persons, who in most instances are suffering from slight ailments for which skilled hospital-treatment is quite unnecessary, is a constant hindrance to medical instruction, increases the discomfort and pain of those who are suffering from severe maladies, and occasions much vexatious and needless waiting.

2. The indiscriminate admission to the benefits of hospitals and dispensaries tempts many who could pay for medical relief to become occasional recipients of charity, and by degrees habitual paupers.

3. The provision of gratuitous medical relief to large numbers of persons, both as in-patients and out-patients, without inquiry or any sufficient regulation, is, as investigation shows, a serious obstacle to the promotion of provident institutions at which medical treatment can be secured by small periodical payments.

4. Hospitals and free dispensaries, as at present administered, usually offer no special advantages to those artisans and laborers who have combined to make provisions against times of sickness, and there is no recognized relation between these hospitals and dispensaries and provident institutions.

5. There is no clear and definite division of the work between voluntary hospitals and dispensaries, and poor-law infirmaries and dispensaries, but the former deal with cases which might more properly be left to the poor-law, and the latter with cases which, from their medical interest, or special requirements, or from the character and circumstances of the patient, might more properly be treated in charitable institutions.

6. By the multiplication of gratuitous and part-pay institutions, and the absence of regulation or organization, those medical men

How difficult it is to get either the profession or the public to take any interest in prevention! Rather than stop the causes once for all, all prefer to peck away at the ever-recurrent effects. Dr. Benjamin Lee tells me that every year the State of Pennsylvania gives $200,000 or $300,000 to hospitals, while all that could be secured for the State Board of Health last year was $6000.

Up to the present generation charity has been a blind, benevolent tyrant; now charity-organization proposes to introduce the justice of freedom, the independence of a true democracy. Instead of charity of the modern sort we are to have the gracious dignity of personal kindness. Instead of a weak sentimentalism that increases the evil, let there be the wise benevolence that prevents it. Instead of vicarious almsgiving there must be a direct and personal helpfulness that usually leaves out of the count all financial dealings. The ideal seeks to cure where it can, but always to prevent the deplored evil.

What is the evil? Dependency. It is, as I have said, a duality of shame and evil, unwelcome alike to giver and receiver, and if not unwelcome, more's the pity! Every dependent is an unnecessary and an expensive burden to the community. It needs only one observation to show how intimately united logically and by the most absolute necessity is the work of charity-organization with that of medicine. There is hardly a dependent whose dependency does not spring from or is not related to physical or mental abnormalism. What is the physician's designation of such abnormalism? Plainly the simple word, disease. The dependent is the patient, curable or not, of society, and he is also the patient of the physician.

There are two classes of such patients: those directly the result of disease or defect, and those indirectly or partially so. In the first class we have the insane, the idiotic, the crippled, the blind, the deaf-mute, the senile, the sick poor, the epileptic. In the second class we have the orphan, the criminal, the pauper, the alcoholic, the beggar, and the tramp.

The fundamental principles of the treatment of dependency by the charity-organization societies are: 1. The personal relation; no patent-medicine cure, or therapeutics by the wholesale. 2. The permanent cure, when it is possible, by proper and thorough means, not the perpetuation and increase of the disease by doles and homeopathic *similia*. 3. The prevention of the disease in future by individual health and vitality. Surely no principles could be more strictly medical. Every physician must heartily assent to them and seek to apply them. It is my chief object now to suggest that the methods advocated by these societies are genuinely medical, and that in dealing with these patients from the strictly professional standpoint, we as physicians have at hand a powerful therapeutic means spontaneously offered to us. Ours also are the duties of cure and of prevention. As ordinary citizens and members of society we must each become members of the charity-organization societies, and as physicians we should use this method of therapeutics just as we do hospitals, climate, nurses, food, and sanitation.

In some respects it seems a great pity that as a profession we have allowed the beneficent exotic of charity-organization to grow almost wholly out of lay ground and not in the sacred soil of medicine. Having done so, however, it is the more our duty to nourish it all in our power and to help to disseminate its blessed fruitage. It is gratifying to learn that physicians are coming to recognize what possibilities of good lie in the movement, and how they are utilizing and guiding it toward splendid results. We may with absolute truth urge that with our professional help the ideal will find a speedier, a more solid, and a more lasting realization than without. It is for the welfare of the movement that its leaders seek to interest *us* and elicit our sincere and powerful coöperation. We indeed rest all our treatment upon the personal and single consideration; we must as therapeutists individualize our cases; we also aim to cure, not relieve, and in relieving perpetuate the disease; we too believe above all things in prevention.

Applying these principles to the second class of our dependents we find a multifold variety of duties and methods at once springing into view. Even as to mendicancy we have an especial professional function. Begging is a crime against the law. Let us help to put the law in action. The self-exposure of the crippled and blind, the shams of the pencil-peddler, the parading of suffering to elicit alms—such things should be stopped. They are usually masked under the excusing guise of physical infirmity. If real suffering exist, ten to one it is deserved, and even if so, there is a proper mechanism of relief and cure, which we as physicians can make operative. It is better to hire such people to be warm than to be cold, to do something useful than to do something hideously useless. There is a place and a possible useful occupation for every tramp and every beggar. Most of them do not want to have their infirmity healed. Ours is the duty of unmasking at least the physical fraud.

And we also know as few others the influence of idleness in the production of pauperism and disease. The physiologic inaction of the occupants of our poorhouses and asylums is a prolific breeder of disease and preventive of cure. Let us help to do away with this foul shame. Our descendants will wonder at our heathenish cruelty and shortsightedness when they read that we house our insane, epileptics, paupers, and even our criminals in forced idleness at an enormous expense to the thrifty producer, and with multiplication of physical and mental evils.

Much of our institutional life is a practical reward for and promoter of laziness, a destroyer of the safeguards of health. The charity-driblets and free-soup

---

whose practice lies among the poorer classes are, year by year, more severely hampered in making a livelihood.

7. There is keen and continuous competition between hospitals which spend, year by year, sums considerably larger than their average income would justify, and are thus driven to resort to all manner of contrivances to meet their liabilities.

8. Year by year, also, new hospitals are (sometimes under very doubtful auspices) established for the treatment of special diseases, without any reference to the provision already available.

9. The hospitals and dispensaries are often ill-grouped for local purposes, and though sometimes a hospital and one or more dispensaries are, from their position, conveniently placed for co-operation, there is no settled relation or agreement between them by which cases may be transferred from dispensary to hospital, and *vice versa*.

10. There is no uniform system of keeping and publishing accounts.

philosophy of life is despicable. Rather than cheap and free food we should teach the poor the proper choice, the proper cookery, and the proper use of food. Any American family wastes more food than would keep a French family of the same social status, but it will be a long time before our people listen to Mr. Edward Atkinson's advice in these respects. A few years ago my friend, Mr. Bond, of Cambridge, England, took charge of the poor-law administration of the city. By the methods of charity-organization he has already reduced the municipal annual expense of this item from about $40,000 to $15,000 with great coincident improvement in the condition of the deserving poor. There are some 218,000 out-door senile paupers in England, and yet in twenty years the mere fall in the prices of food, etc., would have enabled every one of them to have insured himself against pauperism had he but saved his excess and from 1874 applied it in the way of insurance-premiums. In Buffalo, N. Y., a comparison of twelve years with out-door relief with twelve years without out-door relief showed a saving of $700,000—and also a saving of in-door relief of over $400,000—in all over a million dollars, and a less number of paupers to-day than fifteen years ago.

As to the criminal, it is yet an open question how far his condition is a result, direct or indirect, of congenital or acquired disease. The relation at least needs to be carefully studied by medical men. But that the criminal should be an expense to the law-abiding thrifty is outrageous.

But it is to the prevention of pauperism that we should look most sharply. Let us see, for example, if we cannot avoid the evils of the English system in its treatment of destitute children, who are crushed together in orphan-asylums and "barrack schools," from 200 to 1400 in each. This costs the producer $150 a head, almost one-half going for officers' salaries.

If we turn to classes of dependents whose conditions result almost directly and wholly from disease we are struck by the magnitude of the task and the multiplicity of methods of cure. It is not my purpose, because of lack both of ability and of time, to review the etiology and suggest the treatment of the evils of insanity, of epilepsy, of idiocy, and the like. It is only by the coöperation of a thousand minds working through many years that we shall reach any satisfactory solution. I desire only to ask the question, Shall we as physicians, and especially shall the American Academy of Medicine, undertake to help in the great work?

As to the hopeless idiot, the impossibility of cure, and the impossibility of reaching the ultimate causes of the production of this class of cases, have led some to the question we all shrink from asking. And yet, despite the dangers, there are those who see no really valid argument against the many valid ones for a legalized, public, beneficent sentence of painless death upon him. We each silently vote the sentence in our silent prayer that if we should become hopelessly idiotic we would not wish to be allowed to live.

The blind, the needlessly blind, are the ghosts in the empty chairs at every ophthalmologic banquet. We are glad that best efforts are being made toward the chief reform. Alas! that we cannot pay the lobbies to get a little law passed to prevent much of the world's blindness. Politics has reached such a state of degradation that a definite sum of "blood-money" seems often required to secure the most cryingly-needed legislation.

The crippled, the chronically diseased, the deaf-mute, the prematurely senile, etc., all have the most vital relations with medicine. We can do much to cure and to alleviate, and all may be made self-supporting, and certainly made more happy, by self-help and self-dependence.

Perhaps of all diseased people the epileptic demands our greatest compassion, and it is precisely he that reacts most wonderfully to our treatment. It is again sadly strange that the best treatment has been devised by the non-medical. Our failure to cure by drugs or by the trephine should have stimulated us to increased effort instead of shamed us into inaction. Intellectual and sensitive, otherwise able-minded and able-bodied, the epileptic is thrown out of work and out of ordinary social life by his mysterious malady. It is gratifying to know that the colony-plan has at last found a footing in England and in America, but it is horrifying to know that there are to-day thousands of these shunned and shunning, suffering souls deprived of the happiness that might so easily be theirs.[1] There is probably nothing in the world that is such an inspiriting example of beneficent blessedness as the Bielefeld Epileptic Colony in Germany or the Magull Home near Liverpool, England. Most if not all of you know well enough about these places, and I need not weary you with details. If not, read the account in the *Charity-Organization Manual*. At Bielefeld in 1891 there were treated 1277 patients, if patients they may be called in this beautiful home-like place, at once most hospitable, but most *unhospital-like*. The colony is largely self-supporting. At the Magull Home, a relatively small institution, but perhaps all the better for that, the "home-treatment" with no bromids, or very little, is remarkably successful. "In fourteen of those who passed through the house during the year, the fits had been arrested at the end of the year." "In the case of twenty-two patients the fits in the first half of their stay during the year numbered 1673, but in the second half, 948, a decrease of 725." Dr. Alexander believes that such homes may be made entirely self-supporting. There is no idleness. Idleness, as Dr. Ferrier says, "increases the instability of the nervous system." The chief and necessary therapeutic measures are country-life, home-life, employment, congenial surroundings, good nourishment, and little or no bromid.

I had a number of notes and gathered data of interest as to crippled children and as to feeble-minded children and girls, and what may be done for them; but I must pass the subjects by.

Another reproach of medicine, and especially of psychology, is insanity. To this I can also make but passing reference. A prominent neurologist has lately passed severe criticism upon his brother-specialists as regards the treatment of insanity. That many of the criticisms are just, few even of those "touched" would deny. But few would also deny that in many respects the charges

[1] In Germany the number of epileptics is about one per thousand of the population. Dr. Peterson puts the number of epileptics in New York State alone at double this number, or about 1200. This would gives us in the United States about 130,000, an infinitesimal portion of which only has proper care.

were often greatly exaggerated, and that many qualifying or contradicting facts were left out of the count. Such, for example, were the unmentioned facts that in the city wherein he spoke the criticised "banishment of the white caps from the wards" had been of profound good, and that the desired abrogation of locks and bolts was also exemplified. Yet another is the fact that there are nineteen training-schools in the United States for the special training of nurses for the insane. But whatever has been done, there remain herculean tasks yet to do. What a shame it is that many thousands of overactive, unstrung nervous systems are in idleness consuming body and mind, hopelessly and expensively, when the burden to the taxpayer, to the physician, and to the sufferer might be greatly lightened or entirely taken off by colonization, employment, and individualization.

And thus we ever return to the same repeated lesson, whatever the kind of dependency we study. The Charity-Organization Society has found a remedy for much, if not all the evils. It remains for us to aid, to utilize, and to realize the clearly realizable ideal.

It corresponds, for example, with the American character to do things in a large and lavish way, and we have the awful and growing evils of institutionalism. A dangerous habit is also exaggerating and deepening the evil: I refer to the voting of the taxpayer's money to private institutions. In New York State nearly $3,000,000 a year are thus given to private institutions for orphan children and the friendless. For charities and correctional purposes the State of Pennsylvania gives to private institutions about one-third of all amounts thus spent. In a series of years this amounted to about $12,000,000. What a wretched and criminal blunder! In politics, as well as in sociology, we need to learn the lessons of other countries and of other methods. We have yet to perceive all the *reductio ad absurdum*, all the ironical truth of the pertinent question, *Quis custodiet ipsos custodes?* Mechanically-working, military-governed, outwardly-splendid, non-curative prison-palaces are not the proper or lasting solutions of the problems of dependency. Charity-organization says we must individualize our cases and get into personal relations with our dependents; and charity-organization is right. It says we must seek to cure, not simply to endure them; that we must give them interesting employment; that we must reward sanity and self-help, not encourage the weak to throw away self-respect; that we must get our dependents into the country and into an approximation to home-life, etc. And in all this charity-organization is right, and the way of the world is wrong. Let us adopt and carry into practice the better therapeutic methods!

MEDICAL PROGRESS.

Sudden Death from the Use of the Bicycle.—PETIT (*l'Abeille Médicale*, September 10, 1894) has observed three cases of sudden death following the use of the bicycle by subjects affected with disease of the heart. The first case was in a man sixty years of age, who, though apparently robust, was affected with cardiac disease. He was aware of his condition, but fearing that his physician would not permit him to use the bicycle he had not consulted him in regard to the matter. The second case was in a man forty-eight years of age, who had recently recovered from an attack of typhoid fever. He was a stout man, and in the hope of removing some of his superfluous flesh had begun the use of the bicycle. The fever had probably resulted in a fatty degeneration of the heart-muscle, and the organ was overtasked in the effort of riding. The third patient was a man about forty years of age. Petit concludes that diseases of the heart and old age constitute contraindications to the use of the bicycle.

The Sterilization of Catgut by Heat.—SCHÜLLER (*Sonderabdruck aus der Aerztliche Praktiker*, 1894, No. 30) has found after numerous experiments that catgut immersed in oil of lavender and exposed in hermetically sealed glass vessels to a temperature of 110° C. for half an hour in a steam sterilizer is rendered sterile and available for surgical purposes. Good, dry catgut in loose, small rings is placed in a suitable glass vessel with a large opening and covered with oil of lavender, care being taken that the glass cover is in contact with the surface of the oil, but not with the catgut. It is essential that the vessel be hermetically sealed. Catgut thus treated is rendered mobile and retains its strength. Before being used it may be removed with sterilized forceps and immediately employed, or it may be placed for a short time in sterilized water or in an aqueous solution of carbolic acid. The same oil may be used repeatedly, or the process of sterilization may be repeated without danger to the catgut. Care must be taken that the oil of lavender is pure and uncontaminated, and the vessels used, as well as the catgut, perfectly dry. Both clinical experience and bacteriologic investigation have demonstrated the sterility of catgut treated according to the method detailed.

THERAPEUTIC NOTE.

Treatment of the Vulvitis of Little Girls.—In the *Revue Obstétricale et Gynécologique*, September, 1894, the treatment of the vulvo-vaginitis of children is summarized as follows: During the first stage, when the parts are inflamed and swollen, they should be bathed with starchy and emollient lotions, and covered with compresses saturated with a boric solution 1 : 100, a sublimate solution 1 : 10,000, or carbolic-acid solution 1 : 100. The active inflammation being arrested, the parts should be well dried with absorbent cotton, and dusted with a powder of iodoform, 4 grams; tannin, 1 gram, and bismuth subnitrate 6 grams; the labia should be kept separated by a pledget of absorbent cotton. When the inflammation extends into the vagina, about 30 grams of the following mixture should be injected: Glycerin, 100 grams, alum and cocain hydrochlorate, each 1 gram. The injection must be repeated after each act of micturition, and must be followed by the iodoform-insufflation. If desired, the injection may be replaced by the introduction of a small vaginal suppository made from the following, divided into fifteen small filiform bougies having a diameter not exceeding 5 millimeters: Iodoform, 8 grams; gum tragacanth and cocoa-butter, each 10 grams. Finally, the general treatment is of the greatest importance. The children should be built up, and sent to the country or seashore. Cod-liver oil, iron iodid, and the phosphates are especially indicated.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 13, 1894.

OLIVER WENDELL HOLMES.

To say that in DR. HOLMES America has lost her greatest physician is not one of the exaggerations to which men are prompted in expressing their grief over a recent death. We have not in mind only his contributions to medical science and literature, which, although overshadowed by his work in general letters, were many and important, but we are thinking of that wider province of the physician that lies beyond the laboratory and the drug-shop, the hospital and the consulting-room.

We doubt whether in the long period of DR. HOLMES' activity any other English writer has done so much for the health of the minds of his readers; and his readers embraced all classes. Rich and poor, old and young, learned and unlearned, found in his pages something that they could understand, and the understanding of which bettered them mentally and morally. And this highest praise that a writer can have, namely, that the best-equipped readers found the most profit and entertainment in his writings, is universally conceded to HOLMES. As the "Autocrat" he will probably be best known to fame, for like all strong and sincere natures he impressed his personality ineffaceably upon the minds brought into contact with his thought, and hundreds of thousands who have never seen him have nevertheless felt the charm of his presence.

We were about to say that his was a simple nature; and the statement would have been true in the one sense that the meretricious in literature or in life repelled him; but his intellect was subtle and complex as civilization. Science, art, nature, philosophy were all his, and all left their impress upon him. Cosmopolitan sympathy and experience modified and were modified by the effects of Puritan ancestry and old-time New England training. In his complex make-up there is no doubt that his medical studies and teaching exerted a dominant influence. In the felicitous poem read by DR. WEIR MITCHELL to the College of Physicians of Philadelphia on the occasion of the presentation to that body of a portrait of HOLMES, Minerva and Apollo are represented as contending for, and at last agreeing to divide, the lad. But, unless we concede that medicine as well as poetry belongs to Apollo, we must hold Minerva to have obtained the "biggest half" in the division.

Much of HOLMES' poetry, and nearly all of his prose, bear internal evidence of the scientific training, acumen, and observation of the author. He himself characterized "Elsie Venner" as a "medicated novel."

Although men like HOLMES are rare, yet it is a great error to think that devotion to medicine is incompatible with wide culture and even with the exercise of considerable activity in general literature. There is no need to cite examples either among the living or the dead, for such must readily suggest themselves to all our readers. The broader the man, the greater his range of knowledge, the more extended his observation, the deeper his sympathies, the better physician he will be. HELMHOLTZ in science, HOLMES in letters, broadened, it is true, out of medicine; yet it was from medicine that they broadened out; and men content to remain within the boundaries of the profession, devoting their chiefest energies to its enlargement, can learn much from the example of these illustrious graduates into larger worlds. Whether it be in diagnosis or in treatment, in criticism of new methods or in just estimate of old ones, in intercourse with patients or with students, a knowledge of men, of letters and of things beyond medicine betters judgment and strengthens influence. It is particularly in intercourse with the community as a whole that the

cultured physician can do the greatest good. His recommendation in matters of public health is more potent, and his influence in favor of public morality is more enduring. He meets as an equal the leaders in all departments of human thought and endeavor, and, commanding their respect, elevates the standing of his most obscure brother.

DR. HOLMES never lost sight of his profession, and never allowed the world to lose sight of it. Throughout his writings, from "The Fly in the Stethoscope" to the good-natured raillery at a too-exclusive specialism in "Over the Tea-cups," he did not hesitate to hit at its weaknesses and foibles; while, apart from the admirable characters in his novels, he has in many noble passages pictured the life and influence of the true, modest, self-sacrificing doctor in terms of the highest appreciation.

President ELIOT, of Harvard College, speaking of DR. HOLMES, said:

His connection with Harvard was through the medical school. He never taught literature or gave any lectures on literature. He taught at the Harvard Medical School for thirty-five years, where he was Professor of Anatomy and Physiology, teaching also histology and microscopy. He began when the Harvard Medical School was not of much account, but lived and worked in it long enough to see it become important. He taught the above branches until 1871, when he became Professor of Anatomy alone, which he continued to teach until 1882. In those busy days, when he lectured in so many branches, he used to say that he occupied not a "chair," but a "settee" of medicine in the Harvard Medical School.

DR. HOLMES was a hard and faithful worker, and one of the brightest men who ever lectured at the medical school. He did a great deal to make the school what it has become. He lectured regularly five times a week throughout the school year, and never failed to be on hand. He was the most careful of men in the preparation of his lectures, and very painstaking in his experiments. He was very exact in dissection.

DR. HOLMES' greatest contribution to the world's medical knowledge was the discovery of the fact that puerperal fever is contagious. He contended so for years, and met with all sorts of ridicule. It is now, of course, an axiom of medical knowledge. I once heard DR. OSLER, of Baltimore, say that this is one of the greatest contributions that a New England physician ever made to medical science.

One of the most medical and most characteristic features of DR. HOLMES' writings was their frank fearlessness. The verses attributed to the "Young Astronomer" aptly describe their author—

"I dare not be a coward with my lips,
Who dare to question all things in my soul;
. . . . . .
My life shall be a challenge, not a truce!"

True, warfare is the last image one would dream of associating with the genial, kindly spirit that so calmly took leave of earth. But though his weapons were satire and jest, they were none the less effective and none the less earnestly used against shams and delusions of all kinds; while at times, as in "Old Ironsides," he could be vigorously eloquent. Yet kindliness is the prevailing note, and if one could imagine DR. HOLMES sending to those he delighted to call his "Beloved" a last greeting, it would be in the closing lines of the "Autocrat": "I hope you all love me none the less for anything I have told you. Farewell."

THE SHORTLIDGE CASE.

THIS now notorious case furnishes an instance of trial by public opinion. It had long been a foregone conclusion that the assassin of his wife would be acquitted on the ground of insanity. The people were prepared for, or rather *had* prepared, the verdict. This verdict was in accord not only with their opinions, but with their prejudices, their knowledge, and their conscience. They had determined that a middle-aged man, of respectable antecedents, a teacher of the young, a father of a large family, must have been insane when he shot down on a public highway his bride of six weeks. The case was tried, and judgment given by the community on the day of the tragedy. Nothing remained for the court but to register the public decree as spoken by the jury. No hideous romance of the Eugene-Aram type would be repeated in this case; the staid people of Delaware County had no relish for such romances. They form a community in which murder can be tolerated better than capital punishment. They believe in the defence of insanity, especially when invoked to shelter a respectable pedagogue in their own midst. They proclaimed loudly their belief to some purpose.

We note in this case the exercise of the prerogative of the Anglo-Saxon jury. This body refuses to be bound by rote, or by formula, or even by evidence. Its genius is constructive, not merely mechanical. The jury decrees, not merely registers, a verdict. It makes justice, not merely cyphers it out. It arrogates to itself a divine function: it is the voice of the people, hence the voice of GOD. It may go back of the spoken evidence, and, by an insight given to no individual, it may judge of the heart of the matter by a sort of divine intuition. It stands

often for justice, but sometimes for the right to do as it pleases and as pleases the public. It is at once the best and the worst, the most ancient and the most antiquated institution of a people who value freedom in law as well as in thought.

The jury in the SHORTLIDGE case exemplified all this. It would have been useless to have offered to it a great array of expert witnesses for the prosecution. By a transcendentalism of justice it was above all this. A divine reason and compassion actuated it. It took this wretched man to itself, and would have shielded him from the cruel scrutiny of a rigorous and exacting science.

In criminal annals the case will rank with those of MERCER and NUTT, who were innocent because the public would have it so. It will be in eternal contrast with that of GUITEAU, and that especially of PRENDERGAST, both of whom were more insane than SHORTLIDGE, but whose crimes outraged the public sense.

From the standpoint of scientific criticism we think that the prosecution too willingly made no attempt to show the presence of motive, and that the defence failed to show the presence of any well-recognized form of insanity. A whole flood of light, it has been hinted, could have been cast upon the question of motive; and whether or not this could have been made available for the jury, the fact remains that the darkest mysteries of this appalling case were not nearly exploited on the trial; were not, in fact, even approached or hinted at.

As to the form of insanity from which SHORTLIDGE was alleged to have suffered, the contention was that it was the form of agitated melancholia. It may be conceded that this form of insanity does occasionally furnish episodes of extreme frenzy, in which the patient quite loses his self-control and even his consciousness. But apart from the fact that these crises are rare, they are never *isolated*, *i. e.*, cut off from all other stigmata of melancholia; and, more important still, they are never *initiatory*, *i. e.*, the primary phenomena of melancholic seizures. They are, on the contrary, *intercurrent*, and well set, as it were, in the surroundings of typical melancholic symptoms. In the SHORTLIDGE case there was no adequate attempt made to prove the existence of precedent melancholic phenomena. Apart from the evidence of a few household servants that the man had been slightly ill for a few days or weeks, nothing pertinent to this alleged melancholia was brought out. The prosecuting attorney apparently felt so sure of losing his case, or was so badly advised, that he took no advantage of this weak line of defence; while the attorneys for the defence were apparently so confident of winning their case that they did not deem it worth while to make their contention scientifically plausible. There were, indeed, some hints at "grip" and at drug-intoxication, but these factors practically were dismissed as innocuous.

But, again, these episodes of *melancholia agitata* are the expression of a profound psychalgia; they lead logically to suicide—not to homicide. It is proverbial that the melancholiac is *not* a dangerous lunatic to anyone but himself. Instances, doubtless, are on record of assaults made by melancholy patients; but even by this loophole the defence did not find it necessary to escape. The contention for the existence of an episode in SHORTLIDGE'S case cannot reasonably stand on the evidence. The history before and after the crime does not support it. If it is to be allowed, then we shall have a new defence in medical jurisprudence. Let us call it, provisionally, "homicidal impulsive melancholia!"

We maintain, in brief, that the trial in this case shed no light upon its hidden mysteries; that it contributed nothing to the science of medical jurisprudence; and that it showed once more that juries are the mouthpieces of public opinion. The life of this unhappy man was, unfortunately, not the only one at issue, for there was at stake, in a sense, the life of every criminal lunatic which in the future will be sacrificed to public clamor as easily as his was saved. Shall we speak henceforth of the Moloch of public opinion? It is not a Moloch, but a stuffed prophet, who delivers himself of judgments.

Meanwhile, as the pathetic district-attorney said in court, "the dead woman sleeps in mother earth."

Finally, the case of the prosecution was prejudiced hopelessly by the mistaken zeal of the victim's friends. These mourners are entitled to the sympathy of all people, for their grief is a sore one; but they should have remembered that the object of the law is justice, not revenge.

EDITORIAL COMMENTS.

The Reliability of the Newspaper-Reports as to Foot-ball Casualties.—A valued correspondent, for whose opinion we have all respect, avers that the newspaper-reports of foot-ball casualties are grossly exaggerated, and says that of his personal knowledge three of the injuries

alluded to in the last issue of THE NEWS never occurred. We gladly accept the correction, and wish that every case of accident that has been reported were a newspaper-lie. We have no wish except for the truth and that the game might be purged of brutality and danger, and that it may be made properly subordinate to intellectual training. Curiously enough, on the same day that our critic wrote, an equally veracious and well-informed gentleman, a college athlete in fact, told us that to his personal knowledge one member of the foot-ball team of an Eastern college received his tuition free and $1000 a year salary until the four-year limit barred him. His scholarship was not good enough to permit his graduation at the end of four years.

Curiously enough, also, by the same mail that brought our critic's letter, the most trustworthy newspapers we can get brought reports of one death on the ball-field in England, and the following, not all of the casualties in the games of one day, October 7th, in the United States:

"It was noticed yesterday that the precaution had been taken of having several doctors, with liberal supplies of court-plaster, arnica, splints, etc., on hand. Several players were disabled, but none seriously so. Wardner, of the Crescents, was the only one who had to retire from the contest. The game had not been in progress five minutes before it had taken a sanguinary turn. There were half-a-dozen bruised noses and bleeding mouths. Most of the rough play was in the scrimmages. The Crescent players were unnecessarily rough, and in one or two instances were guilty of flagrant slugging."

"Cornell defeated Union College at Ithaca yesterday by a score of 39 to 0. The Union men slugged fiercely, eight Cornellians being injured."

"In the Harvard-Andover game yesterday Gray, of Harvard, broke his leg just above the ankle. This is the second time he has met with this accident while playing. Connor broke his collar-bone and will not play any more this season. Brewer has a bad ankle and is on crutches."

We sincerely trust these will also be proved false reports. It is certainly not to the self-interest of the newspapers to make foot-ball unpopular by exaggerating the reports of accidents or by any other means, and it is strange that they should make such mistakes. We had always supposed that but a fraction of the number of accidents actually happening get into the newspapers. There are many reasons why both their severity and their number should be minimized by the players, by the newspapers, and especially by the college-authorities and athletic associations.

The Harmonizing Influence of the Local Medical Society.—The power of the local medical society for good cannot be better exemplified than by the success of the Cleveland Medical Society. Organized not two years ago, the Society has already a large membership-list, and is actively engaged in a movement to form a library and to secure a permanent home worthy of the dignity and importance of the organization. At the last quarterly meeting of the Society, held September 28, 1894, Dr. W. W. Keen addressed the Society on the subject of "Amputation of the Breast." On the following morning Dr. Keen held a clinic in the Cleveland General Hospital in the presence of a large assemblage, illustrating his remarks of the evening before. The Society has on previous occasions been addressed by Dr. Wm. Pepper and Dr. Howard A. Kelly. By these means the Cleveland profession has been brought into harmonious union; and what has been accomplished in Cleveland can be accomplished elsewhere, the good work extending from town to city, to county, to State, and finally to the American Medical Association. A united and harmonious medical profession means higher medical education and intelligent medical legislation.

Philadelphia as a Medical Center.—If we may trust the newspaper-statistician the following is the number of students pursuing courses of medical study in Philadelphia:

Medical Schools.	
University of Pennsylvania	875
Jefferson	700
Hahnemann	325
Medico-Chirurgical	300
Woman's	200
	2400
Special and advanced students, not counted	100
Dental Schools	600
Veterinary	100
Total	3200

There seems a somewhat suspicious tendency to large, round numbers in these figures, but we suppose they are not all too "gross exaggerations." Indeed, we might suggest that the noble array of nurses should not have been omitted. In any event, it is a huge number, and a great increase over previous years. One wonders if this greater interest in medicine may be accounted for by a keen sense on the part of these young folk of coming duties and opening possibilities aroused by foot-ball evolution and the attendant work to be thrust upon the profession! Even the dentists will have additional work at the present rate of progress, and the veterinarians may also hope for much practice from those who ride a hobby over-hard!

Tubercle-Bacilli in Butter.—The frequent occurrence of the tubercle-bacillus in milk has naturally led to the question as to its occurrence in milk-products, especially butter and cheese. The identification of it in these is somewhat difficult, and few observers have interested themselves in the investigation. In a recent number of the *Correspondenzblatt für Schweizer Aerzte*, O. ROTH, of Zürich, reports some tests of commercial butter, and discusses the question at some length. He examined twenty samples, in two of which he found virulent tubercle-bacilli. He refers to an investigation by Brusaferro, who found one sample containing tubercle-bacilli out of a total of nine examined—about the same proportion as that obtained by Roth. Roth finds that boiling cream interferes seriously with the yield of butter, but thinks that it will be feasible to use prolonged heating below the boiling-point. The proper remedy, however, is such control of the dairy as will eliminate all tuberculous cattle.

Medical Statistics of the Japanese Navy.—In view of the attention which the Korean war has drawn to the

Japanese, it may be of interest to summarize some of the facts given in a recent sanitary report of the Japanese Navy. The report is in English. It relates to the year 1892 and emanates from Yasusumi Saneyoshi, F.R.C.S. Eng., Director-General. The influence of modern preventive medicine is apparently exhibited vividly by a table showing the number of cases of kak'ke (beri-beri) annually since 1878. In that year the number amounted to nearly one-third the force, and was even higher some years later. In 1884 the proportion fell to a little over one-tenth the force, and the next year it dropped to about 0.6 per cent., and since then it has been insignificant. In 1892 only three cases were reported from a total of nearly ten thousand men. These cases were all from a prison, and are stated to have been caused by deficiency of food combined with overwork.

Data on Keeleyism.—Rev. Dr. J. M. Buckley, editor of the *Christian Advocate*, of New York (150 Fifth Avenue, New York City) solicits specific data in reference to "Keeley Institutes." He asks only for information from physicians and ministers, and desires to make a thorough and impartial investigation of the Keeley business.

Dr. Buckley is an able journalist and editor. He was a student of medicine for three years, and has visited nearly every institution for the insane in the United States, and was sent to Europe by the Governor of New Hampshire to examine the institutions of Great Britain.

He is a D.D. and an LL.D., and has written extensively upon psychologic subjects, as well as upon sociologic, anthropologic and theologic problems. He has published a work upon *Faith Healing*, *Christian Science and Kindred Phenomena.*

State Board of Medical Examiners.—An autumn examination will be held by the Pennsylvania Board. Its influence is already clearly felt in the solicitude shown by some of the medical schools concerning the fitness of students to pursue the study of medicine. It was rare in former years to hear the dean of a medical school advise a pupil not to enter or continue in the course unless indeed the student had paid all the fees that the college could exact. We hear now, however, occasionally of students being advised that they are not sufficiently prepared to enter upon the medical course. It is to be hoped that the Pennsylvania Board will maintain the position that was assumed in the first examination. The questions were highly satisfactory. They were such as any well-educated graduate could answer, and if perfect impartiality, fairness, and strictness are maintained the effect upon the colleges and upon the profession will be most beneficial.

SELECTION.

HUMORS OF HOMEOPATHY.

Richard Bentley, the famous scholar who had as much experience of controversy as any man that ever lived, used to say that no man was ever written down except by himself. We commend this maxim to the attention of the disciples of Hahnemann. These guileless persons often complain that they are evil-entreated by the professors of scientific medicine, their doctrines being misrepresented and their practice unjustly ridiculed. But are not their worst enemies those of their own household? Take the following samples of their teaching as set forth in all seriousness in their own organ. The *American Homeopathist* gravely assures all whom it may concern that if a patient sleeps with his knees apart chamomilla is indicated; if with his legs stretched out at full length, pulsatilla; if with one leg drawn up and the other stretched out, stannum. If the patient has his head always turned to one side, cina is indicated; if he bends his head forward, staphysagria; if backward, hyoscyamus. So much for the head and the legs. The hands and arms are the object of still more mysterious refinements. If the patient lie with his hands on his abdomen, pulsatilla is indicated; the same drug is to be used when a woman sleeps with her hands over her head, but when a man does so, he requires nux. There is something suspicious in this difference in which we fear the "New Woman" will see a fresh instance of the denial of equal privilege with the tyrant man. We confess ourselves utterly unable to appreciate the clinical significance of the phenomena that have been enumerated; it would almost seem as if the prophets of the pilular philosophy believed man to be under a curse like that of Ernulphus, and that he is banned in all his limbs—in sleeping, in sitting, in lying, etc. There is one position of the hands which, strangely enough, is not provided for; the resources of homeopathic therapeutics seem to fail before the contingency of a patient who, like the vulgar little boy of the *Ingoldsby Legends*, should "put his thumb unto his nose and spread his fingers out." This omission is the more remarkable since the homeopathic practitioner would seem to be prepared for even less decorous manifestations on the part of his patients. Thus we are told that "if a patient 'cusses' you, spits in your face, and pulls your whiskers," you are to soothe her excited feelings with chamomilla. There is a refreshing candor about the following: "If a patient gets suddenly better, it is a bad sign"—for the doctor, we presume. The *North American Journal of Homeopathy* published recently an article on "Some Peculiar Sweats," in which also the subtleties of homeopathic therapeutics are strikingly displayed. Thus we are told that if only the upper half of the body sweats, nux vomica or opium is the thing; if the lower, crocus cyclamen; if the back, ananita or phosphorus; if the right side, aurum or sodium; if the left, fluoric acid and jaborandi; if the face alone, ignatia. Lastly, if the patient sweats "in spots" the sovran'st thing for this distressing condition is tellurium. For sweats in the morning, angostura (to the profane mind more suggestive of dinner-time) is prescribed; for sweats while eating you have a specific in "oleum animalis;" we can only hope that this drug agrees with those to whom it is administered better than the component elements do with each other. It is interesting to learn that if the sweat smells like horse's urine its natural fragrance may be restored by nitric acid. Then in the *Southern Journal of Homeopathy* we find some curious information about "Peculiar Coughs." Thus, when the cough comes on at the inconvenient hour of 6 A.M., you must put your trust in cedron; if it is worse when the patient lies on his belly give him baryta; if it is worse when lying on the left side, mercurius. We are unkindly left in the

dark as to what is to be done if the cough is worse when the patient lies on his right side or on his back. When the cough is aggravated by music creosote is indicated. We are thankful for this suggestion, but it is disappointing that no information is vouchsafed as to how we are to deal with those other common exciting causes of cough—a dull sermon or a drowsy lecture. We could add indefinitely to this *florilegium*, but this would hardly lead to edification. It would be gross flattery to call this stuff heresy or even superstition; it is sheer unadulterated nonsense. It is the homeopaths themselves who write themselves down—what poor Dogberry was so anxious to be written down. Certainly the most malicious "allopath" could not invent anything that tends to laughter more than these simple gentlemen invent on themselves.—*British Medical Journal.*

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Abstract of the Proceedings of the Seventh Annual Meeting, held in Toronto, Ontario, September 19, 20, and 21, 1894.

(Continued from page 390.)

Second Day—Afternoon Session.

Dr. C. C. Frederick, of Buffalo, read a paper on "The Relations of Renal Insufficiency to Surgical Operations." The author reported observations based on nearly three hundred operations at the Buffalo Woman's Hospital, supplemented by the experience of several prominent operators. By renal insufficiency is meant any condition of the urine which shows deficient elimination of waste products, whether from functional inactivity or from disease of the kidneys. Whether renal insufficiency is a contra-indication to operation depends on the consideration of three factors: 1. The amount and nature of the insufficiency; 2. The character of the lesions for which operation is proposed; 3. The causal relation which the patient's disease holds to the renal insufficiency. Every patient's urine before operation should be collected for twenty-four hours, except when operation is urgent, as for example, in ruptured ectopic pregnancy. In examination of urine the important fact to ascertain is whether the kidneys are crippled or in full or nearly normal functional activity. Women with chronic endometritis are especially liable to functional insufficiency. Most gynecologic patients who are run down physically present the same condition. A knowledge of the state of the patient's kidneys is of value to the operator and anesthetizer. Renal insufficiency renders the patient more liable to shock from operation and is followed by a slower convalescence.

Dr. I. S. Stone, of Washington, D. C., followed with a paper entitled "Some Results of Ether-Anesthesia in Abdominal Operations."

Dr. Eugene Boise, of Grand Rapids, Michigan, read a paper on "The Cause of Thirst Following Abdominal Section." The author, after stating the generally accepted proposition that thirst is a sensation indicating that the tissues of the body are in want of more water, argues that the sensation as felt in the mouth and throat is reflex, and that the real point from which the sensation arises is in the abdominal viscera; that from these the sensation is conveyed to the consciousness by fibers of the sympathetic system of nerves; that while ordinary thirst is caused by the withdrawal of water from the tissues to refill the veins depleted by excessive perspiration or otherwise, the thirst following abdominal section is caused by the withdrawal of water from the abdominal viscera to fill veins partially collapsed by reason of diminished blood-supply because of contraction of the arteries of the viscera. He briefly stated those physiologic facts which are universally accepted, or have been experimentally proved, on which the theory is based: (1) Thirst is a sensation indicating that the tissues need more water. (2) The sensation felt in the throat is reflex. (3) The origin of the sensation is believed by leading physiologists to lie in the sympathetic system of nerves, because (*a*) no cerebro-spinal nerves can be found which convey the sensation to the consciousness, and (*b*) nutrition is presided over by the sympathetic system, and thirst is a disturbance of nutrition. (4) The origin of the sensation is probably from the abdominal organs because (*a*) these are so rich in sympathetic fibers, and (*b*) introduction of water into the stomach so instantaneously allays thirst. (5) The sensation invariably follows the withdrawal of any considerable amount of fluid from the body; the withdrawal of such fluid causes proportionate collapse of veins and capillaries. (6) Capillaries tend to remain at normal tension, and when suddedly collapsed in any degree attempt to regain that tension by taking water from the surrounding tissues. (7) Irritation of sympathetic nerves causes contraction of the arterioles supplied by such nerves. (8) Sudden contraction of the arterioles supplying any organ is followed by lessened tension in the capillaries and small veins of that organ. (9) Abdominal section invariably causes direct and reflex irritation of the abdominal sympathetic nerves. (10) Such irritation causes contraction in some degree of the arterioles of the abdominal viscera, with consequent lessened tension in their capillaries, and compensatory withdrawal of water from their tissues. And is it not probable that such circulatory disturbances give rise to the sensation of thirst?

Dr. Hulbert, Second Vice-President, took the chair, and President Rohé delivered his Address. He selected for his subject "Intestinal Obstruction Following Operations in which the Peritoneal Cavity is Opened." He said obstruction of the bowels causes between 1 and 2 per cent. of the deaths following ovariotomy and other operations involving opening of the peritoneal cavity. Sir Spencer Wells lost eleven out of his first series of a thousand cases of ovariotomy from this cause. Fritsch places his mortality from ileus post-laparotomian at 1.6 per cent. Klotz has reported 31 cases of intestinal obstruction, with five deaths due to this complication in a series of 421 abdominal sections and 148 vaginal extirpations of the uterus. The speaker had seen a case in which the small intestine was doubled upon itself, and so firmly adherent that the gut was entirely impervious. Similar cases have been reported by Skutsch and Tuttle. Joseph Price quotes an interesting case from Louis, in which an adherent ovarian cyst emptied by the trocar so dragged upon the bowels as to cause obstruction. Volvu-

lus sometimes occurs after abdominal section, but probably only after some previous adhesion or constriction of the bowel. Two cases reported by Nieberding illustrate this. The symptoms of intestinal obstruction post-laparotomian are essentially the same as those of primary obstruction. Klotz has had much success in treating acute obstruction following abdominal section by the following method: As soon as symptoms indicating obstruction appear he washes out the stomach with from four to six quarts of warm salt solution. Should this fail to relieve the symptoms he repeats the procedure, and then passes into the stomach through a tube a large dose (one-and-a-half to two ounces) of castor oil. In all cases so treated the active peristaltic movements set up caused passage of flatus and feces within ten hours. Evidently it is only in cases of fresh and friable adhesions that this method can be successful. Rectal injections of water or air may at times be curative when the obstruction is due to intussusception, volvulus, or soft adhesions of the lower portion of the intestine, but when the obstruction is due to cords or bands they can manifestly be of no avail.

Third Day—Morning Session.

Dr. L. H. Dunning, of Indianapolis, Ind., contributed a paper on "Nephrectomy," in which he reported four cases, of which the following is a synopsis:

Case 1. Nephrectomy for painful movable kidney. An unsuccessful nephrorrhaphy had been done two-and-a-half years previously. The patient had been bedridden four years. A lumbar nephrectomy was done, the patient recovering, and obtaining entire relief from pain. The author deplores the necessity of removing a healthy kidney only because movable and painful. He thinks that the success of recent methods for anchoring the kidney will obviate the necessity of such a procedure

Case 2. Nephrectomy for persistent hydronephrosis due to stricture of the ureter at its pelvic extremity. The tumor was mistaken for an ovarian one. It was removed by a median abdominal incision.

Case 3. Sarcoma of the kidney in a child two years old. Nephrectomy and recovery. The tumor had been discovered only four weeks previously. A median incision (abdominal) was employed.

The writer has collected the histories of twenty cases of sarcoma of the kidney, operated upon since 1885, in children under five and-a-half years of age. Of these 5 perished and 15 survived the operation, thus showing a mortality of 25 per cent. This is a surprising decrease in mortality, and is probably due to improved details in technique rather than to radical changes in the method of operation.

Case 4. Nephrectomy for uretero-vaginal fistula following vaginal extirpation of a cancerous uterus. The operation was done four weeks after the hysterectomy. The ureter was torn across in enucleating a nodule of cancerous tissue from the folds of the broad ligament on removal of the uterus. Nephrectomy was done four weeks subsequently, because of intermittent closure of the fistula and the morbid mental condition of the patient. The carcinoma had recurred in seven weeks, and the patient died three months later of exhaustion and septicemia.

"Progressive Cutaneous Atrophy of the Vulva (Kraurosis Vulvæ)." Dr. C. A. L. Reed, of Cincinnati, read a paper with this caption. He reported six cases in which the pathologic and clinical features were characteristic. The first changes obvious to the naked eye consist of small vascular areas around the introitus vaginæ. These areas are not elevated as if seats of merely inflammatory engorgement, but are slightly depressed relatively to the adjacent epithelial surfaces. They are exquisitely painful to the touch, and efforts at sexual intercourse are generally agonizing and futile. About this same time inspection will reveal a narrowing of the vaginal orifice, associated with diminished elasticity of the structures. The cutaneous or muco-cutaneous surfaces will now be observed to have lost a certain proportion of their pigment, giving them a more or less translucent appearance, which increases until it becomes so transparent that the larger capillaries and minute ecchymoses may be readily discerned beneath it. The skin thus affected becomes tense, effacing in a more or less degree all of the normal folds of the vulva and narrowing the vaginal orifice until, in the case of a multipara, "incredulity may be excused when the patient states that she has borne children."

Knowledge relative to progressive cutaneous atrophy of the vulva is too nebulous to justify final conclusions. That which seems to be conclusively demonstrated may be summarized as follows:

1. Progressive cutaneous atrophy of the vulva is a distinct disease. 2. It is of very rare occurrence. 3. It is essentially inflammatory in character, differing from other inflammations of the skin in the marked progressive atrophy which succeeds the stage of hyperemia and infiltration. 4. It is limited in its manifestations to the vulva. 5. It is manifestly not of syphilitic origin. 6. Its etiology is so obscure as to suggest a primary causal lesion in the trophic nerve-supply of the vulva. 7. The affected areas may be successfully excised.

Dr. George F. Hulbert, of St. Louis, read an interesting paper on "The Element of Habit in Gynecic Disease," an abstract of which would not do it justice.

One of the interesting features of the meeting were remarks on intestinal anastomosis and a beautiful demonstration of the uses of the Murphy button by Dr. J. B. Murphy, of Chicago.

"Restoration of Intestinal Continuity Without Mechanical Devices," was the next paper, by Dr. W. E. B. Davis, of Birmingham, Ala. The purpose of this paper was not to claim originality for any special technique, but rather to consider the various operations and to show that mechanical devices can in a great proportion of cases be better dispensed with by the surgeon who has had much experience in intestinal work, either on the lower animals or on the human intestine. Still there is a place in anastomotic work for bone plates, catgut plates, and other devices of this sort, and the Murphy button, but the experienced surgeon will find the field of their application very limited. These devices are of great assistance to the surgeon of limited experience in this class of work, and should be recommended in the event of an operation having to be done by one who has not had the opportunity of becominn familiar and skilled in suturing of the intestines. The Murphy button is a valuable device for cholecystenterostomy, and is superior to anything yet suggested for that purpose. The button is so small that it can pass

through the intestine without causing any trouble, and it can be depended upon with almost absolute certainty to produce satisfactory adhesion and a competent opening between the gall-bladder and intestine. The end-to-end operation or circular enterorrhaphy is a dangerous procedure, from the fact that injury to the mesenteric border is liable to produce sloughing, and it is never possible to say that a surgeon will not have this complication follow the operation. Besides, any stitch-method in the end-to-end operation requires so much time that it should be objected to usually on that account. The Murphy button can be used very satisfactorily for this purpose, and when end-to-end operation is to be resorted to Dr. Davis is of the opinion that this device should be used unless the surgeon is an expert in intestinal suturing. The operation of Abbe is a plausible one, but is not so reliable as the one which has proved satisfactory in the experimental work of the author. The incision is not made so long as in the case of Abbe, and is about three inches in length. In the case of gastro-enterostomy the intestine and stomach are both brought into the wound, and the incision three inches in length made in both. Interrupted sutures are taken through coats of the bowel and stomach around the entire length of the incisions, and are tied on the inside, the last stitch being tied on the outside and turned in. A continuous outside safety stitch is then taken through the peritoneal and muscular walls. In bringing the small intestine together the same procedure is followed, the interrupted through-and-through stitch of large silk being taken instead of an overhand stitch, as recommended by Abbe, and only one row of outside sutures, which may be interrupted or continuous, preferably the latter. This operation can be done very quickly, and is more reliable than the various ones with mechanical aids to anastomosis. Particularly is this method of operating valuable in cases of simple stricture of the bowel, and there will be a great many of these cases now, inasmuch as there are more operations done on the intestines.

DR. F. BLUME, of Allegheny, Pa., reported a very interesting case of "Cholelithiasis" in a woman thirty-seven years of age, in which the number of calculi removed, besides minute concretions, was 123, weighing 14 drams. The stone removed from the gall-bladder weighed four and three-quarter drams.

"The Reason Why Patients Recover from Tuberculosis of the Peritoneum after Operation" was the next paper, by Dr. ROBERT T. MORRIS, of New York. The author stated that he had been experimenting with a view to determining the reason for the cure of tuberculosis of the peritoneum after operation, it being a well-known fact that more than 80 per cent. of these cases recover as a result of simply exposing the peritoneal cavity to the air. Dr. Morris collected fluid from the abdominal cavity of patients with tuberculosis of the peritoneum, placed it in an incubator for forty-eight hours and developed the bacteria of putrefaction which would ordinarily enter in such fluid exposed to the air. From this fluid Dr. Eiloart then isolated a toxalbumin, the product of the growth of putrefactive bacteria in this peritoneal fluid. The toxalbumin employed to destroy tubercle bacilli in culture-tubes destroyed them very promptly. A control experiment, which was not yet completed, was in progress for determining if these bacteria were absolutely dead. However, enough had been proved to show that tuberculosis of the peritoneum recovers after operation because putrefactive bacteria produce a toxalbumin in the fluid which is fatal to tubercle bacilli in the peritoneum. The reason why it is more effective in curing cases of tuberculosis of the peritoneum than tuberculosis of the knee-joint is because the anatomy of the peritoneum is such that any toxic agent absorbed by the lymphatics of the peritoneum is brought into close contact with the entire structure; whereas, in the knee-joint, the lymphatics are fewer and with more definite channels.

The following officers were elected: *President*, Dr. J. Henry Carstens, Detroit; *First Vice-President*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Second Vice-President*, Dr. Henry Howitt, Guelph, Ont.; *Secretary*, Dr. William Warren Potter, Buffalo; *Treasurer*, Dr. X. O. Werder, Pittsburg.

The place of meeting for 1895 was referred to the Executive Council for decision.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Abstract of the Proceedings of the Twenty-second Annual Meeting, held in Montreal, P.Q., September 25, 26, 27, and 28, 1894.

(Continued from page 392.)

SECOND DAY—MORNING SESSION.

The Executive Committee recommended the creation of a new commitee, consisting of five persons, to be entitled a "Committee on Steamship and Steamboat Sanitation." This was approved by the Association.

DR. N. E. WORDIN, of Bridgeport, Conn., read a paper on "The Restriction and Prevention of Tuberculosis." He showed that consumption was a communicable disease, and that the principal source of danger of its spread lay in the sputum ejected by a phthisical patient when it had become dry. The breath of a consumptive contained no bacilli, and was not infectious. Phthisis might be communicated by osculation, and among the hygyenic commandments should be one for the syphilitic and the consumptive, "Thou shalt not kiss." He considered that the most practical and the quickest way of restricting the spread of the disease will be to put it on the list of infectious or communicable affections to be reported to the health officers. There should be a thorough disinfection of all houses in which the disease has occurred, and this should be put on public record.

Dr. E. GAUVREAU, of Ste-Foye, P. Q., read an interesting paper on "Culture and Collection of Vaccine-Lymph." He described the process followed in the institution with which he is connected for the culture and collection of vaccine-lymph, showing that every care is taken to insure absolute safety to the people using the points.

DR. F. O. DONOHUE, of New York, read a paper entitled "The Examination of the Milk-Supply for Tuberculosis in the State of New York." In May, 1892, New York took a step forward in authorizing its Board of Health to make investigations in reference to the existence of tuberculosis in cattle. The relation of the milk-supply to infant mortality from tuberculosis was insisted upon by all health-officers who had made the subject one

of systematic observation. That milk and its product convey tuberculosis had been amply proved. When it is considered that milk is the principal aliment during childhood, and enters largely into the diet of all classes, it is a highly important question. Statistics of New York State show that for a period of eight years last past every eighth death was caused by tuberculosis. The State Board of Health evolved the lesson that tuberculosis existed in the dairy cattle to quite a large extent, and that special legislation was necessary to deal with it. It would take time to eradicate this disease from the dairy cattle. It is confidently expected that future legislation will be enacted, carrying with it an appropriation commensurate with the magnitude of the work.

Dr. Paul Paquin, of Missouri, contributed a paper entitled "Should the Marriage of Consumptives be Discouraged?" He held that the marriage of a tuberculous person with a healthy person must lead to the infection of the latter, and that the children born of tuberculous parents are always naturally predisposed to tuberculosis. Thus the centers of infection are increased, and the danger to so-society is made much greater. No tuberculous person should marry, and it is perfectly proper for science to interfere and use all its influence to prevent such marriages.

"The Climatic Segregation of Consumptives," was the next paper, by Dr. Henry Sewall, of Denver. He proposed the following plan for the treatment of pulmonary tuberculosis in its early stages, viz., the establishment of favorable points in Colorado of a series of cottage sanatoria. The cottage-plan he thought was eminently the best in its adaptation to the character of the climate, the people, and the disease. The efficiency and feasibility of such an institution had already been established in the Adirondack cottage of New York, which might well serve as a model for extensive development. These sanatoria should be located at points of various altitudes above sea-level, from five to eight thousand feet. They should be located with due regard to climatologic conditions, purity of water supply, beauty of scenery, accessibility to railways.

There was no afternoon session, the Association having, by invitation of the local members, taken a pleasant trip over the Lachine Rapids.

Second Day—Evening Session.

This session opened with an interesting sketch, illustrated by lantern slides, of "The Quarantine Appliances at Grosse Isle," by Dr. F. Montizambert, General Superintendent of Canadian Quarantine. Dr. Montizambert briefly and interestingly explained the mode of boarding ocean ships, examination, disinfection, and hospital treatment.

"Some Points in the Hygiene of the Young in Schools," was a paper read by Dr. J. Chalmers Cameron, of Montreal. He asserted that the nation which would be the most prosperous is that which seeks the highest development of its members, and proceeded to show how closely allied the mind and body are, and stated that they developed simultaneously. The speaker dwelt on the need of thorough instruction in hygiene to the young. A man with a good body and poor education is often in a better position for securing a good livelihood than the man with a good mind in an unsound body. Therefore the necessity exists to give physical as well as literary instruction.

Mr. John Mitchell, of New York, read a paper entitled "Plumbing in Sanitation." He advocated a semi-annual inspection of all houses for sanitary measures.

Dr. T. D. Crothers, of Hartford, Conn., read a paper on "The Influence of Inebriety on Public Health." The facts he desired to make prominent were:

1. The influence of inebriety on public health is of far greater magnitude and more closely associated with the various sanitary problems of the day than is realized at present.

2. Our present conception of the extent, nature, and character of inebriety is erroneous, and based on theories that are wrong. Our methods of dealing with inebriates are most disastrous and fatal in not only destroying the victim, but in perpetuating an evil we seek to lessen.

3. These patients must be recognized as diseased, and should be housed in farm-colonies, under military care and medical treatment. They must be organized, employed, placed in hygenic surroundings, and made self-supporting.

The present duty is careful medical study of this class of cases and full recognition of their needs and requirements. The sanitary problems that confront our civilization are very closely associated with the inebriate class.

Third Day—Morning Session.

The Secretary of the Association, Dr. Irving A. Watson, of Concord, N. H., read a short paper on "A Journal of the American Health Association," in which he spoke in favor of the Association publishing a quarterly journal, instead of an annual volume of *Transactions* as at present. In his opinion, a quarterly journal could be published at less cost than an annual volume of transactions, and it would increase the influence and strength of the Association by making its objects better known.

The matter was referred to the Executive Committee for its action.

"Vaccine and Vaccination" was next considered by Dr. Ralph Walsh, of Washington, D. C. So-called cowpox being simply modified variola, the admixture of glycerin with vaccine lymph will destroy all extraneous bacteria without injury to its peculiar active principles. The admixture of glycerin with vaccine lymph not only destroys the extraneous bacteria, but prolongs the activity of the lymph. The selection of lymph and the simple but important operation of vaccination had not received from the profession the attention they deserved. The physician should see that each infant brought under his care is successfully vaccinated during the first year of its life, and each child again at sixteen, or, better, to the point of saturation during infancy. The accumulation of unvaccinated material, and consequently the increased danger of outbreaks of smallpox, is caused by the general physician failing to perform his duty at the proper time.

Dr. G. P. Conn, of Concord, N. H., followed with the "Report of the Special Committee on Car-sanitation." He said the railway employé should be instructed in the use of hygienic appliances, and all roads having a surgical department should extend this work into the domain of hygiene, and give the surgeon-in-chief authority to inspect, instruct, and to hold responsible such

employés as are in any way concerned in maintaining a healthy condition on our trains.

DR. FELIX FORMENTO, of New Orleans, as Chairman of the International Committee on Yellow Fever, presented his report, in which he pointed out that since the modern health-regulations adopted by the State of Louisiana yellow-fever had practically disappeared from the State, and that with an efficient system of quarantine the dreaded disease can be excluded.

MR. RUDOLPH C. HERING, of New York, presented the Report of the Committee on the Disposal of Garbage and Refuse. He had no faith in the schemes for the disinfection of garbage. The plan of separating or reducing the garbage also offers dangers, and, all things considered, incineration seems to be the best method.

DR. DURGIN, of Boston, reported a process for drying garbage as it is produced in the kitchen, after which it can readily be burned in an ordinary stove, thus doing away with the whole question of the disposal of garbage. The apparatus to secure this result consists of a sheet-iron box fitted with grates and connected with the stove-pipe. The heat passing from the stove to the chimney dries the garbage.

DR. N. E. WORDIN, of Bridgeport, Conn., followed with a paper on "The Disposal of Garbage."

DR. JESUS E. MONJARAS, of San Luis Potosi, Mexico, and DR. S. GAUTHIER, of Upton, Quebec, read papers on "The Advisability of Teaching the Rules and Principles of Hygiene in the Primary Schools by Means of Object Lessons."

DR. T. D. REED, of Montreal, read a paper entitled "Hygiene of Vision in Schools," and DR. T. M. BRENNAN, of the same city, one entitled "A Few Remarks on School Hygiene."

DR. ANDREW MCPHAIL, of Montreal, contributed a paper entitled "One Hundred and Twenty Cases of Paralysis in Children." The belief was held at first that the outbreak was one of cerebro-spinal meningitis, but he showed in the clearest manner that it was a true myelitis. In some children the paralysis came on without any symptoms; in others there was a previous illness of a few days, resembling indigestion. There were also notes of six cases in adults, three of which terminated fatally. In conclusion, he dwelt upon the necessity for having in every State a properly-conducted laboratory and a competent staff to deal with such outbreaks, and a board of health with authority to investigate epidemics and perform autopsies.

DR. L. LABERGE, of Montreal, read a paper entitled "The Advance of Public Health in the City of Montreal." He outlined the development of the several matters connected with the public health of the city and the legislation by which they were governed with reference to milk-inspection, meat-supply, ice-supply, etc.

"Myopia in its Relation to School Hygiene." This was the title of a paper by DR. A. F. FOUCHER, of Montreal. The eye afflicted with myopia is an extremely delicate organ, which should be but sparingly brought into use; therefore we cannot exact from it the labor which we have a right to expect from an emmetropic eye. The speaker presented charts which illustrated that myopia is more prevalent in the secondary than in the primary schools. In the primary schools of Russia it is 14 per cent., and in Germany, Austria, France, Holland, New Zealand, United States, and Switzerland, 13 per cent.; Norway, 11 per cent.; England, Roumania, and Belgium, 13 per cent. In the secondary schools in Austria it is 38 per cent.; in Switzerland, 36 per cent.; and Germany, France, Russia, and Denmark, 36 per cent.; Italy, 38 per cent.; Sweden, 34, and England 38 per cent.

DR. HINGSTON, of Montreal, spoke of the influence of the Canadian climate on health.

DR. S. W. ABBOTT, of Boston, as Chairman of the Committee on Nomenclature of Diseases and Forms of Statistics, presented his report. The committee considered changes in the nomenclature and classification of diseases, and causes of death, uniform methods of reporting statistics, uniform methods of estimating population and death-rates, and the adoption of a standard of age-distribution. It is plain that a fair comparison could not be made of the death-rates of countries, cities, and towns in which age-distribution is widely different; hence the importance of adopting some conventional standard to which all populations may be referred or with which they may be compared.

FOURTH DAY—MORNING SESSION.

DR. T. M. BRENNAN, of Montreal, read a paper entitled "A Plea for Aseptic Vaccination." The speaker urged the necessity of performing vaccination under antiseptic conditions.

DR. K. CAMERON, of Montreal, followed with a contribution on "Infection by the Bacillus Pyocyaneus as a Cause of Infant Mortality." It was not until 1889 that this bacillus was found to produce a definite general infection in young children. The author reported four cases of pyocyanic infection, and drew the following conclusions:

1. That the infant tissues are susceptible to the invasion of the bacillus pyocyaneus.

2. That the bacillus is distinctly pathogenic, setting up a disease-condition peculiar to pyocyanic disease.

3. That this disease is characterized by a train of very definite symptoms, such as diarrhea, fever, rapid emaciation, rigidity of the legs, and hemorrhagic and bullous eruptions.

4. That the disease appears to be very fatal.

As this combination of symptoms occurs not infrequently in young children, especially when congregated in nurseries and foundling asylums, he ventured to infer that a certain proportion of the deaths which now appear upon our records of vital statistics under the headings of gastro-enteritis, purpura, or marasmus, were in reality cases of generalized pyocyanic disease.

The closing paper of the Convention was read by MR. J. W. HUGHES, of Montreal, entitled "Evolutionary Developments of Domestic Plumbing during the Past Thirty Years."

Several of the papers on the program were read by title and referred for publication in the *Transactions* owing to the absence of the authors.

The following officers were elected: *President*, Dr. William Bailey, of Louisville, Ky.; *First Vice-President*, Dr. G. P. Conn, of Concord, N. H.; *Second Vice-President*, Dr. G. Mendizabal, of Orizaba, Mexico; *Secretary*, Dr. Irving A. Watson, Concord, N. H.; *Treasurer*, Dr. Henry D. Holton, Brattleboro, Vt. *Place of Meeting*—Denver, Col., the date to be decided upon by the Executive Committee.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXV. SATURDAY, OCTOBER 20, 1894. NO. 16.

ORIGINAL ARTICLES.

THE TREATMENT OF CHRONIC OÖPHORITIS BY LOCALIZED ELECTRICITY.[1]

BY EDWARD SANDERS, M.D.,
OF NEW YORK.

IN no branch of medicine or surgery does fashion govern our actions and modes of treatment more than in gynecology. Theory after theory, method after method of cure have from time to time been introduced with a great flourish, and, having the glamor of a great name to guarantee their power, have for a while taken a firm hold upon our affections, until some other and perchance better measure has pushed its predecessor aside, only in time to suffer a similar fate. Each, however, has added something to the total of our general knowledge, and assisted us somewhat toward reaching the goal for which we are all striving—perfection in diagnosis and treatment, the reduction, if such be possible, of medicine to an exact science. Thus we have had Bennett with his inflammatory theory; all genital ailments in the female, according to him being dependent upon inflammation of the uterus, which was to be combated vigorously by caustic applications. This for a while prevailed, and every physician wielded his speculum and his little stick of silver nitrate. Then came Graily Hewitt and his assertion that all depended upon uterine displacements; and pessaries, big and little, round and square, thick and thin, and of almost inconceivable shapes, were forced into the vagina, and the average female trotted about encumbered like a pack-mule, only her load was carried not without but within, there to do its best or worst unseen. Reaction, however, set in, though still to-day pessaries are used rather indiscriminately. Then came Tilt, with his ovarian theory; but this influenced practice but little at the time, though at present there seems to have been a revival of it. Following this we had Marion Sims, with his operative craze, and this has gone on growing and growing almost up to the present day, until it has become a very serious matter for a woman to consult a gynecologist, whether urban or suburban, for fear that the verdict may be, "out with your ovaries," or some other form of operative interference. But, thank the good Spirit that watches over us poor physicians, the reaction has set in at last, wiser counsels are beginning to prevail, and from time to time a voice, feeble though it be, is raised, and we hear protests against indiscriminate and needless operations. Like its predecessors, the operative method will take its proper place, and those only will be submitted to cutting in whom the indications justify such interference.

We are now entering upon a new phase in gynecology; in fact the road is already long behind us, though considerable ground yet remains to be covered. That mysterious yet extremely manageable force, electricity, which the laity so dread, and which we physicians so little understand, is rapidly taking its place among the active agents employed to combat female ailments, and all around us we hear praise or blame, one staking his all on electricity, another maintaining its absolute uselessness. Between these widely opposed factions it is our duty as unbiased judges to learn the truth, and thus determine the proper standing of electricity. Electricity as a curative agent in gynecology is not a new thing, but up to within a comparatively short period, even as late as 1884, it was used in such an irregular, unscientific, and erratic manner that all deductions based on such use were absolutely worthless from a practical point of view. Uniformity of application was an unknown thing, and as regards dosage, means were not at hand to measure the amount given, the number of cells determining in an uncertain and unreliable way the current-strength, the poles being used without any knowledge of their special actions; while such batteries as were to be obtained were crude and extremely uncertain in action, having more humors than a spoiled child. All this is now changed, cells are being steadily perfected, so that they can be depended upon to work in a definite way when work is required, the results of weak and strong currents are gradually being made known to us, the different effects of the individual poles are matters which now can be positively foretold, while instruments for accurate measurement and the gradual turning on or off of the current are at the command of all.

It has been my privilege during quite a number of years to have carefully investigated the various applications of electricity in gynecology, and, although my applications now amount to a very large number in the treatment of the various genital

[1] Read at the Tenth Annual Meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn on May 22, 1894.

affections in the female, in no one of them have I found this agent more useful than the one we are now about to consider.

As a clinical entity chronic oöphoritis is of comparatively frequent occurrence, more so, in fact, than is generally supposed, though pathologically its existence is somewhat more often made evident by changes discoverable upon the post-mortem table alone, changes which during life were unsuspected. Thus it is probable that fully 2 per cent. is the margin between clinical and pathologic diagnosis. During a series of years every gynecologic case presenting itself to me had the ovaries carefully interrogated, even when there were no symptoms referable to these organs, and among 5262 such cases of genital disease 289, or 5½ per cent., were found suffering from the disease in question. Such cases were very rarely simple, although occasionally so, uncomplicated oöphritis being an exceedingly rare affection; but they were almost invariably conjoined with some other genital disease, endometritis most frequently, or some form of tubal disease. On the post-mortem table both Pollock and Hennig have found the malady in about 8 per cent. of all cases examined. We thus note, as before stated, that about 2 per cent. go undiagnosticated during life. Nor is this surprising when we remember the difficulties surrounding the examination of the ovaries. Every pain in the region of these organs does not necessarily mean their disease, nor does its absence indicate absolutely a healthy organ. I have seen a number of cases in which examination alone revealed the presence of advanced ovarian disease, there being nothing outside of physical examination pointing to the existing chronic oöphoritis. The diagnosis of disease of the pelvic organs, as we all know, even in the hands of the most expert, is often a very doubtful matter, which operation alone can clear up, and even then, after the offending organs are removed, the doubt can at times be solved by the microscope alone. Only a short time since I was present at a celiotomy, the right ovary and tube being removed by one of the most expert and well-known of New York's celiotomists, yet even after removal the diagnosis remained unmade. Before operation the case was supposed to be one of pyosalpinx, yet during and after removal absolutely no indication of pus could be found, the ovary itself being perfectly normal, while a number of small communicating cysts were found in the broad ligament beneath the tube, which the operator thought might possibly be the remains of an old ruptured extra-uterine pregnancy, but decided to await the results of microscopic examination before expressing a positive opinion.

Considering then about 6 per cent as the detectable frequency of chronic oöphoritis, making the disease a comparatively frequent one, the important question arises, the diagnosis being accurately made, What shall we do in the way of cure? Up to within a comparatively short period but two methods were available, the relatively mild medical measures or the radical one of the knife. Of late, however, a third method claims our attention—disputing the palm with surgery—electricity, whether in the form of the direct or constant current, galvanism, or the indirect or interrupted current, faradism.

A new measure, before it can lay any claim to recognition, must have certain advantages over the older ones, and must be positive, capable of proof and easy of demonstration. If we have an old ruin which we are desirious of replacing by a more modern and stable building, we would not proceed to build directly upon the old, but rather would first remove it to give place to a newer and a better structure, using, perhaps, such parts of the old as are still of value. Now, I do not mean to say that either medicine or surgery are ruins as far as chronic oöphoritis is concerned, but what is claimed is that in a large number of cases the former means are absolutely useless, while a resort to the latter will be found unnecessary after a fair, sufficient and unbiased trial of the agent here recommended.

Medical measures alone against this disease, it can easily be shown, are almost valueless. In recent cases they may succeed sometimes, in old-standing ones absolute failure is almost always the rule.

Such has been the experience of most who have written upon the subject, and such has been mine after many trials of many and diverse agents. "Now a few words on the treatment," says J. Matthews Duncan, than whom there has seldom been a closer and more accurate observer, speaking of this very disease, "and I begin by telling you that you will find a great many cases to be chronic, and this is almost a synonym for incurable. I advise you, indeed, in many cases which resist a properly conducted treatment, to give up the attempt at cure. You will only bother your patient, make her a valetudinarian, and do her harm by further persistence in attempting to cure a disease which proper treatment has failed to remove." Goodell, another acute observer, remarks: "Very little can be said as to the medical treatment of disease of the appendages. It has been dogmatically stated that no treatment other than surgical can be of any relief, yet we are forced to admit that the treatment by drugs and local applications is usually unavailing, although this is due in part to the fact that we seldom see these cases early enough in the disease." Others have expressed similar opinions, and further clinical experience but proves such to be true. We may sometimes temporarily relieve by drugs, whether applied locally or administered internally, but a cure is but seldom obtained, and then only in what

may be termed recent sub-acute cases. Chronic oöphoritis, it is my firm belief, is rarely amenable to medical measures alone.

Medicine having failed, a resort to surgery was but natural. Surgery, being a radical curative measure, which entails a certain danger to life, must be radical in its results. It must cure quickly and thoroughly, and must not be followed by results which are as serious and distressing as the original disease for which it was employed. Oöphoritis in itself, complicated as it almost always is, carries but little danger to life with it, its complications alone constituting its dangerous elements, and even then pus-tubes and ovarian abscess being the only ones that make it dangerous to life. Hence, abscess aside, if surgery does not do what it claims to do, with minimum risks and maximum benefits, it should be set aside for a safer if only equally beneficial measure. That surgery frequently does not do what it claims to do I hope here to show.

1. The operation of salpingo-oöphorectomy is dangerous to life. Take the most skilful specialists, and their operations will show a certain death-rate, the very best and confessedly a remarkable one not falling below 3 per cent; the majority having a mortality decidedly higher than this. True, many of these operations are for diseases of the tubes; but as in both cases the manipulations, methods and technique are the same, while the two forms of disease are usually conjoined, no wide variation in mortality is probable, whether the operation be directly for oöphoritis or for salpingitis. Oöphoritis, although generally complicated, is, as before stated, but rarely dangerous to life, the large majority of its complications, as evidenced by my experience in 250 cases, residing in the uterus itself in about 90 per cent., while the tubes were involved in only about 15 per cent. of all cases, excluding instances of catarrhal salpingitis. The only truly dangerous complication is distention of the tubes, especially when due to pus, and this condition is in my experience found in only about 8 per cent. of all examples of oöphoritis. Considering all cases, no matter what the complication, we may safely conclude that fully 90 per cent. of all instances of chronic oöphoritis carry absolutely no danger to life with them, but simply entail suffering and chronic invalidism. From this point of view, save only as regards coexisting pus-tubes and ovarian abscess, the necessity of a resort to surgery, therefore, must be looked upon as more than doubtful. To subject a patient to the risk of losing her life by operation when life is not endangered by the disease itself is not right, either in logic or in ethics, except, perhaps, only when all other measures have failed and to live on, suffering, has become unbearable. It is not enough to have tried medical measures alone, for these, as we have already shown, most often fail. The agent here recommended should be given a fair trial also, and if this be done the probabilities are that the knife will not be needed, except in a rather small number of cases.

It is to be understood that I am speaking only of cases of chronic oöphoritis without complicating pyosalpinx or other abscesses, the presence of pus in the pelvis being to me always and invariably a contra-indication to the use of electricity in the treatment of any form of pelvic disease, all other complications, excepting acute inflammation here, interfering in no way with the use of this agent. Apropos of the foregoing, I can do no better than quote the following, by so able, conservative, careful, and conscientious an observer as Goodell: "The death-rate from chronic diseases of the appendages is greatly overrated, so much so that, in my opinion, more deaths result from the operation of removing the tubes and ovaries in the hands of even the most successful gynecologist than from the disease itself." Only a short time since I read the following by Dr. Reamy, of Cincinnati (in the *American Journal of Obstetrics and Diseases of Women*, April, 1894, p. 525):

> In forty years I have not seen five cases of death directly traceable to ruptured pus-tubes. And I doubt if the gentleman's experience has been different. I will go further, and make the statement, the truth of which cannot be controverted by the facts, viz., that in the gentleman's own practice during the last five years more women have died after he has operated upon them for the removal of diseased tubes and ovaries, as a result of the operation, than have died among an equal number of women presenting the same symptoms of pus-tubes and pus-ovaries, in the same community, and who were not operated on at all. In making this statement I make no reflection upon the gentleman's operative skill. On the contrary, I assert that the same comparison will hold true of my own work or that of any other gentleman present. It is a principle and the exhibition of clinical truth that I seek.

Comment upon such statements from gynecologists of such large experience is unnecessary.

2. Operators themselves are becoming dissatisfied with the results. Emmet believes that the value of the operation of oöphorectomy, meaning thereby removal of tube and ovary, is very much more limited than Tait, its author, would have us believe. Lusk writes: "The more the question is studied the more clear it becomes that the loss of her ovaries does make a difference to a woman. It is time to echo in this country Doléris' cry in France: 'Too many useless mutilations; not enough conservative gynecology.'" The late Dr. C. C. Lee was convinced that something must be radically wrong, and that an evident necessity existed for the clearer demarcation of cases appropriate and inappropriate for operation. Doléris believes that eight-tenths of the women operated upon have submitted needlessly to mutilation. Having the best of opportunities

for seeing a large number of gynecologic cases, Doléris had come to believe that conservative treatment was usually more successful than the radical operation in the cure of pelvic inflammations. "The latter," he writes, "may be justifiable for myoma and encysted abscess of the tubes, but when constantly undertaken for follicular ovaritis, catarrhal salpingitis, for pelvic neuralgia, and real or pseudo-hysteria, the subject will bear a little investigation." Mundé, in a paper on the "Conservative Treatment of Salpingitis," remarks: "I believe the time has come when it is well for those of us who are doing abdominal work habitually, and as a matter of our almost daily routine, to take the field against the hasty and habitual removal of the uterine appendages simply because they happen to be more or less diseased."

Thus I might go on quoting writer after writer, all to the same effect, but of what use multiplying complaints when the fact is patent that operators themselves have become dissatisfied. Of late years quite a large number of papers have appeared advocating conservatism, both in the proper selection of cases, as well as in the frequency and plan of operation; and the names of Lusk, Mundé, Polk, and Goodell at home, and Doléris, Pozzi, and Martin abroad but emphasize these pleas for greater care and circumspection. All these cries for conservatism only indicate the dissatisfaction with the results obtained following oöphorectomy. If the masters complain, we ordinary mortals must bow the head in assent.

3. The results are not as radical as the operation. Even the surgeons, as we have already indicated, admit this, though claiming better results than facts would seem to warrant. Thus Skene Keith reports among 23 operations, 19 cures, 2 failures, and 2 instances of improvement only. Keppler in 46 operations met with 39 cures. Boldt in 112 operations had 58 cures. 10 failures, 24 in which improvement only was obtained, and 11 that were either not heard from or in which insufficient time had elapsed to note results; besides these he had 8 deaths. Dr. John Williams maintained, and he was not contradicted, that "in so far as he could gather from the most reliable statistics, about 30 per cent. of patients from whom diseased appendages were removed were cured by operation, many more were benefited and cured by time and other treatment, while the rest continued to suffer. Doran observes that oöphorectomy for chronic disease of the appendages, is, as a rule, followed by speedy convalescence; but, unfortunately, a permanent cure is not so frequent, while in a considerable minority the pains which preceded the operation continue. One of the latest authoritative expressions, from the point of view of the specialist, is that of Dr. Howard A. Kelly in Hare's *System of Therapeutics* (1892, vol. iii, p. 814), which reads as follows, speaking of operations for ovaritis and salpingitis: "Cases which recover promptly from the operation may even continue to suffer just as before; and under the most favorable circumstances the patient goes through a prolonged convalescence, and if she makes a perfect recovery she is usually a year in reaching full health."

The late Dr. C. C. Lee, a careful observer, made it a point to keep track of his operated patients as long as possible, so as to note ultimate effects. Thus he collected 26 of such cases, having kept them under observation for a long time, with the following results: 15 were completely or comparatively successful, 7 were only partially benefited, while 4 were absolute failures. The beneficial effects of the operation, however, only followed after a considerable period of time, the pain persisting often for one or two years to a greater or lesser degree, absolute relief becoming evident only after considerable time had elapsed. In 16 instances only did this distressing symptom entirely disappear after one or more years of further suffering, in 8 instances the relief was never more than partial, while in 2 others no change at all was noted. In 21 of these 26 cases there was some form of oöphoritis or ovarian descent present, and considering pain as the pivotal symptom, in 11 only was the cure in these cases complete; in the other 10 only partial benefit being obtained. Such results as the foregoing certainly do not speak in very flattering terms in favor of such a radical operation as oöphorectomy. To endanger life without corresponding great benefit as the result of such risks incurred is not a very alluring commentary upon the wisdom and conservatism of celiotomists.

4. There are certain after-effects following removal of the appendages which entail as much suffering and danger upon the patient as the disease for which the operation was originally undertaken, if not more.

The artificial menopause, which is thus brought about, is extremely slow in its completion, and is accompanied by much annoyance and suffering. This is a well-recognized fact to-day. Menstruation often persists for some time, either regularly or irregularly, even after absolute removal of both ovaries and tubes, occurring 8 times in 19 instances in my experience, carrying with it the continuance of all symptoms previously referable to that function. If the menopause be brought about, its slowness of appearance but prolongs the flushings, the sweatings, the confusion of ideas, the headaches, the sleeplessness, and the other hundred-and-one petty annoyances that so commonly accompany the physiologic establishment of this change, only intensified and prolonged by its artificial production.

Such is the opinion of Goodell, and also of Hegar, who says that "the artificial menopause induced by the operation is often attended with more serious complications than those which are not rarely observed in the natural change of life." (*Brit. Med. Journal*, December, 1886, p. 1280.) Melancholia and even absolute insanity are not uncommon, more often, apparently, than after other operations. Glavecke, as quoted by Goodell, declares that "in almost all cases the mind becomes more or less affected, and not infrequently melancholia results." In fact he noted actual melancholia in 11 of 33 cases of which he was able to obtain accurate information; while Lee observed depression in 9 of the 26 cases of which he was able to obtain subsequent records.

The sexual sense is often abolished, while dyspareunia either persists if previously present, or may even be instituted by the operation, as I have seen. This loss of desire was formerly maintained not to occur, the reverse being claimed, but further experience has shown that with the removal of the ovaries, the desire for sexual congress is often gradually lost, entailing much unhappiness and conjugal dissatisfaction. Besides, the ability to procreate is forever gone, and in several instances in my experience this has led to the abandonment of the wife by the husband. "My own experience," says Goodell, "would lead me to the conclusion that in the majority of women who have been castrated the sexual impulse soon abates in intensity, much sooner than after a natural menopause, and that in many cases it wholly disappears." Zweifel has found, as the result of the examination of 26 cases, that desire was lost in 3, weakened in 3, unchanged in 10, while it had never existed in 10 others. Lee also found the sexual appetite diminished in 3 of 11 cases. That is, in about one-third of all instances of salpingo-oöphorectomy the sexual appetite was more or less affected unfavorably.

Intestinal obstruction due to constricting bands occasionally occurs. Dr. Carl Beck has met with two such cases, and claims to know of a half a dozen similar ones. Operation here becomes imperative, and deaths are not uncommon.

Abdominal hernia is another sequel to the operation that sometimes occurs, involving the danger of strangulation and death, and either requiring the wearing of a truss or necessitating the recourse to a second operation for its cure.

Fistulæ, either simple or fecal, sometimes follow, constituting a source of great annoyance and discomfort, and making life more miserable than the original disease, and usually also calling for a second resort to surgery.

Within the pelvis many changes causing distressing symptoms may result from the operation, such as adhesions between bowel and uterus, or uterus and bladder, or uterus and the other surrounding parts, the effects of a pelvic peritonitis consecutive to the operation. Symptoms arising from such adhesions are unusually distressing and persistent, and almost impossible of relief.

During a number of years I have personally met with, interrogated, and carefully examined thirty-one cases of oöphorectomy performed by some of the most skilful operators in New York City, the results in almost every case being not particularly flattering to the operator; the intervals intervening between operation and examination varying from two months to seven-and-a-half years, the average interval being one-and-a-half years. Of these thirty-one cases only two may be considered to have been cured by surgery. The other twenty-nine continue to suffer, some less than formerly, others as bad as ever, while still others are, if anything, worse. Thus, considering pain as one of the deciding symptoms, and it is usually this that brings the patient to the surgeon, in only seven was it absent, once it was described as being diminished in intensity, five times unchanged, five times as still "considerable," nine times as still great, and four times as increased; in one of these last instances the patient describing her sufferings as "terrible." A careful analysis of these thirty-one cases shows that in a few only was benefit actually obtained, while in almost all of them but little or nothing was practically accomplished; some, in fact, being really made worse. Thus, in nineteen instances in which both ovaries were removed menstruation persisted in three for a short time, finally to disappear entirely; while in seven others it had continued up to the time of coming under observation; in four irregularly, in two regularly, and in one it was too frequent and very profuse. When one ovary only was removed menstruation persisted in all, regularly in seven, irregularly in three, and too often in two instances. Four times was dysmenorrhea complained of, two of those in whom but one ovary was extirpated describing as intense their sufferings at the time of the flow.

Pain, either pelvic, abdominal, or lumbar, had continued in all but seven cases. Sometimes diminished, though usually unchanged, it was in some instances described as aggravated; in fact, in one case the patient maintained that it had been instituted by the operation. Benefit in some cases followed quickly, but was only temporary, and with time the pain recurred as badly as or even worse than before.

Nervous symptoms closely approximating those indicative of the physiologic menopause were present in thirteen of the nineteen cases wherein both ovaries were removed, while observed in only four of the twelve instances of removal of one ovary. These were persistent during a long period of time,

showing but little evidence of abatement, and were the source of extreme suffering, both mental and physical, rendering life miserable and a burden both during waking and sleeping hours. Hysteria, sometimes of a severe type, existed in seven cases; while headaches were bitterly complained of in as many as eight instances. Tremblings, palpitations, flashes of heat, chills, flushings, vertigo, nausea, vomiting, frequent urination, retention of urine, sleeplessness, thirst, free perspiration, distention of the abdomen, constitute but a partial list of the symptoms of which these women bitterly complained. Two suffered from confusion of ideas, two from great excitability, while one stated that at times she acted as if insane, so her friends told her. One suffered from frequent epistaxis following the operation, while in five painful defecation, indicating rectal involvement, was noted, in one the pain being so intense that evacuation of the bowel was avoided as much as possible. The state of the sexual sense could not be determined in the large majority of cases. In one patient sexual congress was indulged in apparently normally and without pain. However, in two others dyspareunia was described as present, being so severe in one as to absolutely interdict intercourse, while in the other it had made its appearance only following the operation. In one other case the atrophy and contraction of the vulval and vaginal parts had been so great as to prevent absolutely the introduction of the male organ, and this in a woman of but thirty years of age two years after the operation. In two others there was narrowing of the vagina noted, while in still another case there was considerable pain at the introitus in attempting the introduction of the examining finger.

Abdominal hernia was met with in two cases.

Now as regards the condition of the parts within the pelvis. The uterus itself was more or less firmly bound down in six cases, while in five others there was more or less shortening of either broad ligament, drawing the uterus to one or the other side. In eight instances exudative masses, indicating previous peritonitis with agglutination of parts, were found, and constituted a source of discomfort and pain. In sixteen instances there was pelvic sensitiveness more or less extreme; sometimes the slightest pressure by the examining finger inducing great pain. With such a condition of the internal parts as here described we can easily understand why such patients should suffer. New pathologic changes, most likely owing their origin to the operation, had replaced the original disease, giving rise to symptoms just as persistent and unbearable as those dependent upon the morbid changes for which the operation was undertaken and even more difficult of relief. Truly a deplorable issue after so much risk to life. A candid review of my cases compels the following verdict as regards cure, benefit in each instance being given to the operation when there was doubt. Twenty-two were in no way improved, seven were partially relieved, and but two were cured. Of course, it is not claimed that such cases are fairly indicative, since they are such as have continued to suffer following the employment of the knife, and have sought other advice than that of the surgeon who operated. They but go to show, however, how many such there are, for it is hardly likely that I alone have been fortunate or unfortunate enough to meet with so many. Others must have had a like experience, and the number of such cases going from dispensary to dispensary, from hospital to hospital, and from physician to physician, without relief, it is impossible to estimate. But their number must be very considerable.

Taking Dr. Lee's results as the standard, we have 58 per cent. of cures, 27 per cent. of relief, and 15 per cent. of absolute failures among those surviving the operation. In round numbers, about one-half of all cases submitted to the knife stand a chance of ultimate complete recovery. Nor is such a result obtained rapidly. Months and even years must intervene, amidst distress and suffering, before a cure is brought about. A radical measure like extirpation of ovaries and tubes should do its work quickly; its benefits should be marked and soon apparent. But, unfortunately, experience has shown that this is not so, and even the surgeons themselves are forced to admit that their results are not obtained promptly and are not up to their expectations. The surgery which removes diseased ovaries and tubes so skilfully and with such comparative safety may indeed be brilliant, but the results are hardly worthy of such brilliancy. It is the old story of the hare and the tortoise, somewhat altered and adapted. The surgeon is the hare who quickly removes the offending organs and then slumbers, considering the race won, the cure wrought; while the cure, the tortoise, plods on slowly. He may reach the goal of recovery ultimately, or he, too, may pause by the way.

It is not claimed that surgery should never be resorted to for the relief of chronic oöphoritis. Far from it. In properly selected cases, when other measures, persistently and intelligently applied, have failed, or when we are sure of the presence of pus, it constitutes the only measure of hope for the patient.

If, therefore, medicine offers no hope, and surgery is only to be considered the court of final resort, and is to be restricted to a smaller field than it at present fills, what is there to take the place of these agencies in the combating of so comparatively common a disease as chronic oöphoritis? I unhesitatingly answer, Electricity, whether the primary or

the secondary current. He who recommends such an agent, such a force as this, in the treatment of a disease like chronic oöphoritis, is almost sure to draw down upon himself the wrath of the gods, the gods of celiotomy, who have come to claim this field as their very own. Electricity is to the gynecologic surgeon what the red rag is to the bull. You praise it before him, and his ire is aroused, and his mental horns, ever ready to strike a blow for his specialty, whether with or without reason, are lowered, and the poor champion of electricity is supposed to be thrown to the ground and mangled beyond the hope of redemption. Nevertheless, truth cannot be crushed by mere words, even by those of a celiotomist, and that electricity is of immense benefit in the management of chronic oöphoritis it shall be my pleasure to show.

(To be concluded.)

THE SPECIFIC CURE OF DIPHTHERIA BY ANTITOXIN.[1]

By FRANK J. THORNBURY, M.D.,
DEMONSTRATOR OF BACTERIOLOGY, UNIVERSITY OF BUFFALO, N. Y.

To Brieger we are indebted for much of our knowledge regarding bacterial ptomaïns, but Behring seems to have been the leader in the recent researches regarding the feasibility of prophylaxis, immunization, and the specific cure of infectious diseases by use of the antitoxins of the blood-serum. Much of this work is comprised in his monograms upon *Blood-serum Therapy* and *Diphtheria*, respectively.

It may be of interest to inquire into the probable nature of the germicidal, antitoxic or immunizing substances which are contained in the blood-serum in association with or subsequent to the invasion of the system by certain acute infectious diseases. The Klemperer brothers, who have contributed so much on the immunization of animals against pneumonia, and have succeeded in preserving various species, absolutely refractory to this disease for long intervals, believe that the antidotal agents referred to are albumins; Halliburton and others regard them as globulins; Gamaleia characterizes them as nucleo-albumins; Victor Vaughan and McClintock, in our country, who claim to have isolated this germicidal constituent of the blood-serum, say it is a nuclein. Behring seems to incline toward its proteid nature, and states that its albuminoid character is doubtful on account of the demonstration of Ducleaux regarding the constitution of these latter substances. Lœffler, Yersin, and others, also believe that the substance in many instances, as in the case of diphtheria, is a diastase or ferment, the important argument being that it is soluble in alcohol. Brieger and Frænkel have defined the diphtheria-toxin as a tox-albumin.

The precise mode of action of the immunizing substances is still *sub judice*, but, according to Behring, they perform their function in one of the following ways:

1. By destroying the living microörganisms.
2. By inhibiting their growth.
3. By depriving them of their power to generate toxic products.
4. By destroying the poisons produced by the germs.
5. By increasing the resistance of the central organs or the cells against the poisons of the bacteria.

In regard to the source of the germicidal agents of the blood-serum produced in the course of the infectious disease, Guitéras and others believe that they are the products of the cells of the membranes, especially the serous membranes, and that they are held in suspension by the blood-serum. Hankin, in a late dissertation, proposes that these antitoxins may be a special secretion of the eosinophile granules of the blood. At any rate, we know that there remains in the system, after an attack of an infectious disease, as a result of the expenditure of the energy of the microörganisms producing the disease upon the secretions and tissue-cells, complex and as yet undetermined compounds, which protect the individual to a greater or less degree against future invasion, and which if properly extracted, may be appropriated in the treatment or cure of the corresponding disease, or in conferring immunity upon such as are susceptible.

The pneumonia-coccus produces a pneumotoxin, the presence of which in the body causes great elevation of temperature, and the subsequent elaboration from the body-cells of a substance antidotal to its action—anti-pneumotoxin. When the anti-pneumotoxin is produced in sufficient quantity to neutralize the pneumotoxin the characteristic crisis of pneumonia occurs, followed by convalescence.

Experimental injection of the pneumotoxin causes the same elevation of temperature as occurs in the natural course of the disease. The same may be said with reference to use of the toxins of tetanus, diphtheria, anthrax, cholera, typhoid fever, and other disease-germs.

In animals prostrated by pneumotoxin, or in those suffering from pneumonia of ordinary origin, the injection of the blood-serum of a convalescent animal causes a rapid subsidence of the symptoms and fall of temperature—an artificial crisis. As intimated, immunity may also be conferred upon animals by the subcutaneous or intravenous injection of this substance, as it may also be by the subcutaneous or intravenous administration of filtered bouillon-cultures of the germ which produces pneumo-

[1] Read before the Buffalo Academy, September 18, 1894.

nia—the Frænkel-Weichselbaum diplococcus or the micrococcus lanceolatus. This immunity, made complete by the use of large doses, lasts for six months, during which time it may be transmitted to the offspring.

It would appear that in the presence of an infectious disease the body-cells and fluids are capable, when properly stimulated, of counteracting the process or contributing to recovery by elaborating an antitoxin which is antidotal to the preëxisting toxin. The blood-serum of animals convalescent from a disease in which toxins and antitoxins have been produced contains substances of therapeutic value. The injection of these substances in the acute stages of these diseases will modify their progress, or in some instances, as we shall see, completely stay them. In tetanus, Tizzoni and Cattani have precipitated an antitoxin from the blood of dogs, rabbits, and horses, which has proved curative in many cases reported from the Innsbruck Surgical Clinic. The last report from the Pasteur Institute in Paris shows a mortality of less than one-fourth of one per cent. in rabies by the use of a substance which Pasteur extracts from the spinal cord of animals inoculated with this disease, and attenuates by drying. We have here a specific, as now conceded by all scientists, and practically an absolute cure.

But it was more especially with reference to diphtheria that I was to address my remarks upon *Serum-therapy*.

The bacillus of diphtheria was discovered by Klebs in 1883, and was obtained in pure culture and its pathogenesis demonstrated by Lœffler in 1884. I will not go into the morphology of the organism further than to direct your attention to the cultures in different media which I present for inspection. I have also stained preparations of the germ under microscopes. A peculiarity which is worthy of notice is the great irregularities in form, which exist commonly in the same culture-medium, but more especially in unfavorable media. The organism takes the Lœffler methylene-blue stain best. For sections, the modified Weigert double fibrin stain of picrocarmin is most effectual. This germ has no spore and is facultative anaerobic, but thrives best in presence of oxygen. The most favorable culture-medium for it is blood-serum with bouillon containing one per cent. each of peptone and grape-sugar. Upon potato the growth of the diphtheria-bacillus is entirely invisible or indicated only by a delicate glaze after the lapse of a number of days. Milk, even at a comparatively low temperature, 20° C., is a favorable medium for the growth of this organism, and we may infer that the latter fluid can act as the source of transmission of diphtheria.

The diphtheria-bacillus, unlike the typhoid and cholera bacteria, resists dryness for months, and it may be found in the throat and be capable of conveying diphtheria for three weeks after the onset of an attack of this disease. It is a very recently revealed fact that individuals may have this germ in their mouths and convey it to others, infecting them with diphtheria, without having the disease themselves. It was shown in discussion upon the subject at the recent Congress of American Physicians in Washington that contamination of the air by sewer gas is very potent in the occurrence of individual cases and the dissemination of diphtheria.

The thermal death-point of this bacillus is 58° C. In the vast majority of instances (it has been said always), the bacilli are only found at the point of inoculation, and the symptoms are often serious consequences; the paralyses, etc., are due to the absorption of the ptomaïn product which is one of the most deadly poisons that we know in either the mineral or vegetable kingdom. Recently a case has been observed in which the Klebs-Lœffler bacillus of diphtheria was found in the blood and in the viscera after death. The case was one of malignant type and occurred in a child in which the membrane had extended to the bronchi. The patient had been tracheotomized.

One-eighth of a cubic centimeter of an old alkaline bouillon-culture which has taken on greatly increased virulence will suffice to destroy a guinea-pig in a short time, when injected subcutaneously. The toxic potency of the diphtheria-ptomaïn is reduced by low temperatures and completely destroyed by boiling. This toxin may be precipitated from pure cultures by alcohol. It appears as a whitish substance soluble in water. One to two decigrams will destroy rabbits. The deadly poison causes local edema and necrosis.

More than a year ago, Brieger and Frænkel succeeded in rendering guinea-pigs immune to virulent cultures of the diphtheria-bacillus by attenuating the virus through age and exposure to heat. From sixty to seventy degrees was the temperature used, and this may be said to be the first reliable means to obtain immunity in animals to diphtheria. Later, a number of methods were employed, as the addition to the virulent cultures of chemical agents, such as iodin trichlorid, the virus being attenuated; and the use of the metabolites produced by the bacilli in the living organism, the animals to be immunized being treated with the juices from diphtheria-diseased animals.

A fourth method consisted in inoculating animals with the active virus and then counteracting the effect by therapeutic agents. The most reliable of the foregoing methods was the use of iodin trichlorid, but good results were obtained in a similar way by the employment of chlorid of gold and

sodium. Behring immunized guinea-pigs and rabbits by a preliminary course of treatment with hydrogen dioxid. A very effectual means of immunization is by injection of the attenuated toxin, and then gradually increasing doses of the non-modified toxin or pure cultures of the bacillus. Animals may thus be rendered highly refractory to tetanus as well as diphtheria.

It will be seen from the foregoing various methods that the keynote to immunity is the attenuation of the virus. The results are dependent, first, upon the occurrence of a reaction unlike that which follows the use of tuberculin, and, secondly, upon the absolute quantity of toxin employed. In entire absence of reaction no immunity follows, and the latter is more pronounced, the more severe, the more protracted the reaction. Behring rendered forty sheep refractory to diphtheria by successfully inoculating them with increasing doses of attenuated virus, until no elevation of temperature followed. Virulent living cultures or toxic media then introduced into the animals produced no effect. The immunity is the result of the development in the blood of an antitoxin which has the power of neutralizing the diphtheric virus. This blood may be withdrawn and utilized as a therapeutic agent in the prevention and cure of cases of diphtheria. An immunized sheep will, when 50 cc. of its serum are withdrawn every month, furnish two liters and a half per year, which, according to Behring's calculations, will suffice to immunize 5000 children or cure 200 when applied shortly after infection.

The duration of the immunity is in direct relation to the quantity of serum injected, and as stated with reference to pneumonia, the condition is transmitted from parent to offspring. The chemic composition of the diphtheric antitoxin, like similar products of the germs of other infectious diseases which have been isolated, is still not clearly understood, but its ability to prevent and remove the effects of the living bacilli in the organism is demonstrated by a large amount of animal-experimentation. The addition of 5 per cent. carbolic acid serves well for preserving the curative substance contained in blood-serum. It being an organic substance, it would naturally tend to decompose. The serum, which is the essential medium of the curative substance, is separated from the blood by coagulation.

As already stated a much less quantity is required to immunize than to cure an animal. This disproportion is vastly less marked, however, in the case of diphtheria than in tetanus, in which from one-thousand to one-million times more serum are required to effect a cure than to produce immunity. Intra-peritoneal is a more effectual means than subcutaneous administration, but harmless. For guinea-pigs the ratio of the curative serum required is to the body-weight as 1 : 1000, when treatment is begun immediately after infection, and 1 : 400 after the appearance of distinct symptoms. According to this rule a child weighing 20 kilos would require 50 c.c. of the serum at the beginning of the disease. The protective substance contained in the diphtheric serum is an absolute specific, *i. e.*, its action is confined exclusively to the diphtheria-germs and their products; it has no effect whatever upon other organisms, and does not influence the body either favorably or unfavorably when diphtheria is not present. Therefore the remedy stands unique among our therapeutic agents, and while capable of great good in the sphere of its usefulness it is harmless outside of this scope. It counteracts the diphtheric process effectively, and even if applied in an amount one-thousand times greater than necessary to produce the desired action it would simply offer a more safe protection or cure as the case might be. But such reckless extravagance in its use is not likely to be practised, for we shall see that the production of a sufficient quantity of this valuable agent is, for the present at least, going to be our chief difficulty. In fact the remedy is not available at all in our own country at the present time.

I have stated that the action of the protective substance in the blood-serum was confined exclusively to the diphtheria-bacillus and its products. We can, therefore, not reasonably expect to relieve to any great extent or cure cases of mixed infection. Such is the type often assumed in diphtheria after several days, and this undoubtedly accounts for the reported failures attending the use of the curative serum in certain cases. In one instance no diphtheria-bacilli could be found post-mortem at all, but only streptococci. In another patient that had been tracheotomized the diphtheria-bacilli were found in the blood and visceral organs, and the child had been sick three days before being admitted to the hospital. This was a case of the malignant type referred to.

We must make an exception for septic cases of diphtheria. I mean cases in which the sepsis is due to germs other than the Klebs-Lœffler bacillus; against such germs or their products the antitoxin of diphtheria is powerless. It is not a cure-all, as Behring states. Septicemia or secondary infection complicating diphtheria may be effectively treated by potassium chlorate or iodoform.

The experiments of Aronson in isolating the protective substance of diphtheria from the blood-serum may be briefly recorded. He succeeded by his particular method in concentrating the curative material contained in 10 grams of the serum into 8 grams of solid powder. This dry substance produced one-hundred times the effect of the serum. It is white, soluble in water, but more soluble in

dilute alcoholic solutions, which furnish all the reactions of the proteins. Dried in vacuo at 40° C., the substance may be heated to 102° or 103° C. without losing its active properties. The body does not possess chemotaxis. From ten to one-hundred-fold the immunizing dose of this substance is sufficient for a cure; the possibilities for successful therapy therefore are much greater than in the case of tetanus, in which the dose to cure an animal amounts to from 1000 to 1,000,000 times that necessary to immunize it. The serum which was used in the treatment of the first cases of diphtheria in Berlin was obtained by Behring from highly immunized sheep. Injections were made preferably into the anterior wall of the chest, in the back, or extremities, with a 10 c.c. Koch syringe. The dose administered at one time varies from 5 to 20 grams, according to the severity of the illness. One-thousand-and-eighty-one cases of diphtheria treated in the Kaiser Friedrich Children's Hospital in Berlin since its establishment, by the ordinary methods of treatment heretofore in vogue, gave a mortality-rate of 38.9 per cent. Some statistics furnish 50 per cent. as the average mortality of true diphtheria in children. One series of thirty-two cases is on record from one of the Berlin clinics, in which only eleven of the patients survived the disease, a mortality rate of 65.6 per cent. The treatment of diphtheria by use of the specific antitoxin has recently been carried on quite extensively in the various clinics of Berlin. Of seventy-two cases treated on the first two days of the disease by the antitoxin all but two recovered. Statistics of this same clinic regarding the treatment of seventy-two cases by methods previously employed, showed that twenty-five patients had died—accordingly a mortality of 34.7 per cent. One-hundred-and-twenty-eight cases treated by antitoxin in various stages of the disease at the Kaiser Friedrich Hospital gave a mortality-rate of 13.2 per cent. It has been stated that the remedy must be used very early to prove curative. It has no injurious effects upon the heart or kidneys, nor upon the system in any way, as shown by observation of one-hundred-and-twenty-eight cases treated by Dr. Katz.

Out of more than 250 cases treated in this way at different stages of the disease 100 per cent. recovered when the inoculations were made within the first twenty-four hours; when made on the second day 97 per cent. recovered; on the third day, 87 per cent.; on the fourth day, 76 per cent.; on the fifth day, 57 per cent. By use of the antitoxin the development of diphtheria may be prevented in persons that have been exposed to the disease, and immunity conferred upon them, so that they can go among epidemics with impunity. If cases can be seen, then, and recognized as diphtheria in the first twenty-four, thirty-six, or even forty-eight hours, we have in the use of the antitoxin practically a specific, and the mortality-rate in this dreadful disease can be reduced almost to a minimum. After the first day or two the value of the method grows progressively less. We have in this the imperative necessity for the recognition of the disease very early if we will make use of the curative serum soon to be placed at our disposal, and thus restrict the ravages of diphtheria. How can this early recognition best be promoted and made certain in large municipalities? Simply by aid of our municipal health-authorities, as has been done in the city of New York, which now stands out as an example to the whole world. This disease is essentially, and for a long time has been, under the supervision of our municipal health-authorities, but the supervision must now be extended to the aid of individual physicians in immediate proof of whether a suspected case is or is not one of diphtheria. The evidence referred to can readily be afforded by an examination of the deposit in the throat for the Klebs-Lœffler bacillus. This is our only *absolute* means of diagnosis in the very early stages of the disease, when recognition for therapeutic reasons is now very important.

Such bacteriologic examination for this bacillus cannot be made by practising physicians, nor will circumstances always permit of having the examination made privately. But if the health-departments of our cities will take the matter up (and this should interest them as the most available means of preventing epidemic extension of diphtheria) and furnish physicians with the bacteriologic proof as soon as possible after a case has been reported, then this heretofore dreaded malady can be made as harmless as almost any disease with which we have to deal. The way in which the work is conducted by the Health-Department of New York is briefly as follows: In that city there are forty stations, mostly drug-stores, at which physicians can obtain culture-outfits, so-called, which consist of small wooden boxes, five inches long, two inches wide, and half an inch thick. These boxes contain two thick test-tubes, in one of which is placed a wire wrapped at one end with a small pledget of cotton. This serves as a swab. The other tube contains a small quantity of culture-media, the composition of which has been described (Lœffler's diphtheric blood-serum.)

When a physician has a case of suspected diphtheria he obtains one of these outfits from the station in his vicinity. They are placed at his disposal, free of charge, by the Health Department. The swab is passed gently over the membrane in the throat by the physician in charge, and then conveyed to the tube containing the medium for inoculation.

The tube is enclosed in the box, wrapped in

cotton, and sent to the Department of Bacteriology, or is taken up by the collectors who go to the stations every day. At the laboratory the necessary bacteriologic examination is made, and in from twelve to fourteen hours the physician is mailed a report of the character of the case, or he may receive it at noon the day following by telephone. He knows then whether the patient is suffering from *true* or *false* diphtheria. The culture-test and microscopic examination of stained slides easily decide the question. It has been estimated that 95 per cent. of physicians having cases of diphtheria have made use of this method. Of 5611 cases examined in New York in twelve months 3255, or 58 per cent. only, were *true* diphtheria, and 1540, or 27 per cent., were false forms of the disease.

With the cure for diphtheria which we have now at hand, the importance of this system in cities for the early recognition of this disease cannot be too highly praised, for it has been stated that it is essentially upon the early application of the antitoxin that the success of the agent depends. Even Koch himself has commended the system inaugurated for the examination and control of cases of diphtheria by Dr. Biggs, in New York, and the Congress of British Hygienists, which recently met in London, lauded it, and made arrangements for its adoption in many of the cities of England, after the instructions and account given them by Dr. Biggs, who was present at the Congress.

From thirty to fifty per cent. of the cases taken to the Willard Parker Hospital, in New York, as true diphtheria were shown by bacteriologic examination to be pseudo-diphtheria, a disease which has a mortality of only about 2 per cent., is non-infectious, and does not require isolation or disinfection. It can readily be seen that it is an enormous saving to the Department of Health to have the cases rightly diagnosticated at the start. This saving much more than counterbalances the expense of the bacteriologic investigation.

To return to the treatment of diphtheria by the antitoxin; it will be some time before the remedy can be produced in sufficient quantity to be available for us. Large animals, such as the sheep and cow, first have to be immunized by being put through a course of treatment which requires from four to six months. Their blood can then be drawn in moderate quantities at regular intervals, without affecting them unpleasantly, and this, representing the antitoxin, is used for the treatment of cases of diphtheria. It requires skilled bacteriologists to immunize the animals, and then it would be well to have had a special course in the Koch Institute for Infectious Diseases. The remedy will necessarily be somewhat expensive, on account of the long time required for its production, the special methods demanded, and the skill on the part of the operator. It has been stated that the antitoxin will cost at the rate of a dollar a dose, although I believe this is placing it rather too high. However, its use for the treatment of poor people in large cities will only be possible when the agent can be provided by the health-authorities. In immunizing animals the quantity of diphtheria-cultures injected is sufficient to kill about 500 animals of the same kind.

The protective substance is contained in the milk as well as in the blood-serum of goats and sheep which are immunized. Goats have been found to be especially well adapted to the immunizing experiments, by reason of their susceptibility to diphtheria and the exceptional retention of the high degrees of immunity which experience has shown it possible to produce in them. The toxins of diphtheria and the antitoxin neutralize one another outside of the body as well as in the test-tube, as shown by the observations of Behring and Kitasato. The quantities of antitoxin contained in the milk of goats, sheep, and cows is far less than that found in the blood of these animals when immunized, although this milk when used in cases of diphtheria will decidedly modify the diphtheric process. Products of a cow which Kossel recently immunized in the Veterinary Institute at Berlin were used successfully in the cure of diphtheric children. Even though the specific action of the antitoxin is most marked in the very early stages of diphtheria, it modifies noticeably the character and severity of the disease in its more advanced stages, and lowers the mortality-rate. Wounds after tracheotomy heal favorably as a rule, and grave cases of laryngeal diphtheria have been cured. Almost always after an injection of the remedy the temperature promptly falls, the pulse is lowered in frequency and improves in volume; the character of the respirations is improved also. The indications for a repetition of the dose are the course of the temperature and pulse and the local appearances. I believe erroneous impressions may have arisen from the reports already issued on account of the lack of proper discrimination as to the character of the cases and the time in which the remedy was used. It has been shown that diphtheria often has septic complications from the very start. We cannot expect that these cases can be cured by the antitoxin, which is a *specific*. In some of the 220 cases reported by Ehrlich, Kossel, and Wassermann, the possibility of recovery was almost precluded by reason of the advancement of the disease. Necropsy showed extension of the exudate far into the smaller bronchi in some cases, and multiple hepatized areas in the lungs, induced by streptococci and a streptococcus infection of the blood.

In other cases which they treated they did not

have enough of the serum to make a showing which did justice to the remedy. In still other instances the fatal termination ensued from complications like nephritis and pneumonia. Thirty were patients that had been tracheotomized. Of sixteen that had been tracheotomized in one hospital in Berlin only four died after the use of this remedy. In twenty-six other cases treated in this, the Elizabeth Hospital, the course was most favorable in every instance, notwithstanding many unfavorable prognoses having been made from the beginning. In a large number of the 220 cases treated recovery without the use of such a remedy as this seemed almost impossible. Other patients could have been saved if sufficient serum had been obtainable to give several doses. It is thought that the frequent occurrence of paralysis may be lessened or prevented by the early employment of the antitoxin. Ehrlich, Kossel, and Wassermann say that of their serum 100 units should be used, and that in severe and tracheotomized cases 400 units should be administered. The treatment is repeated on the same day or on the day following, according to the character of the symptoms. From four hundred to 1000 or 1500 units may be administered in all. No results correspondingly favorable have ever been obtained in the treatment of diphtheria, notwithstanding the use of this remedy in many cases in the late stages. In the early stages experimental and clinical evidence shows the antitoxin to be curative.

It may be of interest to give some further account of the physical properties of the diphtheric antitoxic serum as *latest* produced. It is a clear, colorless liquid, thick in consistency, quite viscid, and has what is described as a "carbolic" odor. A proportion of 0.2 per cent. trikresol is efficient in preserving its organic composition, as well as the carbolic acid previously referred to. Two firms in Berlin are at present producing antitoxin. The one product is the "Behring Ehrlich Heilserum" and the other is Aronson's. The two remedies vary only in strength, and are both effectual.

Of the former there are also two preparations. No. II is two-and-a-half times stronger than No. I. The latter is used in mild cases in children under ten years of age. A high degree of immunization of animals is necessary for the production of the stronger serum; therefore a constant supply cannot be guaranteed at present. This remedy is a very effectual curative agent in severe cases of diphtheria at any age, and the dose is 1.15 cc., which represents about 150 antitoxin-normals. The dose of Behring and Ehrlich's form No. I is 1 cc., which is equal to 60 antitoxin-normals.

Gentle massage is always advisable after a hypodermatic injection, and this is practised when antitoxin is introduced hypodermatically. Abscess-formation resulted only once in two hundred injections made at the Kaiser and Kaiserin Friedrich Hospital, Berlin. The usual dose which Aronson administered is from 5 to 10 cc. Ten cc. may be given in a very severe case. Here, as always in making hypodermatic injections, the syringe should first be sterilized, and this is best done by submerging it for five (5) minutes in and injecting through it boiling water. An erythematous eruption sometimes appears after antitoxin treatment, which subsides after a few days. Patients with laryngeal stenosis often rapidly recover, and malignant cases begin promptly to improve after an injection. For maintaining immunity by antitoxin, injections had better be repeated after three or four months. Ten cc. or 60 of Behring's antitoxin-normals suffice for immunity or for prophylaxis. Fifty cc. may be given, and if repeated do no harm. Aronson's serum, made at Schering's factory in Berlin, is twice as strong as other products which he has tried. Five grams of Aronson's serum are equivalent to 500 grains of that which was originally used by him. Dr. Louis Fischer, of New York, who has just returned after a course of study with Prof. Baginsky and Dr. Aronson in Berlin, has treated with antitoxin one child that was suffering from diphtheria, which is I believe the first case reported in which the antitoxin has been used in this country. The diagnosis of diphtheria was demonstrated bacteriologically (which is the only *absolute* method) and the symptoms of the disease were pronounced. Five cc. of Aronson's serum were administered, and the next day a marked improvement was noticeable. On the third day the greenish membrane had entirely disappeared. On the fourth day no symptoms of the disease remained, and on the sixth day the child was entirely well. A transitory albuminuria disappeared under the treatment.

Recently Dr. Katz, of Berlin, inoculated with antitoxin 72 children that had been exposed to diphtheria, and only eight of these developed the disease. The latter cases were of very mild form. Of 130 children inoculated by Dr. Aronson in families in which diphtheria had occurred, only eight cases developed. Dr. Behring states that even at the present time the mortality of diphtheria under treatment by antitoxin may be safely placed at 5 per cent. As regards dosage and age, further, the following rule may be formulated: Under two years, during the first two or three days, 2 to 3 cc. are given; from two to ten years of age, 5 cc. are administered; over ten years of age, 10 cc. Aside from its marked curative effect this is an ideal method of treatment as regards simplicity; the troublesome spraying and swabbing of the diphtheric patient's throat, which are not unattended with danger, and the frequent internal administration of drugs are dispensed with.

On the theory that the change from toxin to antitoxin is a chemic one, Surinow has attempted to produce properties in the serum of diseased animals similar to those possessed by the blood of animals which are immunized. Electrolysis was used for the purpose. By oxidation or reduction there resulted the production of antitoxin, and the same effect followed the application of electrolysis to diphtheric bouillon-cultures. Some successful experiments are recorded from the use of antitoxins thus produced. If this method proves reliable it will greatly simplify our means of obtaining the valued antitoxin, which is now expensive on account of the great length of time required to immunize animals.

The French have not been slow to profit by the researches of their German brethren. M. Roux reports 448 cases of diphtheria in children treated by the new method at the Hôpital des Enfants Malades in Paris during a period of six months ending July 28, 1894. The improvement in the death-rate attributable to treatment with the new remedy was over 27 per cent.

We have every reason to believe that diphtheria will now be made a harmless disease, and that in the blood-serum of immune animals we have a more simple and reliable means for the vaccination of children against diphtheria than is offered even by vaccine-virus for the prevention of smallpox.

NERVOUS AND MENTAL SYMPTOMS OF LATENT AND INTERMITTENT NEPHRITIS WITHOUT ALBUMINURIA.[1]

By LUDWIG BREMER, M.D.,
of St. Louis, Mo.

For years I have in my neurologic and psychiatric practice met with cases presenting localized or general troubles, whose origin and nature seemed to be obscure, and whose connection with renal lesions became apparent on examination of the urine, although the albuminuria, generally considered essential, was absent. A typical example may stand for quite a number of cases that have come under my observation in the course of years.

Several years ago I was called upon to examine into the mental condition of a gentleman past sixty, who had rather suddenly developed symptoms of mental aberration. After a few days of indefinite malaise he astonished his family by the assertion that he had seen a negro climb up a tree that stands in front of his house and peep through the window into his room. There were other statements of a similar absurd character, which he made with the positiveness of matters of fact. When I saw him, he conversed fluently and, as it seemed, rationally on ordinary everyday topics, but I found that he had lost his bearings as to time and space. Although in his own sleeping-room, he had a vague notion that he was away from home, and, to the great alarm of his family, he was uncertain about the season of the year, not to speak of the day of the week or the time of the day, of which he had completely lost all track.

Remembering several cases of nephritis in which the same mental phenomena had presented themselves, I made, after excluding alcoholism, a preliminary diagnosis of uremic intoxication. That this loss of the conception of time and space is a common symptom in alcoholic insanity, especially in some forms of alcoholic imbecility is, I think, a fact well known by all psychiaters of average experience.[1]

The urine was found to contain no albumin; its specific gravity was 1026; its color dark-brown; hyaline and granular casts were present in moderate amount. The man had had two attacks of Asiatic cholera—one in 1849, the other in 1866, which left him in an enfeebled condition from which he had never recovered. A diagnosis of chronic parenchymatous nephritis had been made by a physician in Germany, while the patient was in that country in search of health, ten years previously. Since then he seemed to have gotten along so well that this diagnosis had been forgotten by the family until revived by me.

The patient recovered completely, and although he has had several slight relapses, manifesting themselves chiefly as lumbago, great lassitude, sleeplessness, and intestinal disturbances, he is now practically well. I have no doubt that the disease dates back at least twenty-eight years—*i. e.*, to his second attack of cholera.

I gave a favorable prognosis, based on the outcome of a case that I had seen in consultation several years before, and in which, relying too much on what the microscope had taught me, I had given a very unfavorable opinion as to the outlook for the patient's life.

In this case there had been, after a few days of ailing, and a spasticity in the calves of the legs (a not unusual premonitory symptom of uremia), a

[1] Read before the Missouri State Medical Association, May 16, 1894, at Lebanon, Mo.

[1] The mild uremic delirium bears a close resemblance to the chronic alcoholic variety. There is the same blandness and suavity of manner, the quiet, rational conversation, which misleads the patient's friends, who pay him a flying visit, into the belief and assertion that there is nothing the matter with his mind. The whole picture, however, is changed as soon as the patient, in the midst of rational talk, makes the assertion, for instance, that he saw Mr. X. down town yesterday, when, as a matter of fact, he has been at his house for a month, or when he avers that to-morrow he will start for home.

fainting-spell, from which the patient awoke in a dazed condition. For two weeks the man did not recognize his friends or his surroundings. Apoplexy had been thought of by the attending physician. The presence of albumin in the urine had not been detected during the whole course of the disease; the amount of urine was about two-thirds of the normal, whilst the quantity of urea excreted during the twenty-four hours was fully up to the standard. There were present cylindroids, hyaline, granular, and epithelial casts, many leukocytes, and a varying amount of uric acid. There was no history of renal or vascular disturbance, and no dropsy.

In spite of my evil prognosis, this man recovered completely, and is to-day in possession of all his mental and physical faculties, although for months a slow and deliberative manner of speech and a sluggishness of the thinking-process was noticeable. Great and prolonged mental strain, the abuse of whiskey, and excessive card-playing at night were probably the exciting causes of this attack.

I have encountered the same microscopic findings, often including numerous leukocytes, the absence of albumin, dropsy and vascular disturbance, often a high specific gravity of the urine (up to 1030 and more) in quite a number of cases, presenting the most heterogeneous symptoms, and, at first sight, suggesting absolutely no renal affection. Edema was present in only one.

I will cite the case of a lady who, after a short period of catarrh of the trachea and bronchi and stomach, accompanied by intense headache, became suddenly partially aphasic. She was not only unable to give utterance to her thoughts, but she could not catch the meaning of what was said to her. There were illusions, hallucinations, as well as megalopsia, everything appearing to her unnaturally large. She has now recovered her mental faculties. Several days ago, almost a year after her aphasic attack, I examined her urine again. Instead of presenting a high specific gravity, casts and leukocytes, and an absence of albumin, I found a low specific gravity (1014), no casts, but the presence of albumin, a complete change from the former finding, with the disease no doubt still persisting. An attack of influenza occurring several years previously was probably the cause of the nephritis.

The same infection seemed to be at the bottom of what appeared like an obscure neurosis in a child of two-and-a-half years old. This patient had an attack of influenza when six months old. After an interval of over a year of apparent good health some gastric symptoms developed; at the same time she began to lose the use of her legs, which were extremely sensitive to touch. She could lie only in one position, on the right side, with the legs slightly adducted. Very large quantities of uric acid and almost every variety of casts, excepting blood and waxy casts were found in the urine, but no albumin. This is the only case of this class under my observation in which edema appeared. No marked improvement had taken place after three months of treatment.

Sometimes a trauma is responsible for the renal disease. I have seen a case of rapidly-developing tabes accompanied by parenchymatous nephritis following a fall from the second story on the nates. The patient died from the degenerative process of the posterior tracts spreading rapidly to the medulla oblongata. There were, post-mortem, the characteristic lesions of the posterior spinal tracts in connection with acute parenchymatous nephritis. In this case only slight traces of albumin could be demonstrated in the urine.

On the other hand, albumin was absent in another case that I saw in consultation a few weeks ago, in which mental dulness, hesitancy of speech, and general confusion were the predominant symptoms. The patient is forty-five years of age. When he recovered his senses he remembered that he had slipped whilst stepping on a banana-peel about a week before the head-symptoms set in, and that with a tremendous effort, and by going through a number of complicated movements, he succeeded in maintaining his equilibrium. A friend, who witnessed the occurrence, expressed his fears at the time that such an unnatural effort was bound to be followed by evil consequences. In this case the disease existed probably in a dormant state before the accident. The man was apparently healthy all his life.

I have seen two cases in which recovery took place that mimicked typhoid fever, with brown tongue, slow pulse, and great somnolence, apathy and mental obtundity. The non-existence of an epidemic of typhoid fever at the time constitutes negative evidence, while the presence of casts in the urine establishes the diagnosis.

Numbness of the hands and fingers, indisposition to work, a sense of pressure in the head, slow pulse, below 60, catarrhal conditions of the respiratory or digestive tract, rheumatic pains, neurasthenic symptoms, melancholia, and mania may be the clinical manifestations of nephritis.

In one case, in a woman of fifty, whose urine presented the characteristics already detailed, a facial neuralgia of a severe type, and lasting with slight intermissions and remissions for months, disappeared suddenly on the supervention of a maniacal attack. When this ceased, after a duration of two days, the neuralgia reappeared. At one epoch of the disease the neuralgia would alternate with attacks of profuse diarrhea, the diarrhea probably carrying off the toxic substances causing the neuralgia.

In quite a number of cases of the kind under

consideration I found rudimentary indications of the symptoms, such as impairment of the conception of time and space, sometimes coupled with a feeling of tension in all the muscles. This muscular spasticity is, I believe, one of the earliest symptoms of uremia. I have seen it in several cases of hydronephrosis due to stricture, prostatic enlargement and distention of the seminal vesicles. Such patients complain of impairment of memory and confusion of dates. Events that took place years ago appear as of recent date.

The prognosis in all of these cases of parenchymatous nephritis is not unfavorable. Quite the reverse, of course, obtains in cases of contracted kidney. Here, as a rule, the vascular and urinary symptoms are plain and readily made out. But in this form of nephritis latency or intermittence may deceive even the best diagnostician. The peculiar features of heart and pulse may be absent. Among a number of cases that have come under my observation I shall cite only one, a rather celebrated case in St. Louis insurance-circles. It was that of a physician, who, while riding in his buggy after nightfall, was, under mysterious circumstances, struck in the head by two small bullets. An operation for the extraction of the missiles, which had not penetrated the skull, was performed under chloroform, but the man died a couple of days later. Suicide by shooting and arsenical poisoning was talked of. The man had carried life-insurance of $80,000—much beyond his means—and most of the policies had been but recently issued. The kidneys were in an advanced state of chronic interstitial inflammation, with an enormous number of glomeruli obliterated. There were also a great many collapsed uriniferous tubules with thickened walls, characteristic of secondary shrinking in the course of chronic parenchymatous nephritis. The kidneys were a little smaller in size than normal.

The man had been strange and peculiar in his manner and actions for a year and more, and had been running from one insurance-office to another. The remarkable feature about his insurance-mania was that the beneficiary was a person (his wife) whom he detested. My conclusion was that this specimen of an insurance-crank suffered from uremic insanity (melancholia) when he applied so assiduously and extensively for insurance; that he had then a cirrhotic kidney, and that, being a nephritic, he died from the effects of the chloroform. The companies had to pay. He had passed the examinations of all the physicians. One, a diagnostician of great ability, found his urine normal, but advised the company against accepting him, on account of his mental symptoms. In spite of this they issued a policy of $10,000.

That arterio-capillary nephritis in an advanced state may exist in apparently strong and healthy men, in a latent state, occasioning no symptoms, until by hardship and exposure during a hunting or a fishing trip, for instance, the slumbering inflammatory process is relit and leads to a rapidly fatal result, was recently demonstrated by the death (from cirrhosis of the kidney) of the wealthiest man in this part of the country, who was of athletic muscular development and apparently in the best of health a short time before his death.

I cannot say anything special or new on the treatment of the class of cases considered in the foregoing remarks. It is, however, worthy of mention that elaterium or elaterin given so as to produce watery stools, alternated with mercurial mass, has generally the effect of clearing up the sensorium of nephritic patients presenting mental symptoms. The rest of the treatment is that generally adopted by the profession. Dr. Stewart[1] relates that he has given thyroid extract with good effect. I think this agent worth trying, and am at present employing it in a case in point, apparently with benefit. I doubt, however, if experience warrants the creation of a third form of chronic (non-albuminous) nephritis closely resembling neither the parenchymatous nor the interstitial variety. It is improbable that an anatomic substratum of a definite character and distinct from the two recognized varieties is underlying the cases here treated of. It is well-known that in some cases it is very difficult, if not impossible, to make an anatomic diagnosis in a case of chronically inflamed kidney, the epithelial and connective-tissue elements being equally involved, or nearly so. Again, the clinical symptoms may change from those of one form to those of another (generally from those attending the chronic parenchymatous to those of the cirrhotic kidney), as was observed in the case related in which aphasic symptoms appeared. Probably we have to look for conditions similar to those found in the kidneys of the physician referred to. A plausible explanation of the absence of albumin does not exist.

The presence of the normal amount of urea in the cases presenting uremic symptoms points to a cause other than the retention of urea. Brown-Séquard's theory of an internal renal secretion whose admixture with the blood is as necessary as is that of the thyroid gland to the healthy function of the nervous system seems not impossible.

The most remarkable feature about the uremic disturbances are their localizing tendencies, attacking either the brain and the special convolutions of that organ (aphasia, localized paralysis) or the spinal cord, a peripheral nerve, etc. This, however, is

[1] "Further Remarks on the Occurrence of a Form of Non-albuminous Nephritis other than Typical Fibroid Kidney." THE MEDICAL NEWS, April 14, 1894.

not without analogy in toxic diseases (poisoning by lead, mercury, strychnin, etc.).

I have encountered three cases of a third form of non-albuminuric nephritis, alternating with diabetes and likewise producing a variety of incongruous and inexplainable nervous and mental phenomena, localized or general, and similar to those already described. The pathology of this condition is still more difficult of comprehension than is that of the cases alluded to. The cases linger for years, have many ups and downs, and, as far as I know, never recover.

CLINICAL MEMORANDA.

ACCOUCHEMENT FORCÉ: REPORT OF A CASE.

BY JOHN G. CECIL, B.S., M.D.,
PROFESSOR OF OBSTETRICS, KENTUCKY SCHOOL OF MEDICINE, LOUISVILLE, KY.

ON the morning of April 2, 1894, I was called by Dr. Atwood Smith to see a patient in consultation. Arriving about 9.30 A.M., I obtained the following history: Mrs. T., aged twenty-two, the wife of a policeman, had been left by her husband about 10 P.M., April 1st, in her usual health, that is, not complaining more than she had been for the preceding two or three weeks. For several weeks her feet and legs had been swollen; she had not suffered or complained of headaches, disturbances of digestion, or vision; there was not much swelling about the face or hands.

Her husband returning from his watch at seven o'clock on the morning of the 2d, knocked, but receiving no response finally forced the door, and found his wife undressed and in bed entirely unconscious. Not being able to arouse her, he at once sent for Dr. Smith. The Doctor sent for counsel, and during the intervening time observed her in three or four convulsions. He at once commenced the administration of chloroform by inhalation during and at intervals between the convulsions, and gave drop-doses of croton-oil in emulsion. Upon examination I found her in labored respiration—about twenty to the minute—the pulse 72, full, round, and hard; the temperature normal, the eyes staring, at times partially closed, the pupils not responsive to light; the feet and legs considerably swollen, some puffiness about the eyelids, restless, rolling from side to side and tossing her limbs about. She had been vomiting and purging. Digital examination revealed the vagina soft and dilatable, covered with abundant secretion, the cervix shortened but firm, the os admitting the examining finger.

She was within six weeks of the expected completion of her term of gestation, and from the periodic restlessness we thought it probable that she was having labor-pains, though little impression was being made on the cervix. The bag of waters was unbroken, and the presenting head could be felt, but it was not engaged. Fetal heart-sounds were heard in both hypochondriac regions, but more distinctly on the left. The uterus was large and irregular in outline.

The diagnosis of multiple pregnancy, owing to the urgency of the condition, was not made out at this time, as it undoubtedly might have been easily done had more care been bestowed upon it. In consultation we determined to control the convulsions with chloroform; to prevent recurrence by hourly doses of fifteen grains of chloral hydrate by the mouth, or thirty grains by the rectum; to continue efforts at purgation by the croton-oil, and to let the labor for the time take care of itself. During the next four hours she received six drops of croton-oil, which did not produce purgation until five or six hours later; also one hundred and twenty grains of chloral per rectum. Notwithstanding this and the administration of chloroform, she had two violent convulsions, the last one being especially severe.

I saw her again at 1.30 P.M., and, Dr. Smith concurring, determined to deliver as rapidly as possible. Accordingly, she was placed in position, a vaginal douche given, put completely under the influence of chloroform, the urine drawn (which proved to be heavily laden with albumin), and cervical dilatation was begun with the fingers. Proceeding slowly, half of the hand, thoroughly cleansed and well oiled, was introduced into the vagina, and one finger into the os externum. In a few minutes a second finger was squeezed in alongside of the first. Then, at short intervals, the third and fourth fingers were inserted, and the four fingers, bunched into a cone, were used as the dilating wedge. The fingers were pushed as high as the presenting part would allow, care being taken not to rupture the amniotic sac; they were then made to oppose each other, the index and sometimes the middle finger being hooked into the cervical ring, pulling it gently in different directions, the other fingers opposing. The cervical ring was thick and strong, and offered not a little resistance. The manipulations were continued for about forty minutes, when I had secured considerable thinning out of the cervix and a dilatation of from one-and-one-half to one-and-three-quarter inches. The head was now engaging, and the waters unbroken. I now had the choice between version (which might not have been an easy undertaking in view of the subsequent discovery of twins) and an effort to apply the forceps. Knowing the dangers incident to the delivery of a living child by the breech in a primipara under the most favorable surroundings, I determined to make an effort to apply the forceps; in the event of failure, I still had the alternative of version. Accordingly, the bag of waters was ruptured, and a small head in the right occipito-posterior position became partially engaged at the superior straight. The forceps was adjusted with some difficulty, the cervix being tightly stretched like a rubber band around the blades when they were locked. I now felt that I had control of the situation, and even though a laceration of the cervix should occur, I would be justified in bringing the labor to a speedy termination. Intermittent tractions at intervals of two minutes were made very gently, and I soon had the satisfaction of seeing the cervical fibers dilate and retract over the forceps-blades and the descending head. The delivery was soon accomplished. The head being very small and the pelvis roomy, the former never rotated, but was delivered with the face looking to the symphysis. The child, weighing about five pounds, was in a state of congestive asphyxia. The cord was cut without ligature, and a small amount of blood permitted to escape; the infant was then quickly resuscitated.

When this child was delivered it was at once ob-

served that a second remained unborn, which presented by the head, in the left occipito-anterior position. It descended to the pelvic cavity in a little while, but the contractions being insufficient, the forceps was applied and delivery accomplished in a few minutes. The second child resisted efforts at resuscitation for a long while, but we were finally successful; though larger than the first, it was weaker, and was asphyxiated from a probable partially premature separation of the placenta. A single after-birth with the two cords attached was promptly delivered, and a firm uterine contraction followed.

The time consumed from the commencement of the dilatation to the complete delivery was about two hours, and we had the satisfaction of having two living children, the mother still alive and in a better situation for the future to the credit of *accouchement forcé*. Owing to the small size of the fetal heads, notwithstanding the unfavorable position of the first, the perineum was preserved entire, and if there was any cervical laceration, it was insignificant. There was no recurrence of convulsions during the delivery. The mother was now allowed to come out from under the influence of chloroform, and a close watch was instituted. In an hour or so she began to purge freely; the kidneys also secreted six or eight ounces of urine.

I saw her again four hours afterward and found her breathing sixty-five times per minute; the pulse, 90; the temperature, 102° F.; very restless, still unconscious, somewhat cyanosed, coarse mucous râles being heard over every part of both lungs. This condition, evidently one of acute edema, had come on suddenly, about three-and-one-half hours subsequent to the delivery. Mustard-plasters were freely applied to the chest in front and behind, a rectal injection of half an ounce of whiskey and fifteen grains of ammonium carbonate given, followed shortly after by the hypodermatic injection of morphin one-fourth grain and atropin $\frac{1}{150}$ grain. This brought relief, and she passed a reasonably quiet night.

At eight o'clock the next morning, April 3d, she awoke to partial consciousness, and had a single slight convulsion; thirty grains of chloral by the rectum, and morphin and atropin were given. The edematous condition of the lungs still persisted; the temperature was 101° F., and the pulse varying from 120 to 150 beats per minute. Later in the morning the morphin and atropin were repeated, and $\frac{1}{100}$ grain digitalin given hypodermatically. At four o'clock in the afternoon the woman had become semiconscious, the pupils responding promptly; the pulse was 120—better in volume and strength; she recognized her friends and was able to swallow teaspoonfuls of water, doses of whiskey, and ammonium carbonate. I directed that morphin and digitalis be continued during the night *pro re nata*.

The temperature for the next two days was exceedingly erratic, varying from normal, or nearly so, to 105° F., making at times very rapid excursions, but the daily average became gradually higher toward the end, fluctuating from 103° to 105° F. The condition of the lungs never materially improved, the coarse mucous râles persisting. I am inclined to think a condition identical with, or certainly very similar to, catarrhal pneumonia developed in the right lung. The urinary secretion from the time of delivery was satisfactory in quantity, showing daily improvement in the amount of albumin. The patient died early on the morning of the 6th, or about four-and-one-half days after delivery, clearly from the pulmonary complication, there being at no time evidence of septic infection. It is probable that the edema was induced by intra-cranial interference with the functions of the pneumogastric nerve.

No. 731 Fourth Avenue.

AN UNDESCRIBED HEART-MURMUR.

By J. N. HALL, M.D.,
PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE IN THE UNIVERSITY OF COLORADO.

In quite an extended search in the literature of diseases of the heart I have been unable to find any note of a murmur such as is here described.

Mrs. C., a widow, thirty-two years of age, a housewife, has borne four children and has had two miscarriages, the last being only a month ago. Ten years ago she had an attack of acute rheumatism confining her to bed for five months. She has had several slight attacks since. She lost considerable blood at the last miscarriage, and is rather anemic. Upon August 6th, when I first saw her, the cardiac area was enlarged to the mammillary line, the apex-beat under the nipple, in the fifth space, and the cardiac action decidedly feeble. An apical systolic murmur, propagated to the mid-axillary line was heard, with accentuation of the pulmonary second sound. There was moderate edema of the feet, and marked dyspnea; the respirations were fifty per minute while sitting in the chair, the pulse 90, and feeble. No pulmonary edema was found.

I exhibited the patient at the clinic as an example of mitral regurgitation, in spite of the fact that the murmur was not propagated to the back. The feeble action of the heart seemed to me sufficiently to account for this, while the lack of such transmission was in my mind more than counterbalanced by the presence of edema and particularly the marked dyspnea, especially upon the slightest exertion. In fact, I take decided exception to the dictum of Cammann and others, that it is necessary to hear a mitral murmur in the back before deciding that it indicates regurgitation. I believe I have seen several examples that were exceptions to this rule.

The woman was given iron and a laxative, and returned on August 29th. Her condition was then about the same, excepting that the anemia was a little improved, and the murmur followed the first sound and the apex-beat, instead of being synchronous with them as before. The cardiac action was still so feeble that digitalis was prescribed, and a few days later the patient was re-examined.

The edema of the feet at that time had practically disappeared. The pulse was 70, and of much better strength. The apex-beat was easily visible and palpable. The murmur followed the first sound, and the visible beat, and was transmitted to the mid-axillary line. The respirations reached 50 per minute five minutes after slowly ascending a short flight of stairs. The basic second sound came just at the termination of the murmur, but at the apex was obscured by it. The case was exhibited to many students, and to Drs. McLauthlin, Lobingier, and Hopkins, of the University of Colorado. There was no room for disagreement as to the facts, viz., that

the apex-beat and first sound, with a distinct movement imparted to the stethoscope, all preceded the murmur. The only explanation of this state of affairs which I can conceive, is as follows:

The mitral valve was incompetent, and regurgitation occurred through it, giving rise to the murmur, as is usual in such cases. The right ventricle, somewhat hypertrophied, gave rise to the apex-beat and a normal first sound, and displaced the stethoscope firmly applied to the apex region, forming the first element in a reduplication of the first sound of the heart. The second part of the reduplication was made by the left ventricle, but instead of a distinct heart-sound a mitral murmur was heard, owing to the regurgitation through the mitral valve. I believe this explanation sufficiently accounts for all the phenomena observed.

Barr has reported a somewhat similar case in which the left ventricle contracted first, with a mitral murmur, and was followed by the normal contraction of the right ventricle. Sansom reports a case in which, over the ventricles "a murmur tailed off from the second reduplicatory sound," at the apex only the murmer being distinguishable. The case later developed a presystolic murmur, and the reduplication disappeared, which would appear to confirm his explanation that it was due to a presystolic flap of the mitral valve. It obviously differs from the case we are considering.

George Johnson believed that reduplication occurs from the contraction first of the hypertrophied auricle, followed by that of the ventricle. It is not reasonable, I think, to suppose that the auricle could possibly cause the distinct apex-beat, even if it could cause the sound. Sansom has stated, nevertheless, that in certain cases of mitral stenosis the auricle may cause a distinct impulse. There has been, I believe, no evidence of mitral stenosis in this case, and I consider it opposed to Johnson's theory.

Hayden believed that the reduplication occurred from a resolution of the first sound into a muscular sound and a valvular element, the latter occurring after the former. It seems to be conclusively proved that the valve closes early in systole, however, and I certainly fail to see any bearing upon the present case. Potain's theory that reduplication is generally only apparent, being in reality due to a presystolic flapping of the mitral valve in association with a normal first sound, evidently would not apply here, as the apex-beat accompanied the first sound.

I hope to be able to follow the case, and shall note any further developments.

THREE UNUSUAL CASES OF ABSCESS.

By M. A. VEEDER, M.D.,
of Lyons, N. Y.

I have had three cases of abscess recently that are somewhat interesting. The first, which pointed just above the sternum and was buried deeply in the muscles of the neck, was very refractory to treatment, until it was found that its cause was inflammation in the pulp-cavity of a tooth near the angle of the jaw, the pus from which had found an outlet on the inside of the jaw-bone, and had worked its way down between the muscles of the neck until it came to the surface, as I have described. The patient had not suffered from toothache, and did not suspect that this was the source of the trouble, although when the tooth was pulled fluid could be made to pass through the sinus, and healing was very prompt thereafter.

In the next case the patient gave an account of having frozen his chin about three years previously, since which time it had been reddened, and at times would break open and discharge pus. He had never had any trouble with his teeth, which were even and regular, and apparently free from any trace whatever of caries. Nevertheless the probe entered a cavity in the bone at the tip of the chin in the direction of one of the lower incisors, which on inspection was found to present the peculiar opaque appearance which exists when the nerve is dead. He was taken to a dentist, and a hole was drilled into the side of the tooth, the center of which was found to be the seat of a cavity having its outlet below, and through which a disinfecting fluid could be readily passed into the sinus opening at the tip of the chin. This cavity was thoroughly cleansed by the repeated application of hydrogen dioxid and of pure carbolic acid and drilling, whereupon the pus-discharge ceased, and the tooth which had been the cause of the trouble was saved.

Another case was of precisely similar character, except that the opening was on the side of the chin opposite the anterior bicuspid tooth. Although the patient had not had the slightest pain in his teeth, when it was suggested that this might be the trouble he went to a dentist and had the posterior bicuspid tooth pulled because it contained a filling and the other did not. This did not remedy the trouble, and some months afterward he sacrificed the other tooth, which resulted in immediate cure. The better plan would have been to have looked for symptoms of the death of the nerve of the tooth, and to have had an opening drilled into the pulp-cavity as previously described, which would have resulted, with proper filling, in remedying the trouble and likewise saving the tooth. It has seemed to me that this class of cases might very readily be overlooked, particularly in the earlier stages, because of the insignificance of the pain referable to the teeth.

HOSPITAL NOTE.

ABDOMINAL ANEURYSM.

By JOHN ALDEN LICHTY, M.D.,
resident physician in the Philadelphia Hospital.

Mrs. M. D., seventy three years of age, a widow, born in Ireland, was admitted to the Philadelphia Hospital, in Dr. Salinger's wards, September 5, 1894. The woman said that she had always been well, had worked hard all her life, was the mother of ten children and had had four miscarriages. She had used alcohol, and to excess, especially within the last few years. For the past ten years she has suffered with dizziness. Within that time a small tumor appeared in the region of the thyreoid gland. For three or four years she has had pain in the epigastric and cardiac regions. This, according to her statement, has shifted gradually toward the right. It is paroxysmal, not increased after eating, and shoots toward the back. The pain in the back has been especially severe within the last few months. About a month

before admission she noticed a pulsation on the right side and above the umbilicus. This she thought was due to her heart, and when asked why she came to the hospital, she said because her "heart was dislocated." She is a tall, slender woman, and looks emaciated, but says she has never been robust. The palpebral fissures are small, and there is a marked arcus senilis. The pupils are unequal, the right being smaller than the left, as the result of an injury to the eye some years ago. Both pupils respond to light and accommodate to distance. The woman's voice is high-pitched and harsh. Examination of the larynx by Dr. Seltzer showed the vocal bands to be normal. The larynx is unusually small.

A small tumor about the size of a walnut is found in the region of the thyreoid gland, more prominent on the left side than on the right. It is very hard, nodular, does not pulsate, and moves with the larynx in deglutition. The left external jugular vein is much distended immediately above the clavicle. The lungs are normal. Cardiac dulness is normal in extent. At the apex a rough sound is heard with the systole. It is not transmitted. At the aortic cartilage the second sound is highly accentuated. The radial pulses are equal. The arteries are very much thickened.

The abdomen is very flaccid. On the right side of the median line and just above the umbilicus, an induration is felt. It is about the size of a lemon, smooth, very tender upon pressure, has an expansile pulsation synchronous with the heart-beat, and extends to the median line. No thrill is felt, but a bruit is heard at the base of the tumor near the situation of the abdominal aorta. The position of this tumor does not change upon putting the patient in the knee-elbow posture. The femoral arteries are very much thickened, but a sphygmographic tracing shows no difference between the pulsations of the two. Marked tenderness is found about the spines of the twelfth dorsal and first lumbar vertebræ, and at this same point a bruit is heard.

From these symptoms and signs a diagnosis of aneurysm of the abdominal aorta was made. The condition could easily be differentiated from a pulsating abdominal aorta by the presence of a tumor, and from other abdominal tumors by the presence of the expansile pulsation and the bruit.

The patient is kept in bed, is on a dry diet, and is given larger doses of potassium iodid. Aside from the pain in the back, she is comfortable.

As is well-known, aneurysms of the abdominal aorta are rare. Crisp, in his elaborate statistics of 551 cases of aortic aneurysms, found only 59 of the abdominal aorta. Many cases reported are found on the autopsy-table to have been only instances of pulsating aortas. But in the foregoing case, in which the abdomen is so flaccid and the tumor can be so easily palpated, there cannot be a doubt of the existence of an aneurysm.

MEDICAL PROGRESS.

Prostatic Hypertrophy Successfully Treated by Castration. —Meyer and Haenel (*Centrabl. fur die Krankheiten der Harn- und Sexual-Organe*, Bd. v, Heft vii, 1894, p. 329) have reported the case of a man, seventy years old, previously in good health, who suffered with marked prostatic hypertrophy, complicated by ammoniacal cystitis. The prostate was palpable through the rectum as a smooth, homogeneous, hard mass about as large as an adult fist. Lobulation was not appreciable. In the presence of alarming symptoms and in the failure of the usual palliative measures, castration was proposed as the final resort, and both testicles were removed. Recovery from the operation ensued without complication. In the course of a week a slight decrease in the size of the prostate could be determined. In the course of another week the organ had lost a third of its former size, while five weeks later still it had lost an additional third. Three weeks after this the gland was reduced to almost its normal size. The distressing symptoms also began to subside within a few days after the operation, and with the aid of antiseptic irrigation of the bladder a satisfactory condition was soon restored, the propulsive force of the bladder progressively increasing. Hand-in-hand with the improvement in the local condition the general state became better, and in a short time the patient was restored to comparative health.

Among the advantages of the operation of castration for the relief of prostatic hypertrophy are pointed out its facility of performance, its almost entire freedom from danger, and the likelihood of success.

Mansell-Moullin (*The Medical Press and Circular*, No. 2889, p. 285.) reports the case of a man, eighty-one years old, who for a number of years had been troubled with occasional retention of urine, relieved by catheter with more or less difficulty and returning after an interval of a month or two. When he came under observation the bladder was greatly distended, and a catheter could not be introduced. Through the rectum the prostate was found to be much enlarged, smooth and hard. The bladder was aspirated above the pubes, and a large quantity of urine neutral in reaction and containing a considerable amount of pus was removed. On the following day small amounts of urine were passed at frequent intervals. The condition continued thus for about two weeks, subsequently growing progressively worse. It was impossible to introduce a catheter. The amount of pus in the urine increased, the cystitis became more aggravated and the patient's strength began to fail. The prostatic growth was now as large as a Tangerine orange. It was considered that a suprapubic prostatectomy involved to much risk. The chance of success if a suprapubic urethra were formed or a perineal drain were inserted was considered better, but in view of the patient's years the prospect was felt not to be a good one. Accordingly, castration was proposed and agreed to. The operation was performed with but slight shock and without rise of temperature. The wound upon the one side healed at once; that upon the other became infected and suppurated a little. From the day after the operation the urine passed more freely. On examination ten days later the prostate, felt through the rectum, was much smaller. Three weeks after the operation it had simply disappeared. An ordinary silver catheter entered without the necessity of more than the usual depression, and when the finger was introduced into the rectum all that could be felt was a fusiform thickening along the catheter not sufficiently large or dense to prevent the shaft being felt distinctly along the entire length. The bladder was beginning to regain power and the urine had become acid.

Gumma of the Parotid Gland.—MANDOWSKY (*Sonderabdruck aus der Aerztliche Praktiker*, No. 32, 1894) has reported the case of a woman, twenty-three years old, who for some time had observed a hard swelling below the lobule of the right ear, in the neighborhood of the parotid. It was related that a glandular swelling had been present in the same situation nine years before, but this had been removed. Subsequently a new swelling appeared which, for a long time, slowly increased in size, but recently had grown more rapidly. The tumor was somewhat larger than a pigeon's egg in size and firm in consistence. It appeared to be adherent to the surrounding structures, and was not movable upon the subjacent tissues. It felt elastic, as if surrounded by a firm capsule. Immediately beneath it was a second, smaller mass, about as large as a bean. Although the general condition of the patient appeared good, and there was no history of eczema or other chronic inflammation, the impression made was that of a tuberculous lymphatic gland. At the patient's request the tumor was extirpated. It was found to lie between the origin of the sterno-mastoid muscle and the ascending branch of the lower jaw, immediately beneath the ear. It was adherent to the surrounding structures, particularly to the parotid gland, from which it could not be separated, so that it was necessary to remove a portion of the gland. In addition to the main tumor, some nine or ten smaller glands were also removed. The subsequent course of the case was uncomplicated.

Macroscopically the large tumor presented the appearance of a fibro-sarcoma. Histologically it proved to be a gumma, which it is believed was of hereditary origin.

THERAPEUTIC NOTES.

Infiltration Anesthesia.—An interesting series of experiments, the results of which have been corroborated by many subsequent observations in practice during a period of over three years, appear to demonstrate the greater effectiveness of intra-cutaneous, over subcutaneous, injection of the anesthetizing fluid in the production of local anesthesia. The principle of infiltration-anesthesia, as briefly stated by SCHLEICH, the originator of the method (*Therapeutische Monatshefte*, 1894, No. 9), is thorough infiltration of the entire field of operation with an indifferent fluid, which need not be an anesthetic. The needle is introduced beneath the papillary layer, and in a direction parallel to the surface of the skin. The injection is followed in a few minutes by the appearance of a white, anesthetic wheal. The foreign fluid fills the tissue-spaces, and forces out the blood and tissue-juices, and is most effective at a temperature of zero, Celsus. The anesthesia of the area of induced edema is said to depend on the pressure of the infiltrating fluid, on the temperature, and on the anemia of the tissues. Intra-cutaneous injection of distilled water, of 2 per cent. solution of sodium chlorid, of 3 per cent. solution of sugar or 0.02 per cent. solution of cocaïn, will produce complete local anesthesia. A 1 per cent. solution of morphin, a 3 per cent. solution of potassium bromid, a 1 per cent. solution of methyl-violet, a 2 per cent. solution of caffeïn, will have the same effect, and this will be enhanced if these substances are dissolved in 2 per cent. solution of sodium chlorid.

Among the operations done under local anesthesia by this method are mentioned uncomplicated celiotomy, amputation of the mammæ, removal of the axillary glands, nephrotomy, herniotomy. removal of sequestra, besides many minor operations.

In the following formulæ the morphin or codeïn is added for the relief of the pain subsequent to the operation; the second agent named also diminishes considerably the necessary dose of cocaïn, which is added to render the injection painless, and so facilitate its application. Without the cocaïn, the induced edema is quite painful for a minute or more, when complete anesthesia follows.

I.

R.—Cocaïnæ hydrochlorat. . . . 0 2
Morphin. hydrochlorat. . . . 0.025
Sodii chlorid. sterilisat. . . . 0.2
Aq. dest. (sterilisat.) ad . . . 100.0—M.
Adde acid. carbol. (5 per cent.) gtt 2.
S.—Strong solution.

II.

R.—Cocaïnæ hydrochlorat. . . . 0 01
Morphin. hydrochlorat. . . . 0.005
Sodii chlorid. sterilisat. . . . 0.2
Aq. dest. (sterilisat.) ad . . . 100.0—M.
Adde acid. carbol. (5 per cent.) gtt. 2.
S.—Weak solution.

The strong solution may be diluted three times with normal salt-solution without losing its efficacy. Undiluted, it is used in the treatment of inflammation, suppuration, or neuralgia. In an operation requiring much time, the weak and strong solutions are used alternately.

The syringe is sterilized by means of a 5 per cent. solution of carbolic acid and absolute alcohol in equal parts, and the pain incident to the first prick of the needle is obviated by the use of the ether or ethyl-chlorid spray.

The advantages of this method of producing local anesthesia are its perfect safety (as large quantities can be injected before the maximum dose of cocain is reached) and the complete insensibility that can be induced and maintained in the entire field of operation.

To Relieve the Thirst of Diabetics pilocarpin may be administered in solution or in pill-form. The pills are best prepared by the addition of glycerin and gum arabic. Each contains gr. $\frac{1}{60}$ of pilocarpin nitrate.

For the solution the following formula is given:

R.—Pilocarpin. nitrat. . . . . gr. ½.
Spirit. vini dilut. . . . . ♏xx.
Aquæ . . . . . ʒj.—M.

S.—The tongue is to be moistened with 5 or 6 drops of this solution four or five times daily.—*Nouv. Remèdes*, No. 11; *Corr.-bl. für Schw. Aerzte*, 1894, No. 18.

For the Night sweats of Pulmonary Tuberculosis.—

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 20, 1894.

PERIODIC PALSY.

THERE have been reported within the last decade a small number of cases of obscure nature characterized by the occurrence of transitory and recurrent palsy, and for which it has not been possible to lay down a well-defined pathology. Among the earliest of these is one detailed by WESTPHAL,[1] which occurred in a boy twelve years old, who for a period of four or five years had attacks of paralysis of all four extremities, occurring at first every four or five weeks, and subsequently several times weekly, and lasting for from twenty-four to thirty-six hours. The paralysis was attended with loss of electric irritability of the affected muscles, diminution of reflex irritability, increased thirst, and free perspiration. Sometimes pain was present, and, as a rule, paresthesiæ were noted.

A case recorded by GOLDFLAM[2] occurred in a young man seventeen years old, who for three years presented attacks of generalized paralysis, lasting at first for three days, later for two days, and finally for but one day, and recurring at intervals of varying duration. Eleven other members of the maternal branch of the family were said to suffer similarly. Males and females were almost equally attacked. The transmission was not continuous and direct, a generation sometimes escaping and the disease appearing in members of a succeeding generation. The frequency of the attacks varied considerably among the individual members of the family, although greater in youth than in advanced life.

BURR[1] has reported the case of a man, thirty years old, who for ten years suffered from attacks in which he was awakened from sleep by a sense of soreness in the muscles of the arms and legs, and on attempting to move found that he was unable to do so on account of weakness. Consciousness was undisturbed, sensibility was not deranged, and the function of the sphincters was maintained. The attacks lasted from a day to a week and recurred about once in four months, though latterly with greater frequency. Recovery from the attack took place gradually in the course of a few days. BURR further cites a case detailed by SCHACHNOWITSCH[2] occurring in a man, forty-four years old, who was subject to attacks of periodic paralysis, which always set in during sleep, and involved the arms and legs, without sensory derangement, but with a subjective sense of stiffness, lasting from three to twelve hours and recurring with varying frequency. Consciousness remained unaffected. It was learned that the patient's father had suffered similarly.

COUSOT[3] has recorded the case of a mother and four of eight children who presented periodic paralysis. There have also been reported a number of cases of periodic palsy of quotidian or tertian or of irregular type, in which the causative factor was believed to be malarial, but quite without adequate evidence. Only in the report of GOLDFLAM is it stated that examination of the blood was made, and in this instance hematozoa were not found.

The most recent of this interesting group of cases is reported by HIRSCH.[4] The patient was a man, twenty-six years old, who, about once a year for a period of six or seven years, was, without obvious cause or exciting influence, seized with a sense of heaviness and fatigue in the extremities, finally progressing to actual paralysis, lasting for about twenty-four hours and suddenly disappearing. The reflexes were abolished, but sensibility was unaffected. During the continuance of the condition there was increased thirst. There was also increased cardiac

activity, and a systolic murmur was heard at the apex of the heart, together with accentuation of the pulmonary second sound. After the seizure the man was as well as before. The patient himself was not neurotic, but it was related that his mother had suffered similarly. In both the facial muscles escaped involvement.

Virtually nothing is known as to the intimate nature and etiology of the disorder here considered, and in the absence of definite knowledge hypothesis has had free play. WESTPHAL thought there might be a sudden disturbance of the nutrition of the muscles or of the muscle nerve-endings as a result of peripheral circulatory derangement. COUSOT sought to locate the lesion in the spinal cord, assuming the existence of a transitory inhibitory influence upon the spinal centers. GOLDFLAM suggested the presence in the body of a virus of unknown nature exerting a toxic influence upon the muscles and motor nervous fibers, and, as a matter of fact, demonstrated an augmentation of the urotoxic coefficient in relation with the occurrence of a paroxysm. From a prognostic point of view the affection is not known to shorten life. Therapeutically there is no specific remedy, and each case must be treated in accordance with its individual features.

An additional interest is given these cases when placed side by side with the affection described by THOMSEN and known by his name, and also as congenital myotonia, and that recently described by RICH.[1] In the first of these latter conditions stiffness of the muscles ensues on attempted movement following a period of rest, and in the second a similar rigidity results on exposure to cold, in both instances with interference with mobility.

In a personal communication PROF. BERNHARDT, of Berlin, calls our attention to a family form of congenital myotonia traceable through six generations described by EULENBERG,[2] and a case of intermittent congenital myotonia reported by MARTIUS and HANSEMANN.[3] In the twenty-eight persons affected by the condition described by EULENBURG exposure even to a slight degree of cold induced transient tonic spasm of the muscles of the face and neck and the muscles of deglutition, so that, for instance, the act of vision or of speech was rendered difficult or was interfered with; in the muscles of the lower and upper extremities the condition of spasm yielded to a state of palsy lasting from a few hours to half a day. Warmth relieved an existing attack and aborted an impending one. Faradic and, in greater degree, galvanic muscular irritability was diminished, the response to galvanism being unduly protracted. The affection differed from Thomsen's disease in an absence of increased mechanical irritability of the muscles. The condition was believed to be a spastic angio-neurosis, dependent upon reflex contraction of the vessels supplying the muscles, as a result of the irritation induced by exposure to cold.

The case of MARTIUS and HANSEMANN was characterized by a sense of weakness in the upper extremities following exposure to cold, or rather sudden lowering of temperature. During the summer the patient remained free from attacks for months at a time. Sudden exposure to cold, however, such as a cold bath, at all times led to an attack. In winter the attack would be repeated daily and usually in the morning, either on arising or going out of doors. It set in with a sense of progressive weakness, even before there was objective interference with motility. Ultimately the fingers became fixed in the clawed position. Passive motion, however, was still possible. The patient was, on vigorous effort, able to close the hand, but was unable at once to reopen it. The spasm relaxed in the course of a few seconds and the patient was again able to extend the fingers. Energetic innervation of the biceps brachii was also attended with prolonged tonic contraction beyond the period of voluntary stimulation. Sometimes the muscles of the face and of mastication displayed similar peculiarities. Only on one occasion, after putting the feet in cold water, was there any stiffness of the lower extremities.

The mechanical irritability of the motor nerves was diminished, that of the muscles tardy and characterized by protracted contraction. The response of the muscles to strong faradic currents was slow, tonic, and persistent; induction-opening sometimes induced only short, lightning-like contractions. Galvanic irritability of the nerves was normal and all of the contractions were brief. The muscles displayed increased galvanic irritability,

with qualitative change; all contractions were slow, with tonic and protracted wave-like elevations and depressions formed at the point of application of the electrode. In the intervals between the attacks the patient was free from all outward abnormal manifestations.

Histologic examination of a portion of one of the affected muscles showed the primitive bundles to be twice the normal thickness, pursuing an undulating course, with the transverse striation in places indistinct. The nuclei of the muscle-fibers were also increased in number, were wider than normal, and were arranged in long rows. The father, the grandmother, the great-grandfather, numerous uncles, an aunt, and other members of the family suffered similarly to the patient, the disease usually appearing in early childhood.

Although on first thought the several conditions here referred to would appear to be widely divergent, future investigation may disclose a more intimate relation among them, the same structures suffering in all—in the one instance, however, with the development of a flaccid or atonic state of the muscles affected, while in the other a spastic state results. All present in common a family distribution and hereditary transmission.

SMALL HOSPITALS.

A LITTLE book on the *Establishment and Maintenance of Small Hospitals*, by A. WORCESTER, A.M., M.D., has lately been published by JOHN WILEY & SONS, New York. It was written to aid in the now widespread movement for the establishment of small hospitals in all centers large enough to support them. After discussing the advantages of the small hospital, the means to be taken to awaken an interest in the movement in any community are stated; the necessary hospital-organization is explained; the medical question is fully discussed, and the necessity (as it is believed) shown of having all the leading schools of medicine represented on the hospital staff. This is done by naming leading physicians of each "school," who are, however, designated simply as physicians, the "regular" physicians serving in turn, the homeopathic members of the staff being in attendance whenever called for by patients.

The necessity of a training-school is shown, and DR. WOODWARD recommends that this be an entirely separate institution from the hospital. For this we see no good reason, and the valid objection that it imposes upon a small community the necessity of maintaining two establishments, when only one is necessary, seems sufficient to overthrow his plan.

DR. WORCESTER takes the stand that the hospital should provide for all needful cases of contagious disease, and this he recommends should be done in a detached cottage-ward. It has been the rule at hospitals to reject all patients suffering from contagious diseases, but this is no longer defensible in communities in which there are no special hospitals for these diseases. The greatest need is often in these very cases, in which, unless removed to a hospital for isolation, the disease may spread through a whole family.

The closing pages of the book are devoted to "Suggestions for Hospital Architecture, with Plans for a Small Hospital," by WILLIAM ATKINSON, architect. The book is commended to all who contemplate the establishment of a hospital in any community in which none now exists.

It may be profitable to refer here to the success which is attending the efforts to establish small hospitals, and to illustrate this by referring to the hospital opened a little more than a year ago at West Chester, Pennsylvania. The building and lot cost $20,000. There are twenty beds in the wards, and private rooms for patients. The cost of maintenance is $250 per month. During the first year 169 patients were received, who spent on the average sixteen days in the institution. During the year, the hospital received $22,000 as an endowment-fund, which is now invested at 5 per cent., and a collection taken for it in the Catholic Church yielded over $700. A school for nurses has been established and is in successful operation. It is in charge of a committee of the Board of Managers.

The field which it is the aim of this hospital to occupy is the whole county in which it is situated. The county-seat being in communication with all portions of the county by railroad, patients can be quickly and safely conveyed to it. An ambulance is also employed to bring in patients from the surrounding country.

To work up and maintain an interest in the hospital and to secure funds and supplies *Ladies' Auxiliary Societies* have been established at numerous places throughout the county. These societies receive annual subscriptions and donations. Some of the churches in the district have taken up collections

for the hospital, others have not. Such small county-hospitals, properly managed, and escaping the evils which have beset larger institutions, should be able to accomplish great good, if in no other way, in avoiding the congestion of city-hospitals, a large part of which is due to the custom of the counties supplying many patients who in one way or another find their way to the city. But all care should be exercised in founding, in framing rules, and in the administration of these and of all hospitals, that dependency is not encouraged, that those who are able to pay shall not be treated without payment, both the profession and the public being thus injured.

EDITORIAL COMMENTS.

An Appeal to the Pity and Better Natures of the Editors and Publishers of The British Medical Journal and The Lancet.—You know, gentlemen, that the paper upon which is printed the "foreign edition" of your otherwise splendid journals, is simply inexpressibly vile. It is at once thicker, and yet more mushy and rotten than tissue-paper, and is, therefore, properly fit for no purpose whatsoever—absolutely none—of civilized or unregenerate man. We can only explain its use on the ground of a contempt of us, the reason for which dates back to Revolutionary times, or perhaps to Simian ages. You certainly would not, and could not, treat a resident of the British Islands thus. We beg of you to remember that, however remote the relationship, we are at least your Teutonic brethren, and that it is your duty to help on the cause of Anglo-Saxon civilization. Please do not forget that even an American can sometimes grumble, and even revolt, after prolonged indignity and injustice. We appeal to your compassion and to your sense of justice: In the name of your contributors, who write to be read of all men, not only of Englishmen; in the name of your foreign subscribers, who have paid for knowledge, not soiled paper; in the name of your typesetters and printers, whose good work is spoiled by your bad paper; in the name of your self-interest, as there are untold thousands of Americans waiting to subscribe when they shall be able to read what you and your contributors have written; in the name of medicine, whose cause you represent, but traitorously, because you spoil good eyes and brains by the unnecessary labor you thrust upon us; in the name of art, as the illustrations in the foreign editions of your journals become subjects of mirth to all outlandish men; in the name of human ethics and good character, because you are sadly wrecking both, and tremendously increasing the work of the future writer of a cursory history of swearing; and lastly, in the name of pure commiseration of your brother editors who, willy-nilly, are compelled to look through your columns to glean from them a knowledge of medical thought and progress. Misericordia! Misericordia!

State Examinations and Licenses to Practice.—A correspondent complains of the non-issue of the formal license to practice, and indulges in general criticism of the conduct of the Pennsylvania Board. Concerning the non-issue of the formal license, it will be proper to apply directly to the Attorney-General of the State. The law, we believe, does not prescribe any printed or written form, and a license to each successful applicant might be issued by proclamation or by simple notice to each person. On the question of the value of strict examinations and the establishment of a State Supervising Board, it may be said that all experienced teachers admit that ability to answer set questions is not a test of talent or genius. Those who carry off college honors are by no means always those who are the most distinguished in after life. It is true that many able physicians have been educated under the wretched system common in the United States up to a recent period, but it is also true that hosts of unfit men were allowed to enter the profession and a degradation of the standard of the schools brought about which is the main factor in retarding reform. To attempt to regulate by legislative methods the scope of instruction in medical schools would lead to dispute and confusion. The utmost that can be accomplished at present is to exercise the wholesome influence that arises from the fact that each college faculty knows that its graduates will be subject to a public competition with graduates of every other college. Moreover, if Pennsylvania were to establish a system of college supervision the graduates of other States could not be excluded except by some uniform test like that of a State examination, so that nothing would be gained over the present method by the additional machinery.

Actual Experience in Filtration.—We take from a recent report of a joint commission designated by various civic and scientific organizations in Allegheny County, Pa., an interesting description of the performance of sand filters at Poughkeepsie, N. Y. These were built upon the European model in 1865, and have been in use over twenty years. They furnish 3,000,000 gallons per day. Since 1876 the beds have been used continually except during the winter of 1881, when the cold weather interfered. This difficulty has now been overcome, and they can be operated at all seasons. All the city supply is filtered, and the inhabitants have become very exacting, insisting on the continuous use of the filters. For brief periods in the year a peculiar turbidity appears which the filter does not remove. The lower courses of broken stone and gravel have never been disturbed since the filter was built, and the sand has also been in continuous use, having been several times removed, washed, and replaced. Chemic and bacteriologic analyses are always satisfactory. In November, 1891, Drown found 1161 points of microbic life in 1 c.c. of the applied water and 62 points in the effluent, a reduction of 95 per cent. In 1892 the reduction was 82 per cent.

Cruelty Among the Hindus.—Hari Kali Sen, himself a Hindu, in a recent number of the *Indian Medical Record* (Vol. vii, No 5, p. 136) details a form of refined cruelty practised among the higher castes of Hindus under the guise of a religious observance and known as Akadashi, which compels widows, infant or mature, healthy or sick, weak or strong, to observe on the eleventh day succeeding each full moon and new moon a fast lasting for twenty-four

hours, during which not so much as a drop of water is permitted to pass their lips. Sometimes a widow is placed in an empty room and kept under lock and key for the time of her fast. Marriage takes place early among Hindu girls, even at the age of seven or eight. The male Hindu is not only entitled to polygamy during his first wife's lifetime but after her decease he may also marry as often as he pleases. On the other hand a Hindu widow of even six or eight or ten years of age, instead of being permitted to marry again, is forced to life-long torture, from which there is no release but death or prostitution.

The Polk Site for the Asylum for Feeble-minded in Western Pennsylvania.—Serious objection has been raised to the selection of Polk as the site for the contemplated asylum for feeble-minded in Western Pennsylvania, on the basis of its great distance from Pittsburg as representing the center of population of that section of the State. Not only will this separation increase the expense of travel of patients and friends, but it will also preclude the possibility of obtaining the strongest corps of visiting physicians, a desideratum, the importance of which has been recognized and illustrated in recent changes made in the medical staff of the Institution for Feeble-minded Children, at Elwyn, near Media, and not far from Philadelphia. There are many reasons why the new institution should be situated near Pittsburg. The energetic protest of the medical profession against the selection of the Polk site should not go unheeded.

The Vitality of Diphtheria-Bacilli in False Membrane.—We have on several occasions pointed out for how long periods convalescents from diphtheria may be a source of infection, and wish here only to refer to a report made by Abel (*Deutsche medicinische Wochenschrift*, 1894, No. 35, p. 692), detailing the case of a girl, twelve years old, in which an attack of faucial diphtheria was, after apparent recovery, followed by the development of fibrinous rhinitis in the membranes, in which virulent diphtheria-bacilli were found as late as sixty-five days after the onset of the primary illness. This observation and others emphasize the caution to be observed in permitting convalescents from diphtheria to associate with others, and seem to show that the false membrane of diphtheria, as well as that of fibrinous rhinitis due to the activity of diphtheria-bacilli, constitutes a specially favorable medium for the preservation of these organisms.

Price No Guarantee of Excellence.—A few days ago a sample of hydrogen dioxid of English manufacture was analyzed in comparison with a well-known American brand. Four ounces of the English preparation cost one dollar, while the same quantity of American article costs about thirty cents. The results are interesting:

	Volumes of O.	Degree of acidity.
English	5.6	36.0
American	10.0	2.4

A sample of an American article which was ten volumes in strength in February last, and had been standing on the laboratory-table all summer, was found to have been reduced to eight volumes, showing, therefore, excellent keeping qualities.

An Antiseptic Suggestion.—A contributor to The News, Dr. Francis L. Haynes, notes that in examining the neat and doubtless thoroughly sterilized packages of surgical dressings now kept in drug-stores, the physician is frequently startled to see the druggist open the packages and handle their contents with soiled fingers, thus rendering the material unfit for surgical purposes. He offers the suggestion that manufacturers carefully seal all packages of surgical dressings (and, we would add, permit the sale only of unbroken packages), and that physicians refuse to accept any materials the purity of which is not thus guaranteed.

Effect of Filtration of Water-Supply.—The beneficial effects of filtration seem to be strikingly shown by the experience of Girard College, Philadelphia. This is located in the district which has been for some years supplied by direct pumpage—that is, the Schuylkill water is thrown directly into the pipes. The typhoid death-rate for 1893 was quite high in that district, although apart from the bad water the sanitary conditions are very favorable. At Girard College, however, there is but little of the fever in a population of over 1500. All the water supplied to the institution is thoroughly filtered.

SELECTION.

PAY WARDS AT THE GREAT NORTHERN HOSPITAL.

We read in a lay contemporary: "The authorities of the Great Northern Central Hospital announce that on October 1st they will open their pay wards to the public. Particular care will be taken to restrict the benefits of this important branch of the charity to the most suitable and deserving cases. *The medical staff have undertaken to attend the patients gratuitously on the same conditions as the patients in the free wards.*" (The italics are ours.) This seems very strange. The persons then who make use of these wards are to pay for everything except medical attendance. It certainly looks like playing the medical profession a little lower down even than usual. These patients might just as well go to a cheap hotel and pay for their room, their food, and their nursing, but refuse to pay their doctor. We have an idea, however, that it may be a kind of sop to the general practitioners of the neighborhood, who, if they lifted up their voices in protest at pay wards, would be told: at any rate the medical attendance is not paid for. Yet it seems to us in these days of competition and low fees amongst general practitioners that persons who can afford to go into a pay ward at a hospital, even though the medical attendance is gratis, could all the more afford to stay at home and pay the general practitioner his fees, which, as time goes on, get smaller and gradually less. Pay wards at general hospitals should be on the same basis as private hospitals for important operations. But in all cases the medical attendant should have his fees exactly as if the case were that of an ordinary private patient.—*Med. Press and Circular.*

CORRESPONDENCE.

THE JOHNSTON EMERGENCY HOSPITAL AT MILWAUKEE.

To the Editor of THE MEDICAL NEWS,

SIR: Something over six years ago the institution styled "The Johnston Emergency Hospital" opened its doors for the reception of patients. The first conception of the idea occurred to Dr. A. B. Farnham, Harv. A.B. 1867, and Bellevue M.D.

Previous to its foundation a number of lives had been lost from the delay in "first attendance," and much inconvenience had been experienced by the police in not having satisfactory quarters for wounded and sick criminals. There were many hospitals in and about the city, but they were far from the center of possible accidents, and their rules and regulations did not permit them to take all persons that might apply. Dr. Farnham was aided in his efforts by the members of the medical society, then called "The Bartlett Clinical Club," now known as "The Milwaukee Medical Society."

By hard work $1500 were collected. Some of the leading men of the city were chosen as directors. An abandoned police-station was renovated, disinfected, and rendered habitable if not aseptic. A graduate from the "Training School for Nurses" of the Cook County Hospital, Chicago, was selected as matron of the institution, and a pupil-nurse from the Wisconsin Training School for Nurses as her assistant. Trusting in the maxim, "The Lord will provide," the doors were opened, and since that time it has done more good than any other institution in the city. The first year was a struggle we well remember. We would meet Farnham with tears in his eyes and the information that there was not coal enough for a day, and this in midwinter, with the thermometer at 0°. Then we learned how to beg, and with a good cause behind us we did beg. During the first year much good that the public could see was accomplished. At one time fifteen firemen who had been engulfed in a burning building were kindly attended to. These acts of mercy gained the hearts of the Common Council, so that at the end of the first year the institution became a city one, with a fair appropriation, and governed by a board of directors appointed by the mayor, who in their turn appointed the visiting staff.

The old place was retained, and, notwithstanding the surroundings, much good work was done. Two years ago, while a cellar was being dug for a new building on the north side, the wall bulged outward, carrying away beds, etc., with a portion of the building. A meeting of the staff was called, and a resolution was sent to Common Council, asking for a new building. The "many-headed hydra" arose, and enemies to advancement wished to close its doors; other hospitals that had formerly refused the admission of such patients, now, in the hour of distress, offered to aid without recompense. While consulting as to where we should build or rent, one of our best philanthropic citizens, John Johnston, banker, arose and presented the city with a $25,000 lot, in the heart of the manufacturing portion of the city and contiguous to the great Union Railway Station.

No position could have been more advantageous, no gift more timely. The gift of the lot was received, but the erection of the building was delayed until the time left for its completion by the condition incorporated in the deed had been nearly spent. Then the Council bestirred itself. Plans for a thoroughly fireproof building, in which all the modern practical as well as theoretic hospital-improvements were incorporated, were placed before the Trustees and Common Council for consideration; one of these was selected, and the work went on.

To-day, six months after the breaking of ground, we take pride in drawing the attention of the medical profession of the world to this "house of mercy" and this monument to the beneficence of a noble man. It will be known as "The Johnston Emergency Hospital." In years to come, long after all of us who have assisted at its birth shall be resting in our narrow house, the name of Johnston will still be read over its door, and the poor man, by accident a sufferer, will bless his name as a public benefactor.

The hospital is built on Sycamore Street between Third and Fourth. The Fourth Ward Park is immediately in front. On the east side runs a twenty-foot alley, which gives ample room for the ambulance to drive in, turn, and back into the recess at the side, between the two sections of the building. The gates are then closed, and the patient can then be taken from the ambulance into the elevator without the "gaping curious crowd" encumbering the way. The building is fifty feet by one-hundred-and-thirty feet, leaving twenty feet of space in the rear for a stable, wherein to keep the ambulance, which will be erected in due time.

The cost of erection has been $51,000. The front is built with Bedford limestone, combined on the second story with Roman brick, and on the third-story roof with Akron tile. The remaining walls are of Milwaukee brick. The building is thoroughly fireproof. The plan of construction is perfect throughout. Much praise must be given to John A. Moller, the architect, for the artistic and useful building he has added to our beautiful city. Each department is so arranged that it can at any time be shut off from the rest of the building. The four executive rooms on the first floor are separated from the rest of the hospital by glass doors. The ward for suspected infected cases has its own entrance on the side, and cannot be entered from the hospital proper. All cases are taken in from the ambulance at the side door to an elevator which, being raised to the second floor, gives the choice of conveying the patient directly either to the sunstroke-room, the preparation-room for operating, the female ward, or the obstetric ward, which is so constructed that it may be closed from the rest of the building. The kitchen and housekeeping apartments are in the basement and on the first floor.

The second floor back is taken up with the operating-room, preparation-room, and sunstroke-room. The resident physician has his apartments on the first floor and the attendants are across the hall. The dispensary is situated on the second floor, in the center of the building, and has electric connection with every room in the hospital. The janitor has his apartments in the front of the basement. Seclusion-rooms are provided for both male and female patients. The plumbing is perfect, there being a toilet-room to every set of apartments throughout the building. The operating-room has eight windows on two sides, and is lighted from

above by a skylight over the whole ceiling. A number of rooms have asphalt floors. The operating-room is of Georgia pine, filled, and oiled.

The ventilating and heating system is that of the Sturtevant Company of Boston, and governed by the Johnston Electric Service of Milwaukee for regulating the degree of heat. By experiment it has been found that the air can be changed throughout the building every ten minutes. The third floor is as yet unfinished, but can be utilized in case of a severe disaster, and can accommodate one-hundred beds. As the city increases in size this floor can be finished and used as a retention-ward.

I have described these plans in detail, as I think they are worthy of merit, and may be of service to other cities whose officials are thinking of constructing a similar institution. The hospital is furnished as perfectly as it is constructed, and nothing is wanted to render the institution a model throughout.

The hospital has a Board of Trustees appointed by the Mayor, eight of whom are physicians. Besides the regular business, they appoint the staff on its own recommendation. The Trustees are: Louis Frank, M.D., President; A. E. Smith, Secretary; S. W. French, M.D.; F. E. Walbridge, M.D.; John R. McDill, M.D.; Horace M. Brown, M.D.; J. S. O'Brien, M.D.; A. J. Burgess, M.D.; Walter Kempster, M.D. (Com. of Health).

The staff is composed of twelve physicians and twelve surgeons, three obstetricians, two ophthalmologists, five railroad surgeons, and eight members of the consulting staff.

I offer this article to the readers of The Medical News with a pardonable pride, to show that the city of my adoption has contributed her portion to suffering humanity. Yours fraternally,

Samuel W. French.

Milwaukee, Wis., October, 1894.
1216 Grand Avenue.

THE BUBONIC PLAGUE IN SOUTH CHINA.

To the Editor of The Medical News,

Sir: The bubonic plague began in Canton and Hong Kong in February or March, but it did not come under the notice of foreigners until April or May. I landed in Hong Kong on the 15th of May and found the city in a state of excitement on account of the plague. The Colonial Government was inaugurating measures to combat the epidemic, and thousands of people were leaving the city.

In Canton the mortality was alarming, and the inhabitants were escaping to the country in large numbers.

The disease had been prevailing for several years in the southwestern part of the Canton province, and had come under the notice of medical missionaries, by one of whom it was described in the *Customs Medical Reports*. It gradually extended up the coast and, as already stated, reached Hong Kong and Canton in the early part of the year.

In Canton it first appeared in the eastern part of the city; then in the central part, and it gradually extended to the western suburbs. Cases have occurred in almost every part of the city, and in some localities the fatality has been great.

There is no notice taken of deaths, even in an epidemic, by the authorities of Chinese cities, and, of course, no statistics of mortality exist. The estimates of the number of deaths vary from 20,000 to 100,000, and even higher.

The disease is a malignant fever, running its course in violent cases in two or three days, but often continuing for four or five days, before the fatal termination occurs. If the patient passes the fifth day without dangerous complications there is hope of recovery.

The diagnostic symptom of the plague is a painful glandular swelling, either in the groin or axilla or neck. This usually appears on about the second or third day, or it may be earlier or later. In some cases the patient may die before the swelling takes place.

The fever varies in intensity, and may not be over 103° at first in cases which terminate fatally, but usually it gets up to 105° before the end. In some cases under our care intermissions have occurred, giving hope of recovery, but the fatal issue occurred on the following day.

Hemorrhage from the mouth and nose is occasionally observed, and the disintegration of the blood, with extravasation into the skin, has given rise to the term black plague or black death.

The presence of fever in association with the glandular swellings makes the diagnosis easy when an epidemic is prevailing, but this cannot be positive until the glandular swellings appear or the case is violent and rapid in its course.

The prognosis is uncertain, but it is unfavorable when the disease is epidemic, even in cases which seem mild. When the patient survives till the fifth day the disease may go on steadily to a fatal termination, but if the fever decreases and there are no brain-complications a favorable result may be hoped for.

A Japanese physician, Dr. Kitasato, has the credit of having discovered the bacillus of the plague. He was a pupil of Dr. Koch, at Berlin, and was sent to Hong Kong by the Japanese Government to study the epidemic. Unsanitary conditions are supposed to favor the development and dispersion of the bacilli, and most favorable fields for its propagation existed both in Hong Kong and Canton. But in the former place the most stringent measures were adopted by the Government, under the direction of the ablest physicians, to isolate the cases and limit the disease. In Canton nothing whatever was done by the Government either to isolate cases or to remove unsanitary conditions. If statistics could be had, it would be interesting to compare the results in the two places, but no means of comparison exist.

It is to be stated, however, that the epidemic ran its course *pari passu* in the two cities, and declined and disappeared at the same time in both.

The pathologic changes produced by the disease are yet for the most part to be studied. Locally, the glandular system is involved, and morbid changes in the blood are manifest, and in many cases a semi-comatose condition indicates that there are changes in the brain. The physicians in Hong Kong who gave special attention to the study of the disease will no doubt publish the results of their investigations. Post-mortem examinations cannot be made in Canton.

The most important element in the treatment is to

remove patients from the crowded unsanitary localities and dwellings where they are attacked. Temporary hospitals were opened in Hong Kong and Canton, where fresh air was abundant and proper attention could be given by trained nurses. Plague-patients brought to the Medical Missionary Society's Hospital were placed in boats anchored in the river, but we lacked the important element of trained nurses. In the native hospitals (large mat sheds) the ventilation was all that could be desired, but the nursing was deficient.

In regard to medical treatment, the rapid progress of the disease gave little room for testing the value of any method.

We treated the fever on general principles, using some antiseptic internally. Because of the depressing influence of the poison, antipyretics had to be used with caution. The mental depression was one of the most unfavorable symptoms, and was, no doubt, responsible for many deaths. One of our patients who had been an attendant on other patients gave up all hope as soon as the glandular swelling appeared.

The probability is that the disease will reappear next year, as it has prevailed for two or three years in succession in the districts southwest of Canton. It has extended to towns and cities which are in direct communication with the provincial capital, and its course in a northerly direction will be watched with much interest. It has now almost entirely disappeared from Canton and Hong Kong. Respectfully,

J. G. Kerr.

Canton, Sept. 10, 1894.

NEWS ITEMS.

Football Casualties.—On Saturday last the following accidents occurred: During a match between the Blackburn Rovers and Burnley teams, a Burnley player fractured his leg, and another "injured his ankle." At Tottenham Marshes a player fractured his right leg, and another player, in a match close by, dislocated his patella. In a match at Idle, between the Windhill and Idle teams, a player fractured his spine and died on the following day.—*Lancet*, September 29, 1894.

A football player, named Hudson, was killed, or rather killed himself, at Shipley, on September 22d. He charged the forwards, and so injured his neck and spine that he died on the following day. Our recent remarks on the dangers attending the present style of play and the need of some revision of the rules have excited the indignation of certain friends of the game; but such incidents as this serve to prove that the best friends of this sport are those who desire to see it shorn of those elements which tend to brutalization. The reports state that during the game at which this accident happened there was so much roughness that three players were ordered off the field. We trust that the comments we have recently made, which have been, we are glad to see, quoted extensively throughout the press, will have the effect of strengthening the authority of umpires and of encouraging them to interfere in time to prevent the repetition of the disasters which during recent years have outraged public sentiment.—*Lancet*, October 6, 1894.

Three Harvard players have been injured in one week. Arthur Brewer was hurt in the Orange game, and Waters and Mackie will not resume work till the last of the week.

"Ans" Beard was not at the field to-day, and inquiry to-night brought forth the fact that he has gone home to Poughkeepsie, N. Y. He had been complaining for several days of soreness, and has developed some stomach trouble. How serious that trouble is has not been learned.—*The N. Y. Herald*, October 16, 1894.

For a Better Milk-supply.—The Philadelphia Board of Health has instructed the Chief Inspector of Milk to indorse as untrustworthy all certificates testifying to the freedom of herds of milch-cows from tuberculosis that are not based upon the use of the tuberculin-test by trained veterinarians. A register is to be kept in which shall be recorded all herds of milch-cows that supply the city of Philadelphia that have been certified as free from tuberculosis by the method approved by the Board of Health, as well as such as have not been reliably certified and which are to be designated as "suspicious." These records shall also contain the names of dealers supplied from the various herds and shall be open to the inspection of the public. All producers of milk supplying the city of Philadelphia who fail after sixty days' notice to furnish a certificate or clean bill of health of their cattle, based on the method of examination demanded by experts and approved by the Board of Health, shall be reported to the Board and be liable to have their milk rejected as being suspicious.

Meetings of Philadelphia Medical Societies:

Neurological Society,	4th Monday of month, Oct.—April.	Oct. 22
Obstetrical Society,	1st Thursday of month, Sept.—June.	Nov. 1
Pathological Society,	2d and 4th Thursdays of month, Sept.—June.	Oct. 25

A Course of Ten Lectures on the History of Medicine will be given in Alumni Hall (College Building) of the Medical Department of the University of Buffalo, by Dr. Roswell Park. The first lecture was given on Octo- 8th, at 8.15 P. M. Subsequent lectures will occupy each succeeding Monday evening till the course is completed.

These lectures have been so prepared as to treat of political, religious, philosophic, and other issues which have influenced the progress of the medical sciences. They are open to all who are interested in the subject.

Dr. W. F. Howard, Jr., has been elected associate professor of pathology in the Western Reserve University.

MATERNAL IMPRESSIONS.[1]

BY HUBERT WORK, M.D.,
OF PUEBLO, COL.

SINCE the time when the cunning and unscrupulous Jacob placed "pilled" rods in the streams where Laban's cattle came to drink, thereby multiplying the "ring-streaked, spotted, and speckled," which by previous agreement were to constitute his wages, the probable influence of maternal impressions on the unborn has been the subject of much speculation. Apparently in the time of Jacob such a probability was not open to doubt, as his historian made no attempt to attribute the success of the stratagem to other than natural causes, and that, too, at a period when most explanations were essayed from supernatural premises. Within the present century, however, scholarly efforts have been made to prove that the immaterial mind could not possibly "mark" or malform the material body. But instances multiply so rapidly that they have become embarrassing to those attempting to attribute them to the possibility of coincidence.

Those who believe that maternal emotions may influence the physical or mental development of the fetus have, in a measure, been silenced by the doubts of the skeptical and by the difficulty of giving a reason, which, together with the maternal instinct that prompts the concealment of congenital blemishes of offspring, have made the number of children having such defects appear much smaller than it really is.

I have no doubt that every observing medical man of ten years' obstetric experience can cite from one to ten or more instances in which the defects in a child corresponded in location and appearance to that which caused the impression upon the mind of the mother; while among the laity the number uncovered by inquiry is almost incredible.

At present, the proposition that maternal impressions may deform the child *in utero* must be proved empirically, by authentically recorded instances too certain and numerous to be explained by mere coincidence, reinforced by the opinions of physicians whose experience and professional standing are beyond question. With this in mind, I sent personally to a few physicians, whose deliberate opinions on any subject cannot be lightly regarded, the following questions:

1. Do pronounced impressions made upon the mind of a pregnant woman predispose to bodily defects and birthmarks in the child?

2. Do such impressions influence the mental development of the child?

3. If, in your opinion, bodily or mental defects are thus produced, which of the emotions most frequently cause these defects?

With the permission of the writers, I quote a few of the replies, not failing to record a single opinion expressing doubt, or denying the probability.

R. A. F. Penrose, M.D., LL.D., Philadelphia:

"1. Undoubtedly. Their influence is very great. Illustrative cases of everyday experience.

"2. I am confident they do.

"3. The emotions of fright, dread, disgust, indeed all the depressing emotions. On the other hand, I am equally sure that the mother's bodily and nervous condition may have the most happy influence on the fetus for good, both physically and mentally."

William Goodell, M.D., LL.D., Philadelphia:

"1. I believe that they do.

"2. I feel very sure that they do.

"3. Unquestionably the emotion of fear."

Louis Starr, M.D., Philadelphia:

"1. Yes.

"2. Yes, but not so frequently as physical development.

"3. Fear and shocking or disgusting sights, as of deformities, etc."

M. P. Hatfield, M.D., Chicago:

"1. I emphatically believe they do not.

"2. Possibly."

3. He gives as causes of these defects and marks: "Prolonged mental strain, especially when conjoined with the lack of proper food."

Matthew D. Mann, M.D., Buffalo:

"1. I think they do; I am sure I have met with instances.

"2. Have never seen anything to make me think that this is the case."

Barton Cooke Hirst, M.D., Philadelphia:

"1. I believe they do, but rarely. I have seen a child with a triangular piece out of one ear, whose mother had her ear violently tweaked in the second month of pregnancy by her husband, in a fit of

[1] Read before the Twenty-fourth Annual Convention of the Colorado State Medical Society, Denver, June, 1894.

passion. How can such a case be otherwise explained?

"2. Indisputably they do. Barnaby Rudge has many a prototype in actual life. I know personally of several cases of idiocy and perverted instincts due to maternal impressions.

"3. I cannot say. Fright and violent anger, I should think."

P. R. Thombs, M.D., Pueblo, Col.:

"1. Yes.

"2. Yes.

"3. The emotion of fear."

A. T. King, M.D., Pueblo, Col.:

"1. Yes. I have a record of three instances where such impressions did interfere with the normal development of the child.

"2. I do not know, as it is quite difficult to follow a child from birth to an age when such mental conditions could be observed.

"3. Fear."

Jesse Hawes, M.D., Greeley, Col.:

"1. Doubtful.

"2. Doubtful.

"3. A few facts seem to show pronounced impressions made upon the minds of pregnant women predispose to bodily defects and 'birthmarks' in the child. *Many* facts seem to teach a contrary belief. Question still *sub judice*, in my belief."

W. A. Edwards, M.D., San Diego, Cal.:

"1. Possibly.

"2. It seems probable that such effect is produced."

E. Fletcher Ingals, M.D., Chicago:

"1. I have never been able to discover any relation between mental impressions and 'birthmarks,' but mental or physical depression may check development, and thus cause defects in the offspring.

"2. I think not, excepting as stated above. The parents, one or both, laboring under cerebral, functional, or organic disease at the time of conception, may, I think, influence mental development."

Frank P. Norbury, M.D., Illinois:

"1. I have reason to believe they do.

"2. It is certainly a fact that mental development is predisposed or predetermined by the hereditary factor, which I believe may be influenced by pronounced impressions upon the mind of a pregnant woman.

"3. It is difficult to say, from lack of extended investigation, but I believe fright or sudden grief will, in an impressionable person, be most marked. . . . The mental habit or mental characteristic will largely determine this point."

F. E. Waxham, M.D., Denver:

. . . . "Personally I have never seen the defects that are so frequently attributed to mental impressions during pregnancy. As there is no nervous connection between the mother and fetus, I cannot understand why a mental impression can affect any particular portion of the anatomy of the fetus.

"I can readily understand, however, that severe mental agitation or mental shock, as from fright, anger, or sudden grief, by influencing the circulation, which may not be re-established, in a certain part of the fetus, may thus influence its development."

. . . . "This, to my mind, is the only reasonable explanation of these deformities. In the majority of cases I believe that mental impressions and bodily defects are simply coincidences. I have known of many cases in which mothers have been shocked during pregnancy, and they were sure that the infant would be born deformed as the result; but never have I known their predictions to come true."

The trend of the foregoing opinions is readily seen. But one is emphatic in his disbelief, yet as a cause of these defects he gives "prolonged mental strain," a state of mind in so many cases dependent upon mental impressions. "Mental or physical *depression*" is also given as a cause, a condition frequently secondary to mental depression in the susceptible pregnant woman; while a third reply advances the theory that "severe mental agitation or mental shock, by influencing the circulation, may influence the development of a part."

I have tabulated a few cases of congenital defects of physical development and "marks," after the plan of Dabney. But, unlike his list, which was taken from reported cases, the following table is made up from my own limited obstetric experience, together with cases narrated to me by physicians whom I meet daily; no attempt having been made to collect such data, and no case has been entered except those occurring in the practice of the physicians reporting:

There being no tangible nervous connection between the mother and the fetus through which disturbing influences might be conveyed, in the sense that a nervous impulse is transmitted, in my opinion the most probable explanation, both for defects of development of a part and of marks and scars as well, is that of the occurrence of a local circulatory stasis, apoplexy or inflammation, at some period of the gestation, induced by deviation from the normal of the chemistry or circulation of the maternal blood. Of the microscopic development of the fetal circulation we know little; but it is not presumable that there is the circulatory perfection in the forming embryo that is known to exist in the adult.

The fetus and the newly-born bleed readily, because of the weakness of embryonic tissue, and for

No.	Physician reporting.	Cause or nature of impression.	Period of pregnancy.	Nature of defect.
1	A. T. King,	Woman saw husband emerge from a mine frightfully burned. Feared child would be marked.	7th mo.	Child born with red spots similar in location and appearance to those on the father. Gradually faded out like the blush of a burn.
2	A. T. King,	Woman frightened by black dog trying to seize her ear. Feared child would be marked.	Beginning 7th mo.	Same ear of child of coarse texture with fringe of black hair on pinna.
3	A. T. King,	Woman suddenly confronted by mangled husband Felt child struggle violently, and announced its death.	8th mo.	Child stillborn on fifth day.
4	F. D. Green,	Woman saw hog disembowel a dog. No fear of defect in child.	Early period.	Absence of abdominal walls.
5	C. O. Rice,	Woman saw dog bite her daughter on right thigh. Insisted that her child would be similarly marked.	4th mo.	Child born at term with red scar identical in location and appearance with the wound of sister.
6	Hubert Work,	Woman frightened by rat striking her temple.	Last half.	Child born with black patch on same temple.
7	Hubert Work,	Woman much disturbed by congenital mark on face of friend's baby.	Entire period.	Child born with mark identical in location and appearance.
8	Hubert Work,	Woman much disturbed by seeing epaulets on husband, by which she knew he had enlisted in army.	First half.	Child born with cartilaginous epaulets.
9	Hubert Work,	Mother frightened in a practical joke by mass of sausage.	Late period.	Child born with skin of one side mottled like sausage.
10	Hubert Work,	Woman frightened by snake falling on shoulder, then to ground.	Late period.	Same side of child from shoulder to toes red.
11	Hubert Work,	This child matured and became pregnant. Feared her child would be similarly marked.	Entire period.	Child born with same marks as mother, but less vivid.
12	Hubert Work,	Woman had ear-ring forcibly torn from lobe of left ear. Thought ear was lacerated, but it was not. Did not fear child would be marked.	4th mo.	Child born with lobe of left ear divided from center through the edge.
13	Hubert Work,	Woman took peculiar delight in imitating walk of talipes equino-varus. Husband tried to prevent it, and impress danger of deforming child.	Last half.	Child born with double talipes equino-varus. No heredity.
14	Hubert Work,	Woman frightened by harelip man.	Early period.	Child born at term with harelip.
15	Hubert Work,	Woman suffered from conjunctivitis. Did not fear marking child.	Entire period.	Child born at term with red blush on eyelids, which gradually disappeared.
16	Hubert Work,	Woman saw enraged husband cut three toes from a chicken. Feared child would be marked.	Last half.	Child born with three stubs of fingers on one hand.
17	Hubert Work,	Woman saw child fall, cutting occiput. Avoided touching herself, believing that the part touched would be marked in child.	5th mo.	Child born at term with red patch over occiput.
18	W. W. Bulette,	A woman falling scalded both hands. No fear of mark on child.	5th mo.	Child born at term. Both hands looked identically as though scalded some weeks previously.
19	P. H. Heller,	Woman frightened by man with harelip. Feared child would be marked.	4th mo.	Child born at term with harelip.
20	P. H. Heller,	Woman saw man with "port-wine" mark on right side of face. Feared child would be marked.	Prior to 4th mo.	Child born at term with similar mark, but smaller, on right side of face.
21	Hubert Work,	Woman saw boy's face lacerated. Badly frightened; feared child would be marked.	8th mo.	Child born at term with red blushes similar to those of the injured boy.
22	Hubert Work,	Woman much impressed by seeing deformed ear of a guest. Feared child would be marked.	2d mo.	Child born at term with ear identical to that of guest.
23	Hubert Work,	Woman fell, cutting vertex. Feared child would be marked.	7th mo.	Child born at term with patch of white hair corresponding in location to injury of mother.
24	Hubert Work,	Woman frightened by seeing husband's arm and hand sprinkled with blood.	Beginning 8th mo.	Child born at term with same arm and hand mottled with red spots.

this same reason prenatal apoplexies are doubtless very common. With the immediate and remote results of such extravasations we are familiar: occlusions, with compensating collateral dilatation, local starvation, absorption, and inflammation, with its changes. The cessation, even momentary, of fetal circulation, cannot but be hurtful. The resisting power of the fetal tissue is below that of the maternal structures, which may not be impressed by the blood changes resulting from the emotional disturbance of grief or fear, or of kindred emotions, but which may be equal to causing an extravasation, or to the lighting up of an inflammation in the peritoneum of the fetus, or an inflammation of the meninges, possibly to a point where the brain is absorbed, and the child born an encephalic; or the palatine arch may suffer, and a cleft palate result; or at a later period inflammatory processes may occur in the scalp, resulting in the growth of a patch of white hair, or develop the unsightly nevus, the fainter blush of a "strawberry" or "fern-leaf;" or, if the process begins nearer the date of birth, the stage may be that of active suppuration, of which there are so many recorded instances; and in these cases the mother may remain exempt, as in those reported cases in which children are born with smallpox, syphilis, scarlet fever, etc., the mother being unaffected.

It is a simple process to trace congenital diseases existing at birth through the different stages of

repair to recovery, and from our knowledge of the healing process in similar lesions occurring after birth, we can form an approximate opinion concerning the time of the fetal lesion.

Case No. 78, of Dabney's table, in which the child was born six weeks after his older brother had suffered a bruised thumb, having a blackened nail identical with that of the brother, and coming off on the same day with his, was clearly of inflammatory origin. Also the case reported by Dr. Goodell, with the granulating prepuce. Case No. 1, of the table in this paper, was doubtless of recent inflammatory origin, and many others can be as clearly traced.

In cases of diminutive digits, it will be noticed that the member, though dwarfed, is entire, even to the shriveled nail, presenting the appearance of a member the nutrition of which has been interfered with, either by inflammation or its sequelæ, the acute process having subsided.

Those cases which present localized blushes, so frequently seen in the newborn, but which in a few weeks or months disappear, are, probably, from previous reasoning, results of maternal mental traumatisms.

That the milk of a nursing mother may be so vitiated by anger or grief as to excite vomiting, collapse, or convulsions in the child, or even cause its death, is no longer a question of doubt; and we know that the same emotions will destroy the fetus. It is not, then, unreasonable to believe that the maternal emotion able to kill the fetus or cause its immediate expulsion from the womb might accomplish the less violent result of a local vascular dilatation or an inflammation with ensuing deformity.

A noticeable feature in all reported cases is that those having a defect of development are attributed to a period of gestation when the part deformed is known to be in a formative state; while those describing skin-lesions are attributed to impressions occurring at periods only after the formation of the integument. The impression which marks the skin, doubtless, would, if received early enough, distort the body.

Observation has shown that the wife, after bearing many children to one husband, has grown to resemble him — not because of those physical changes common to age, but the physiognomy is similar. And it has also been noticed that the first-born more naturally resembles the father than the mother, particularly if pregnancy promptly follows marriage. Dr. Harvey, in the *Edinburgh Medical Journal*, has described the case of a creole woman who bore fair children to a white man, but afterward to a creole male bore other children who much resembled the white man, both in features and complexion. The influence of the first male upon the future progeny of the female has been recognized for many hundreds of years. The subsequent offspring of the Earl's Arabian mare that escaped to the desert and mated with a quagga, and of the domestic sow that mated with a wild boar, together with the instances cited in Abdel Kader's celebrated letter on the Arabian horse, are evidences of this, while the kennel-master of to-day regards as worthless the female dog which has mated the first time with a mongrel, after which she cannot be relied upon to transmit the characteristics of herself or of the purest sire. The blending of the blood of parents through the medium of the fetus has been offered in explanation of such influence, as being more reasonable than the possible influence of the mental impression coincident with the first sexual approach. The former theory perished when the physiologist learned that the fetal blood gave up to that of the mother waste only, in exchange for oxygen and nutriment, by osmosis.

Whether or not the mental stability of the child is influenced by the state of the mother's mind before its birth, because of the time necessarily elapsing between the impressions and the evidence, is a matter more difficult to demonstrate than the question of bodily defects. Yet there is a greater unanimity of opinion among physicians within the scope of my inquiries on the former than on the latter point; a vast majority evidently believing with Esquirol, that "it is often in the mother's womb that we are to look for the true causes, not only of imbecility, but often of different kinds of mania." This case, reported by the same authority, is so typical of the many coming under the observations of those given to such inquiries, that I quote it. "A pregnant woman, otherwise healthy, who was greatly alarmed by the threats of a drunken husband, gave birth to a child that had been so much affected by the mother's agitation that up to the age of eighteen years it was subject to panic-terrors, and then became completely maniacal."

The following conclusions seem justified by the information which has been available to me on this subject:

1. That both physical and mental defects follow maternal mental impressions with such frequency as to establish the relationship of cause and effect.

2. That these conditions are the result of changes in the blood, chemic, circulatory, or both, seems probable.

3. That the probability of defects in the fetus, from mental causes, is dependent upon the "mental habit or mental characteristics" (Norbury), or susceptibility of the mother.

4. That maternal anticipation of defect in the child has in itself no influence in the absence of a strong impression.

5. That the impression need not be lasting to cause defects.

6. That personal maternal injury is no more likely to mark the child than the sight of it in another.

7. That the defect is not necessarily similar in location or appearance to the object creating the impression, but is likely to be. The apparent constancy of likeness is due to the reporting of such cases only.

If we accept this theory, strengthened as it is by the opinions and beliefs of our greatest teachers and by constantly recurring cases equally reasonable and no more mysterious than a majority of medical theories upon which we base rules of practice, it becomes a part of our duty to so instruct those who depend upon our advice at such times, to avoid contact with those physically or mentally deformed, surgical operations, the sight of acute suffering, convulsions, confinement, death-bed scenes, or attendance on the injured, whether animal or human. And the possibilities of such impressions should be urged upon our municipal authorities, that the distorted stumps of the organ-grinder might be removed from the public thoroughfares, and the disease-corroded tramp be deterred from soliciting alms from every housewife who may chance to answer his knock.

THE TREATMENT OF CHRONIC OOPHORITIS BY LOCALIZED ELECTRICITY.

By EDWARD SANDERS, M.D.,
of New York.

(Continued from p. 429.)

About five years ago I began the use of electricity in the treatment of chronic oophoritis—at first with considerable doubt, but as time passed and positive results became manifest, with more and more confidence. Up to that time medical means had been my only reliance, and these failing, as they almost always did, except in the more recent cases, a resort to surgical interference was all that remained to be recommended. At present this latter advice is only given when electricity in proper cases has failed: for it is not claimed that it will always and invariably succeed. Due care being exercised in the selection of patients, it will cure in the large majority of cases; but experience has shown that there are certain instances in which it will fail or even do harm. Its failure to rapidly relieve symptoms I now regard an indication for operation, while their aggravation is an almost sure sign of the presence of pus. When it does succeed, and this it will do in fully 90 per cent. of all cases, the relief it gives is quickly obtained, although cure of the disease itself is not so soon brought about. Often patients declined further treatment simply because they could not understand why they should persevere when they no longer suffered, for it is remarkable how soon pain and the other distressing symptoms of the the disease vanished, even though the lesion itself showed no positive sign of improvement.

Electricity can be employed in the large majority of cases of chronic oöphoritis, there being, so far as my experience goes, but three contra-indications to its use: the presence of pus, that is, pus-tubes or pelvic or ovarian abscess; the coexistence of acute pelvic inflammation; while the presence of old, unyielding, and extensive adhesions between the various pelvic parts invariably leads to failure. Loose or recent adhesions do not forbid its use. When pus exists, its presence will be shown, when otherwise not indicated, by aggravation of pain, or the occurrence of an intermittent, bearing-down pain, labor-like in character, as I have a few times observed. These latter symptoms present themselves during or shortly after the application, so that their occurrence is of diagnostic significance, and forbids the further resort to electricity. When widespread adhesions exist no harm follows, but absolutely no benefit can be expected. Outside of these three contra-indications there are absolutely no others, no matter what complication may be present in the case; in fact, the treatment directed against the oophoritis will also serve to benefit and even cure all other uterine or tubal conditions coexisting, as, for instance, subinvolution, areolar hyperplasia, chronic endometritis, catarrhal salpingitis, pachysalpingitis, and even hydrosalpinx.

The advantages of electric treatment are manifold: (1) its safety; (2) the ease and painlessness of its application; (3) its non-interference with the daily routine of patients; (4) its restoration of parts to a normal or comparatively normal condition; (5) the possibility of future gravidity; (6) non-mutilation; and (7) when failure occurs the possibility of a resort to the more radical measures of surgery.

Now, as regards safety. Up to the present I have employed electricity many hundred times in the treatment of the various diseases of the female genitalia, and only once has there been an accident, and in this instance the fault was mine. This also has been the experience of all who have employed this agent.

As we have seen, the principal and most persistent opponents of electricity in gynecology are the celiotomists, and no wonder, for it invades the field which they consider their own. They claim that the difficulties and dangers of operation are increased by its previous use; that septic processes are set up, resulting in abscess-formation and adhesions; that valuable time is lost by what they call mere tinkering, and in this way results jeopardized.

Against these claims we have their boasted steady diminution in death-rate, which certainly does not indicate increased complications. Besides it has been conclusively shown that as a matter of fact the positive galvanic pole is actually a destroyer of germs, being one of the best antiseptics we have at present. In addition the same precautions, the same perfection of technique, are at the command of the electrician as are employed by the surgeon; and slovenly electrification like slovenly surgery must pay the usual penalty attached to carelessness. Due care, proper precautions, and due obedience to indications being exercised, the employment of electricity, as shown by the general experience of electricians, is absolutely without danger. In the foregoing remarks electro-puncture is left entirely out of the question, for this method I do not employ against chronic oophoritis.

These cases being "walking cases" may be treated in the office, care being taken to keep them comparatively quiet for an hour or so after the application. This done the woman may be allowed to go about her business attending to whatever work she may have to do. This, of course, within the bounds of reason.

It has been claimed that the use of electricity prevents future gravidity; that the woman is rendered as sterile as though she had had her ovaries removed. This, in my experience, is not true, for of the cases treated no less than seven became pregnant under observation, one in fact being twice delivered of living, healthy children after a previous sterile interval of four years. One other case had borne no child for five years, another for eight years, while still another had not conceived for eleven years. This result is all the more wonderful when we remember that sterility is the rule in chronic oophoritis.

The only disadvantage of this plan of treatment is its tediousness, months intervening before a cure is obtained. But, as we have seen, this is also true, and even to a greater degree, of surgery—one, two, and even more years often being required before the patients consider themselves well, even after their ovaries and tubes have been removed. So, as compared with oophorectomy, this objection falls to the ground. Besides, although six months or more are needed to cure the lesion itself, the symptoms often disappear after a few applications; not always, however, remaining permanently absent, though when they do recur they soon again disappear after further applications.

The plan of treatment recommended is comparatively simple, and requires only the ordinary apparatus called for in scientific electro-gynecology. A good working cabinet battery, consisting of a galvanic and a faradic apparatus is essential; my preference being for that made by the Waite & Bartlett Manufacturing Co. Connected with the galvanic battery we require a milliampèremeter and a rheostat. The galvanic cells should be sixty in number, connected up in series in such manner with a current-selector that any number of cells may be thrown into the circuit. In practice, however, it is best to employ the whole sixty cells, regulating the strength of the current by means of the rheostat; in this way the wear and tear falling upon all the cells alike, so that when our battery does give out it does so like the one-horse shay—all together. With the exercise of ordinary foresight there is no danger of shock, care being taken that all connections are properly and firmly made. The prefered rheostat is the so-called New Bailey Current Controller, latest pattern, which permits us to turn the current on or off with the utmost nicety and precision, and without fear of polarization.

The faradic apparatus should consist of four cells so arranged that one or all can be thrown into the circuit, and having a series of coils of coarse and fine wire, the latter being most useful in the relief of pain, and, therefore, the one most employed in chronic oophritis. Above all, the Engelmann coils, as supplied with the cabinet previously recommended, are to my mind the best so far in the market. The latest faradic apparatus recently introduced by this authority would seem to be even better.

The electrodes needed are few. A pad, either of clay, as recommended by Apostoli, or, what I prefer, one made of felt covered by oil-tanned chamois, which has the advantage of being durable, cleanly, and always ready for use, may be used for external application. The internal electrodes are a clay ball, a platinum sound, and a bipolar vaginal and a bipolar intra-uterine. The clay ball had best be modified by giving it a block-tin center and a chamois leather external covering, thus making it more durable and safer; the usual carbon center being in time softened and separated from the shaft, and in this way giving rise to shock, with its incident pain and fright.

When the simple relief of pain is our first object, the faradic current, fine coil, with very fine interruptions, is to be resorted to, the electrode used being either the bipolar vaginal or the bipolar uterine, the strength of current being regulated by the patient's sensations, never using a current strong enough to produce pain. The length of the sitting should be between ten and twenty minutes. Frequently I have employed faradism by placing the clay ball in the vagina and the felt pad over the abdomen or posteriorly over the lumbar region, according to the position of the ovary, the current being thus passed directly through the diseased

vagina. As a rule, when we resort to faradism it is only in the beginning of the treatment, the single object attained being the relief of pain. Generally, however, from the very start, galvanism is the form of the agent to be preferred, for in these cases it not only relieves pain almost as well as faradism, but it has the advantage also of at once initiating the cure of the disease. Faradism simply overcomes the symptom pain; galvanism relieves suffering, while at the same time bringing about a cure. Therefore, galvanism is the agent *par excellence* for the cure of chronic oophoritis. With the patient on her back, the knees drawn up and separated, the clay ball, wrapped in absorbent cotton wet with carbolic acid-solution, is passed, without using a speculum, up into the vagina to the vault, laterally, right or left, or posteriorly, the object being to bring it as close as possible to the affected ovary. When the ovary is about in its normal position, the external pad is placed over the lower abdomen; when the ovary is prolapsed into the lateral pouch or the cul-de-sac of Douglas, over the back. Care should be taken that all scratches, scars, moles, etc., are protected by some non-conducting material or oiled silk, rubber tissue, etc., and that all bony prominences are avoided, for otherwise pain will be caused. As regards the selection of the active pole: In the beginning, when it is very important to relieve the existing pain of the disease, the positive pole had better be preferred, for although its curative qualities are not as marked as those of the negative, yet its sedative properties are far greater. Pain having been relieved a persistent use of the negative pole should be entered upon. When uterine or tubal complications are marked and severe it will be best to resort to the platinum intra-uterine electrode.

The strength of current should vary between 50 and 150 milliampères, never less, if possible, than the former strength, never greater than the latter; the strength selected varying with the duration of the disease and the object to be attained, due attention being paid to the sensitiveness of the patient, and absolute pain being always avoided. As a rule, it is best to begin with the lower intensity, persisting with it if good results follow; but otherwise, if there be no visible improvement, the intensity should be gradually increased until the highest named is reached. Old-standing cases usually require the strongest currents. The duration of the sitting varies with the milliampèrage employed, three minutes with 150 and seven minutes with from 50 to 75 milliampères. The number of séances had best be about three a week in the beginning; later on, when decided improvement has taken place, two sittings a week only will be found sufficient, and toward the latter end of treatment one a week only will be called for. Of course, it goes without saying, that no applications are to be made just before, during, or immediately after the menstrual epoch.

The usual antiseptic precautions should be taken, cleanliness being as essential here as in surgery; while the patient should be directed to rest for an hour or so immediately after the sitting.

The average duration of treatment in my experience is about four months, though some cases do not recover in less than one year. Relapses are rare, though occasionally occurring, but again yield to the same plan of treatment.

So far I have treated 67 cases of chronic oophoritis by electricity. But of these only a minority are available in the determination of the actual worth of the method; for only 30 persisted in the treatment long enough to obtain positive results; while in 37 attendance was suspended too soon or was too irregular. Of the 30 in whom the treatment was carried on to the end, 27 were completely cured, while in only three was there absolute failure. That is, fully 90 per cent. were cured without risk to life or inconvenience of any kind whatever. Of these, five had been previously advised to have their ovaries removed by well-known New York specialists.

Only two of these cured cases were uncomplicated, the other twenty-five having various existing conditions which more or less modified and prolonged treatment. Thus, in seventeen cases there was complicating chronic endometritis, once there was uterine subinvolution, twice areolar hyperplasia was present, once adhesive uterus, once old pelvic peritonitis (giving rise to considerable matting together of parts), ten times there was prolapsus ovarii, once the ovary was adherent, three times there was pachysalpingitis, and in one other case hydrosalpinx was found. It is not claimed that the treatment in these cases always restores the ovaries to an absolutely normal condition, but this it does in the majority of cases. Even when, for instance, the ovary has remained prolapsed, or still gives to the touch indications of persistent change, all symptoms have disappeared and have remained absent as long as the patient remained under observation—often for months, and even years, after all treatment had been suspended. The average duration of treatment was about four months—in some the cure being wrought in less time, in others a longer time being consumed. Cure is obtained quickly in recent cases, old standing and widely complicated ones requiring more prolonged and persistent treatment. But, as we have seen, this is nothing as compared with operative interference, for when cure does follow in such it is usually only made apparent months and even years after the offending bodies have been removed. A noteworthy fact is here again to be emphasized—that

in no less than seven of these cured cases pregnancy occurred. This is all the more remarkable when we remember that sterility is the rule in chronic oophoritis, and it has been claimed that electricity is as sure to prevent conception as the actual removal of the ovaries. Thus one great objection to the use of electricity falls to the ground.

Of the three cases of failure, in one there was universal matting together of the pelvic parts by very old, unyielding, and dense adhesions to such a degree that some years before coming under my care removal of the ovaries had been attempted, but abandoned, by the late Dr. Hunter. Another case was one also of widespread unyielding adhesions. In both of these cases some temporary benefit was obtained at first, but the final result was failure. A third case was one in which treatment was, I believe, abandoned by me too soon, the sufferings of the patient being so great, and permanent benefit failing to follow rapidly, that operation was recommended. This was done, both tubes and ovaries being removed. One year later some improvement was noted, but the woman still suffered from as much pain as before operation, while menstruation continued regularly and accompanied by great pain during the flow.

Of the thirty-seven uncompleted cases no less than thirty were being more or less progressively benefited up to the time of abandonment of treatment. I have little doubt that some of these went on improving, as it is a remarkable fact that healthy action having once been set up by electricity continues even after the use of the agent has been stopped altogether. The same fact has been noticed after the cessation of the electric treatment of fibroids. That such is true has been proved to me by the presentation after a long interval of several patients who had previously voluntarily ceased attendance, but who remained absolutely free from symptoms referable to the ovaries during the interval, and in whom examination showed the cure to be complete. The complicating conditions in these thirty cases were eighteen times endometritis, twice areolar hyperplasia, three times adhesio ovarii, four times hydrosalpinx, once pachysalpingitis, and once uterine fibroid.

The seven cases of failure do not speak against this plan of treatment, for in not one of them was it continued long enough to determine anything, the number of sittings in none exceeding five, the rule being that only one or two seances were given.

To quote from a previous article (*The American Journal of Obstetrics*, etc., 1893, vol. xxviii): "Very few of these (cured) cases made uninterrupted recoveries; pain would for some time be absent entirely, only to recur on some indiscretion; menstruation might become perfectly regular, but occasionally the previous irregularity and dysmenorrhea would return temporarily. One symptom which almost invariably remained permanently absent after it had once vanished was dyspareunia. The patients' general condition also usually steadily improved. Intercurrent ailments always had a bad effect upon the symptoms, for on such occasions they almost invariably recurred, though never with their former intensity, and then only to again rapidly disappear on continuance of the treatment. The ovarian disease itself, though rapidly modified, was not so quick to disappear as the rational symptoms it produced. But almost from the beginning of treatment there was steady modification and improvement in the local lesion; sensitiveness diminished, the ovary became continually smaller and smaller until it reached its normal dimensions, and, if descended, as a rule it steadily rose up to its normal position, though there were a number of exceptions to this rule, the ovary remaining down, but otherwise becoming normal to the touch. Most of the cases were seen and examined months after the cessation of treatment, and remained well in spite of hard work and a return to their old mode of life, which was generally one of hardship."

To recapitulate: The main elements for success are (1) proper selection of patients, pus-cases, cases of acute pelvic inflammation, and those in which adhesions are old and extensive, being unsuited to this plan of treatment; (2) the use of a good-working apparatus, a well-constructed cabinet, an accurate meter, and a reliable, smooth-working rheostat, constituting the main essentials, together with the employment of the proper electrodes properly placed; (3) absolute cleanliness; (4) careful regulation of sittings as regards frequency, strength of current, duration, and seat of application; (5) rest for a short time after each sitting; (6) continuance of treatment during a period of from four months to one year; (7) indications being followed and treatment persisted in, we may expect a cure in fully 90 per cent. of all cases.

So firm is my faith in this plan of treatment that I would consider myself culpable, in the absence of pus, acute inflammation, or extensive adhesions, medical measures having failed, in recommending operation without having previously persistently employed faradism and galvanism. Electricity failing, the knife alone, and then only, is to be thought of. If this rule be followed a comparatively small percentage of the cases of salpingo-ovarian disease, pus-cases excepted, will demand operation.

126 East Eighty-second Street.

Treatment of Leukoplakia.—Rosenberg (*Münch. med. Woch.*, No. 39, p. 771) has successfully treated by applications with a brush of a 20 per cent. solution of potassium iodid an obstinate case of leukoplakia linguæ, which had for seven years resisted varied forms of treatment.

SUPRAPUBIC CYSTOTOMY FOR CHRONIC CYSTITIS.[1]

By J. S. PRICE, M.D.,
of Beaumont, Texas.

The older writers seemed to have known but one indication that would warrant opening the bladder above the pubes, and that was vesical calculi. Notwithstanding the time-honored law of placing an inflamed organ at rest, the bladder was denied that physiologic rest for which it so often appealed, for the reason, perhaps, that the pathognomonic click of a stone could not be elicited.

It is the purpose of this paper to point out some of the salient indications demanding the operation of suprapubic cystotomy among those cases of chronic cystitis that have proved intractable to other more conservative measures. Like its close companion, symphysiotomy, it is fast finding a place in surgical procedure, and, not unlike unhinging the pubic symphysis, it has its contra-indications.

In Chelius' *System of Surgery*, translated from the German edition published 1847, the high operation is spoken of as follows:

"Cutting for the stone by the high operation consists in opening the bladder between the upper edge of the pubic symphysis and the fold of peritoneum passing over the bladder; this operation was first performed by Franco in the year 1561, and he must be considered as the discoverer of the method, although Archagines had previously proposed it. Rouset closely describes the proceeding and points out its advantages. It found, however, but little acceptation on account of the still general opinion of the great danger of wounding the bladder, until it was first again performed in England by Probi; then brought into some repute by John Douglass, Cheselden, Prye, Thornhill, MacGill, Heister, and Moran. The lateral operation, however, soon displaced it; but Frere Comes' fortunate experience (1779) raised it again for a short time."

Dr. William T. Belfield, of Chicago, very happily remarks that cystitis, in his opinion, belongs in the same category as jaundice, dropsy, and fever—a symptom and result; a signal to search for a cause. Keyes classifies the causes of cystitis as follows:

1. Traumatism, mechanical or chemic;
2. Extension of inflammation;
3. Exacerbation of preëxisting inflammation;
4. Specific action of drugs;
5. Neurosis; to which Dr. A. Vander Veer adds
6. General or systemic infection.

In considering the first members of his classification one of the most prolific causes will be encountered in dealing with strictures of the male urethra. Here we are confronted with cystitis arising from two factors, mechanical interference from impermeable stricture, coupled with an extension of gonorrheal infection to the walls of the viscus. If seen early in its history the merest tyro in surgery is equal to the emergency, and relief is speedily given by an external perineal urethrotomy, but unfortunately such is not always the case, as a pen-picture from Dr. W. B. Rodgers, of Memphis, Tenn., well delineates:

"A perineum red, tense, and bulging; a scrotum almost projecting itself forward, firm, tense, infiltrated, and here and there marked by fistulous openings discharging foul-smelling pus. Careful inspection shows but the faintest outline of a perineal raphé, and that thrown to the side; palpation fails to detect scarcely more than the sides of the subpubic arch; *per rectum*, the finger locates the prostate and pubic rami for a short distance; but all else felt anteriorly is a hard, swollen mass.

"The history of the case is one of multiple stricture of years' standing; efforts at dilatation have resulted in false passages; the urethral tissues have been cicatrized to the last degree by electricity in the hands of a novice. The bladder is now filled to its capacity; the new-formed perineal abscess has produced a high temperature with occasional rigors, and an hour's careful effort, aided by anesthesia, has not succeeded in passing a guide beyond the bulb. Such is a case for external perineal urethrotomy without a guide.

"An anatomist can readily reach the healthy urethra through the normal perineum without the aid of the staff or other urethral guide, and that, too, with comparatively little danger to the patient; he has his landmarks to go by; but when these are destroyed by old fistulæ, by new collections of pus, destroying the median line, and even the course of the urethra itself by inflammatory processes, blending and matting together in one conglomerate mass every muscle and plane of fascia, the scene has changed, and anatomical knowledge and skill are taxed to their utmost, as line by line the tissues are divided from without, until finally, aided by good light and the sense of touch, the urethra is found, opened, and a probe is steadily passed onward to the bladder.

"The opening of the membranous urethra by an incision through a pus-infiltrated perineum without the aid of a urethral guide has been rightly styled one of the most delicate and difficult operations in surgery."

Fortunately for the less brilliant operator, there is a nearer route to the bladder, on reaching which the proximal opening of the urethra can be entered with a soft-rubber bougie and made to locate the strictured portion from within, the steel sound indicating the distal portion of the stricture. We can safely cut down between the two and bring the soft instrument partially through, leaving it in the strictured portion until healing takes place. Dr. Hunter McGuire conceived the idea of relieving those confirmed cases of chronic cystitis arising from enlarged prostate, when catheter-life was no longer practicable, by the establishment by means of the simple operation of suprapubic cystotomy of an artificial urethra, through which we are enabled to drain the bladder and treat the chronic inflammation which always attends these cases. The most gratifying results have invariably attended his work.

The perineal operation fails to afford perfect drainage to the bladder, especially in the old, in whom the posterior wall of the bladder has become literally lower than its outlet; consequently, if an inflam-

[1] Read before the Southeast Texas Medical Association.

matory process be engrafted, we find the organ placed *hors de combat* in the matter of completely evacuating itself. Hence, bacterial and chemic changes take place in the residual urine, thus tending to perpetuate a cystitis that would yield to ordinary remedial measures in the young.

Tuberculosis of the bladder has always been an opprobrium to the science of surgery, yet it would seem from the gratifying results reported by those who are authorities on this subject, that

"In suprapubic cystotomy we open up a direct route for the more effectual treatment of the tubercular lesions, and thus not only constitute the most efficient palliative measure, but also the most effective procedure in retarding the local extension of the disease by direct, vigorous anti-tubercular treatment." (Senn.)

If malaria can be excluded, I believe, when in doubt, we are justified in opening the bladder in all cases of chronic cystitis; we are then able to discover and treat the cause under conditions most favorable to recovery. It might be urged that we could arrive at a correct diagnosis by the use of the cystoscope; but unfortunately we are not all familiar with its use, and in nine cases out of ten when its use becomes necessary to a diagnosis the result is operative procedure in the end; hence, the general physician will not go far amiss if he operate at once on all his cases of chronic inflammation of the bladder that fail to respond to the routine treatment of this malady.

In answer to a letter addressed to leading American surgeons, Dr. B. F. Hadra, of San Antonio, Texas, among others, replies as follows:

"In my opinion, cystotomy, or rather cystostomy, is the rational treatment in cases of chronic cystitis that have resisted the usual treatment by internal medication, by injection, dilatations, etc. The procedure gives an easy opportunity to find the pathological cause (if cystoscopy is not resorted to), which often is hidden. Thus small calculi, polyps, tumors, tuberculosis, etc., may be diagnosticated and attended to at once; then it will allow a good drainage, the evacuation of the residual urine, a thorough washing, and the establishment of a permanent canal. In tubercular cystitis the operation has sometimes been followed by the same beneficial effect as the corresponding operation in peritoneal tuberculosis, perhaps by admitting air. In prostatic enlargement, it seems but reasonable to give the viscus another chance of thorough evacuation; I am though, of the opinion, that, as a rule, the suprapubic operation should be done, even in the female. Perineal cystotomy, as a method to procure drainage, is a total failure, simply from anatomical reasons. Cysto-vaginal fistulæ are repugnant and hard to keep working. All this is overcome by a suprapubic artificial urethra, which can be borne for a lifetime without much annoyance, if properly attended to, and the operation is almost free of danger and in the grasp of the general practitioner."

Dr. William T. Belfield, of Chicago, replies as follows:

"Regarding chronic cystitis as almost invariably a secondary condition, a consequence of some antecedent morbid condition, I do not treat the cystitis by cystotomy or in any other way. I endeavor to recognize and detect the cause that I feel sure exists. Sometimes it is impossible to remove the cause when found; carcinoma or tuberculosis, for example; in such a case an artificial incision may be a desirable palliative measure. Sometimes it is impossible to detect the cause even with the cystoscope; in such a case, an incision serves both for exploration and for drainage. But a cystotomy as a means for treating cystitis I never make, because, as already stated, there is something back of the cystitis which the surgeon should search for. He may find the cause at any portion of the urinary tract from meatus to kidney, or in the adjacent organs—uterus or broad ligaments in women, rectum in men, etc. Cystitis, in my opinion, belongs to the same category, as jaundice, dropsy, and fever—a symptom and result, a signal to search for a cause."

Dr. Hunter McGuire writes:

"I have relieved chronic cases of cystitis repeatedly by performing suprapubic cystotomy and relieving the bladder."

In one of Dr. McGuire's clinical lectures the simplicity of the operation is so well portrayed that I give it as an example of the ease with which the operation may be done. Speaking to his class of students, while lecturing on the formation of an artificial urethra in chronic cystitis from enlarged prostate, he said:

"With this small scalpel I make an incision through the skin and superficial fascia in the median line, commencing about two inches above the pubic bone, and extending down to the level of its upper border; the recti muscles are now exposed, and I separate their fibers with the handle of my knife, and the wound is deepened to the tranverse fascia. This I incise, and you see the pre-vesical fat, which always lies just in front of the bladder. There are several large veins running through it, so I shove them aside without injuring them, and scratch through the friable tissue. My finger now rests upon the walls of the bladder, and I can plainly feel the fluctuation of water it contains. I place the back of my knife against the upper border of the pubis, and boldly push its point through the wall of the bladder and cut upward about half of an inch. I take a stitch through its walls and the skin at the margin of the wound, and the operation is completed. It has not taken me more than two minutes, and I have used no instrument except this little knife. The loss of blood has not exceeded a teaspoonful, as the incision has been made through tissues which contain no vessels large enough to be dignified by a name."

In conclusion I will give some notes of a case that will demonstrate the point that I have striven to establish in this paper:

T. I., colored, aged eighteen years, has no history of venereal disease; his present disease dates back to childhood, when his parents, after using all persuasive means at their command, finally thrashed the child for an enuresis over which he tried in vain to make them understand he had no control. His complaint grew worse as years passed by, compelling him to leave his work every hour or two during the day to evacuate his bladder. Strange to say, he never sought medical aid until I was called to him one night. Vesical tenesmus had become so un-

bearable that he was unable to sleep. A collection of his urine revealed almost half blood, a condition that he had more than once noticed. The symptoms simulated so closely those of stone that I was quite certain that with the ordinary silver catheter I could relieve the bladder and at the same time confirm my diagnosis. The catheter was passed, and no sooner did it reach the cavity of the bladder than a decided sensation was conducted to my fingers; while not quite sure, I believed it to be a stone with which my catheter had come in contact. The interference seemed to aggravate his condition very much, so much so that morphin had to be given to restore quiet. His father was informed that an operation was necessary, to which he readily agreed. The boy was brought to the office the following day, where I had invited several of my confrères to assist in the proposed operation. After again examining his bladder it was found to hold only about six or eight ounces of liquid, which we used to distend the viscus thoroughly. The same sensation, as if some hard substance suddenly came in contact with the sound, could by a certain movement again be elicited. It was decided to try systemic measures, which had hitherto been neglected, that we might ascertain the benefit to be derived therefrom. He was very much emaciated, and was placed on Basham's mixture of iron. I was compelled to use some form of anodyne constantly, as no improvement had taken place in the vesical tenesmus, which grew so unmanageable that relief must come from some other source, and hence his father was requested to bring him again to the office, where a suprapubic cystotomy was performed, with the kind assistance of Drs. Blewett, Perkins, and Selman. Upon opening the bladder there was an alarming gush of blood, as if a large vein had been cut. This was speedily controlled by a bichlorid solution. The bladder was very much thickened, and adherent anteriorly to the abdominal walls.

The index-finger, when passed around the walls of the bladder, received a sensation as if the entire surface was covered with papillomata. This, of course, explained all the foregoing history, the diagnosis of which my microscope and sound had failed to reveal; had they so served me in making a diagnosis, it will be understood that the treatment would have been the same—a point that I trust I have well established in this paper.

An attempt was made to scratch away some of these growths, but their extreme vascularity compelled me to desist.

It is claimed that pyoktanin, or methyl-blue, has a peculiar affinity for the nuclei of embryonal tissue, and is a great pus-destroyer; consequently, with this rationale of its action, it was used in a solution of about one dram to the quart of water, flushing the bladder through the urethra, and allowing the solution to escape through the upper opening. Pus, though at first very abundant, rapidly diminished, until finally there were no traces to be seen on irrigating. The bladder-cavity was so small that it was impracticable to close the opening, which has a constant tendency to close; hence, he has to pass his urine more frequently than usual. Though this is a source of annoyance, the boy says that he is much more happy than formerly.

CLINICAL LECTURE.

PREMATURE MENOPAUSE; RETROVERSION; REMOVAL OF APPENDAGES; RETRO-DISPLACEMENT WITH FIXATION.

Delivered at the Jefferson College Hospital, March 13, 1894.

By E. E. MONTGOMERY, M.D.,

PROFESSOR OF CLINICAL GYNECOLOGY, JEFFERSON MEDICAL COLLEGE; GYNECOLOGIST TO JEFFERSON AND ST. JOSEPH'S HOSPITALS; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

PREMATURE MENOPAUSE.

Gentlemen: I bring before you to-day a patient with the following history: She is twenty-seven years of age, had good health as a child, and the family history is a good one. She suffered no special diseases during childhood; puberty occurred at fourteen, the menses were regular, the intervals being five weeks, the periods lasting three days, the discharge profuse and quite painful. She has been married four years, has had no children, indeed, has never been pregnant. Menstruation continued regular after her marriage, but gradually became less, and continued for periods lasting a shorter length of time, until October last, when it ceased. When married her weight was ninety-eight pounds; at present it is one hundred and seventy. She enjoys excellent health, without pain or ache. I bring her before you to consider the history, which presents a record of having a slight physique, with menstruation regular, painful, and rather profuse. In a short time she has increased largely in weight, and associated with it is a cessation of menstruation. This is one of the cases in which it is quite probable there has been a premature menopause, and it is more than likely due to the excessive amount of adipose tissue, which has developed in this individual to such an extent as to be, to a certain degree, an indication of disease. The excessive rapidity of the deposit of adipose tissue has resulted in the arrest of the menstrual function; possibly in the change of the ovary itself, so the process of maturation of Graafian follicles has been arrested, and this is one of those cases in which undoubtedly ovulation has been discontinued, and with it the accompanying pelvic congestion which causes menstruation. These cases are not very frequent in occurrence, but occur occasionally, and it is well known that patients may have amenorrhea attendant upon a large amount of deposit of adipose tissue, particularly where this deposit has occurred rapidly and in a way to indicate, almost, disease of itself. The probability of restoration of the function in such a patient is rather doubtful. If she was very desirous of having children it might be well to put her on a course of diet which would decrease the amount of fat, giving her largely albuminous foods, cutting off starches, sugars, and fats, and giving a very limited amount of liquids. In addition it would be well for her to be placed upon the use of alteratives, such as the chlorid of gold and sodium in conjunction with tonics, as extract of nux vomica; the action of the bowels should be regulated. In other words, our course of treatment should be directed to increasing the quantity of blood and decreasing fat. I question whether in this

patient any plan of treatment would result in cure of the condition and increase the probability of conception.

I have received to-day a letter from a graduate of this school, asking me to send him my best prescription for amenorrhea. This is a very difficult task. I do not know of any prescription that can be designated as the best one for amenorrhea. The treatment must be dependent upon conditions present in the patient. We must examine the individual and treat the particular symptoms. As you can readily understand, the treatment in this patient would be very different from that in an individual suffering from chlorosis, in whom the absence of menstruation was due to a serious blood disorder.

RETROVERSION.

The next patient has been treated in the out-patient department since the 12th of December. She is twenty-one years of age; puberty occurred at fourteen; the menses are regular, lasting six days. Three years ago she had pain in the abdomen, which occurred before each menstrual period and continued for two days; she has been married three years and has had two children, the last born five months ago. The labors were normal, and she was in bed eight days during each puerperal convalescence. She has never had a miscarriage. At the time she applied for treatment she complained of pain in the back, a feeling of weight and tension in the lower abdomen and pelvis. She has had a hemorrhagic discharge at times, and before the class some time ago the diagnosis of subinvolution was made, and she was directed to be placed upon the use of tonics and hot-water vaginal enemata. She has been given quinin, ergotin, iron sulphate, and hot-water enemata. The uterus was retroverted and in a state of subinvolution. As I examine her to-day I find the uterus occupies its normal position, the fundus lying forward, the cervix directed backward. When she first came under our observation she had been delivered but two weeks previously, and suffered consequently from a large subinvoluted uterus which fell back of its own weight.

A backward displacement of the organ necessarily interfered with its circulation, keeping up the tendency to subinvolution. The first step, consequently, in the treatment of such a case would be to replace the organ and maintain it in its replaced position. This procedure will bring about a change in the circulation. Just so long as the organ remains in the abnormal position circulation is interfered with, and we shall have her suffering from arrest of involution and increased weight of the organ. The only way to bring about proper involution of the organ is to replace it and maintain it at a higher level. The circulation is thus improved, and we may hope for an improved condition. After the delivery of the woman, as she lies on her back, the heavy uterus drops backward, or if a bandage is tightly applied, the fundus may be forced backward. If this position is maintained for a length of time, it settles further down in the pelvis, and the displacement is increased by constipation, by any intra-abdominal pressure, which necessarily is directed against the anterior surface of the fundus and drives it further down into the pelvis. The process of involution is necessarily arrested by the interference of the circulation, and, as we have already said, the first thing to do is to replace the organ and use means to maintain it.

Ordinarily the organ is very readily replaced. This is done in one of three ways: 1. By placing the patient upon her back with the limbs flexed, and, introducing two fingers into the posterior fornix, we push up the fundus with the middle finger, while the index hooks over the front of the cervix, pushing it backward and upward. This action on the lower end of the lever tilts the other end forward until it can be grasped by the hand over the abdomen and dragged forward in the position of anteversion. 2. The patient is placed in the same position as before, the sound or one of the repositors is introduced, and the restoration of the uterus to its normal position accomplished. If a sound is used, it is curved so that it passes into the canal without producing undue pressure, and then its external end is rotated through a wide arc, and by pressure with the finger against the fundus through the posterior cul-de-sac or through the rectum, and pressure backward upon the external end of the sound, the fundus between the two is carried forward. This method of procedure, however, is one that should be rarely exercised on account of the injury that must necessarily take place to the uterine mucous membrane. 3. The third method of procedure consists in placing the woman in the genu-pectoral position, that is, upon knees and chest. In this position the intra-abdominal pressure is not only removed but to a certain degree aspiration induced, when, by introducing Sims' speculum the vagina becomes ballooned and the fundus of the organ is carried upward. We should not make the mistake, however, of supposing that the abnormal position is necessarily corrected; the fundus will be carried up and remain in its abnormal position. This can be corrected by grasping the cervix with a tenaculum or volsellum, pulling down upon it and carrying it backward and forward, when the position is at once corrected.

We now have to consider how it shall be maintained in this position. The most usual method of maintaining the uterus is by means of the pessary. Of pessaries we have a large variety. Those most frequently used are the modifications of the Hodge pessary, known as the Smith-Hodge; I like still better the Thomas and Mundé, both of which have a thickened posterior bar. The latter, probably, is the better, as the pessary is broader at its posterior surface and converges toward the anterior. It is important in using the pessary to make sure that it is well adapted to the patient for whom it is used. To determine this the parts should be carefully measured to see that the pessary is of proper length and width. The length can be determined by passing two fingers into the vagina, pressing up into the posterior fornix and measuring the point at which the arch of the pubis strikes against the finger. This gives the length of the pessary that can be readily borne. A pessary too short will permit the fundus to fall backward and subsequently bend over the pessary, forming a retroflexion which will give more discomfort than the original condition. The width that can be comfortably borne will be determined by separating the fingers in the vagina. A pessary that is too long will press uncomfortably against the posterior fornix or will project from the vulva and give rise to distress in sitting and walking. If it presses against the lateral or posterior wall it may give rise to ulceration

and the cicatricial tissue following will be so tender that a pessary subsequently cannot be readily borne. As it is introduced the parts should be carefully examined that it does not cause undue pressure, and instruction should be given the patient how it may be removed in case it causes distress. If the parts are tender and the pessary cannot be borne, a tampon of gauze, cotton, or wool should be introduced, to hold the organ up. In this way the posterior fornix may be stretched, inflammatory exudation absorbed, and tenderness relieved, so that subsequently a properly fitting pessary may be worn. It should be kept in mind that the posterior bar of the pessary does not support the fundus of the womb; in other words, the womb does not rest on the pessary, but by a pulley-like action upon the posterior fornix of the vagina the cervix is drawn backward and upward, and consequently the other end of the lever falls forward. When a pessary is introduced the patient should be cautioned to return at the end of a week for an examination, and subsequently she should not go for longer than two months without its removal for cleansing. During the time the pessary is worn no injection of metallic salts should be used, for the reason that they may lead to a deposit upon the surface of the pessary, roughening it and rendering it a source of irritation. Even when injections are not used, the secretions of the vagina will lead to deposit of their salts upon the surface of the pessary, causing it to become roughened. This roughening irritates and abrades the mucous membrane, leads to the formation of granulations which may subsequently completely envelop the pessary. I was called to see some few years ago a woman who had worn a pessary for twenty-six years without its removal. In her case the posterior half of the pessary was completely imbedded in tissue that was probably half an inch in thickness over the posterior bar of the pessary. The appearance of this tissue and the character of the discharge associated with it led the physician to suspect it was a form of malignant disease. Examining the case, I did not care to cut through the dense tissue to remove the pessary, so I drew the pessary down on one side with a pair of bone-pliers, cut it in two, and on the opposite side in the same way, then the remaining portion was slipped out of its groove. The irritation subsided and the patient recovered. In this case the result, of course, was a cure of the displacement for which the pessary had been used, but we would not care to follow such a plan in many cases. When we find the pessary cannot be borne, a tampon may be applied. Tampons may simply consist of gauze or wool, or may be medicated with various agents. Some preparation of glycerin is most generally used for this purpose, for the reason that it has a marked affinity for the watery portion of the blood and acts practically as a hydragogue, producing a free depletion of the bloodvessels. With the glycerin we may combine various medicinal agents, such as potassium iodid, muriate of ammonia, or ichthyol, agents which have a marked alterative effect upon the mucous membrane. Of these agents probably ichthyol is the most efficient, using it in ten to fifteen per cent. solution in glycerin. It acts not only as an alterative agent, but it has a positive anodyne effect upon the pelvic tissues. In consideration of the replacement of the uterus, we may find in some cases the fundus of the organ is caught beneath the promontory of the sacrum, where the bone is markedly curved. In such cases we are unable to accomplish the restoration. We may, however, readily effect it by catching the cervix by means of a tenaculum or volsellum, dragging down upon it, while the fundus is pushed upward with the finger, either in the rectum or posterior fornix of the vagina; then carrying the cervix upward and backward, the fundus is brought forward into its proper position. There are some cases in which the fundus of the uterus is held in a retroverted or retroflexed position by adhesions between it and the rectal wall, or the uterus may be more or less bound down in such an abnormal position. This can be overcome in one of two ways: first, opening the abdomen, tearing up adhesions and bringing the uterus forward. When this is done it is a preferable procedure to fasten the uterus by means of the introduction of sutures, performing the operation known as hysterorrhaphy or ventro-fixation. The other method is one that is less rapid in accomplishing it, and yet is one that is certainly effective, and that is by means of pelvic massage. Introducing two fingers into the vagina and with the other hand over the abdomen, bring the offending organ between the two hands, lifting it up a number of times, and stretching the ligaments as far as they will permit, then moving the uterus from side to side, in this way putting the parts through a massage which results in the absorption of any exudation or bands of adhesions, and subsequently the entire freedom of the uterus. Another method of procedure that has been suggested for maintaining a retroverted uterus in its normal position is known as the Alexander operation, which consists in making an opening upon either side over either inguinal ring, exposing and drawing out the round ligament. This method of procedure, however, is subject to a number of objections. First, in such cases the round ligament may have become so atrophied that it is useless to serve the purpose; second, where any inflammatory condition has existed in the pelvis the ligament may have been more or less bound in its groove and does not readily slip; third, it is necessary to make two wounds in a position in which it is difficult to protect them and preserve the parts from subsequent infection; fourth, any infection which takes place here may result in the failure to fix the round ligaments, and these infected structures slipping back carry infection beneath the peritoneum to a point which is difficult to reach, so that the patient necessarily suffers danger. On the other hand, by ventro-fixation we have but one wound; the uterus is more certainly brought forward in its normal position; it is applicable to a greater variety of cases, and the danger of infection is much less.

REMOVAL OF APPENDAGES.

This patient is twenty-three years of age; her father is living and healthy; the mother died from bronchitis. She was healthy as a child; puberty occurred at fourteen; menstruation is normal; she married at seventeen, and has had three children. The first labor was protracted, instruments were used, and the perineum lacerated. Her last child was born two years ago, without instruments. Four weeks later she was sick with a pelvic inflammation, and was confined to bed for three weeks. She had a second attack four

months later, which also lasted two weeks. A month before entrance to the hospital, on the 14th of February, she was confined to bed a week with a third attack; she complains of pain in the left inguinal region since the first attack of inflammation, also pain over the sacrum, and she has frontal and coronal headache. Three months after her first labor the perineum was repaired. On operation, we found the left ovary partly occupied by a small cyst. The tube was enlarged and occluded, both tube and ovary were removed. The right ovary was normal in size, but projecting from it was a hematoma which was equal in size to another ovary. The tube was similar to that of the left, and was also removed. The wound was closed with a single row of silkworm-gut sutures. Subsequent to the operation the patient had an elevation of temperature and some suppuration in the line of the wound, which rendered recovery slow. She has been suffering since the operation with some pain in her abdomen. You see the line of the cicatrix here and suppuration in the median line. One point of interest in this patient is, that following operation on the perineum she has had a great deal of discomfort in sitting down. The operation known as the Tait operation was performed, and the inconvenience has been induced by carrying the incision too far out upon the integument, so that a band of tissue was formed which is rendered tense by separation of the limbs, and in sitting down this becomes extremely painful. I propose to give relief by cutting through the band and stitching the skin edges together on either side. Such an example as this should teach you to be careful in operation not to bring your union out upon the skin-edges, as such a cicatricial band gives rise to very great discomfort. In examining this patient's pelvis I find no special trouble. The uterus is slightly flexed, there is some induration of the broad ligament on the left side; nothing, however, that indicates any suppurative condition or collection of pus. The patient has been kept perfectly quiet, her bowels regular, douches of hot water given in the vagina, and counter-irritants over the abdomen; with administration of tonics, a certain amount of rest will be sufficient to bring about her relief. This may also be very greatly expedited by the practice of uterine massage, as the manipulation of these tissues is just as effective in promoting absorption or exudation as it could be in ankylosis of the limb.

RETRO-DISPLACEMENT WITH FIXATION.

The next patient is twenty-five years of age, and both of her parents are still living. She has been suffering from some pelvic disturbance for quite a length of time. She comes to-day for the purpose of undergoing careful examination. As we introduce the finger into the vagina, we find it comes in contact about an inch-and-a-half from the vulva with the cervix, which is directed in the axis of the vagina. As we pass the finger into the posterior fornix it comes in contact with the posterior surface of the uterus, showing that the fundus of the uterus is lying in Douglas' pouch. Pressure shows that there is a certain amount of fixation in the broad ligament, more particularly on the left side. This is one of the cases in which there may be a question with regard to the treatment of the patient by means of uterine massage. The first thing is to secure, as a prerequisite, the coöperation of the patient. If the patient resists at every effort at the correction of the displacement we shall have great difficulty in bringing about the desired result. At present the fixation is so great that we could not at once bring about replacement of the organ. Adhesions occur between the rectum and the uterus, and prevent us bringing about the relief by manipulation, which could be accomplished otherwise, and it will be necessary to subject her to uterine massage for a length of time in order to break up and absorb the adhesions and enable us to bring the organ forward.

CLINICAL MEMORANDUM.

A CASE OF GUNSHOT WOUND OF THE HEART.

SERVICE OF DR. KERR,
SURGEON TO THE EMERGENCY HOSPITAL, WASHINGTON, D. C.

[Reported by JAMES R. CHURCH, M D., Senior Assistant Resident Physician.]

WHILE a case of gunshot of the heart, with survival for a time after the injury received, is not unique in the annals of surgery, yet such instances are of interest as an indication of what perhaps may develop some day along this line in parallelism with the surgery of the brain.

A. W., a white man, sixty-seven years old, was brought into the receiving-ward of the Emergency Hospital at 5.40 P.M., suffering from a gunshot wound of the thorax inflicted at 4.50. Upon his admission he was in a state of collapse, the features pinched and pale, the body covered with a clammy perspiration, and the dressings over the wound stained with blood. The wound, which had been made by a pistol-bullet (32 caliber), was situated one-and-a-quarter inches below the mammary line and a little to the left of the center of the sternum, and through it considerable blood had escaped. The pulse was almost imperceptible, the respiration fair, the mind wandering. The man was put to bed, the usual therapeutic agents were employed, and transfusion was performed, but the condition became steadily worse, and death took place at 7.45.

A post-mortem examination was made, which showed that the ball had pierced the sternum just above the xiphoid cartilage, and entered the pericardium to the right and at the lower part. The sac was filled with blood, both fresh and clotted. The heart was pierced through the right ventricle, as shown in the photograph, which shows the anterior wound, one-half inch in diameter. The wound of exit was five-eighths of an inch in diameter and ragged. The diaphragm was perforated and the omentum wounded in several places.

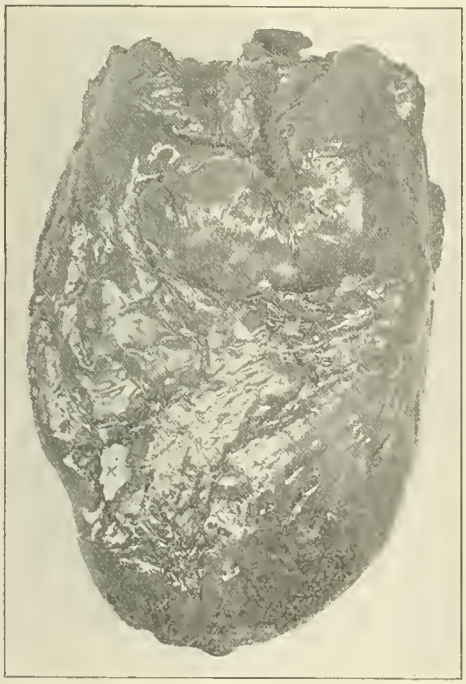
The ball itself was lodged under the skin posteriorly between the ninth and tenth ribs.

The hemorrhage had been very fierce. the pericardium being choked with blood, the pleural cavity containing a large quantity, and the peritoneal cavity considerable.

The question which naturally presents itself in view of such cases is the possibility of some reparative measure. If a man can live for three hours with such an injury, it does not seem beyond the bounds of possibility that, with the advance of surgery, operative interference may at sometime be justifiable. The surgeon of to-day hesitates to meddle with the heart, but the views of cardiac surgery are probably no more pronounced now than

were the opinions on brain-surgery fifteen years ago, when Dante's motto of "Leave all hope behind, ye who enter here" was the common verdict of the profession in regard to any operation involving the cortex.

In the *Index-Catalogue of the Army Medical Museum* there are reported 22 cases of direct injury to the heart, all of which lived over three hours; 17 lived over three days; 8 lived over ten days; 2 lived over 25 days; 1 died on the fifty-fifth day, and there were three well-authenticated recoveries. Dr. S. S. Purple, of New York, gives in the *New York Medical Journal* (vol. xiv, pp. 411–434), an account of a recovery from a wound penetrating both ventricles (confirmation of the diagnosis by post-mortem nine years subsequently), and a tabulated list of 42 cases which survived injury for from thirty minutes to seventy days. Dr. C. E. Lavender, in the *Proceedings of the Medical Association of Alabama* (1851, pp. 104–181), reports a recovery from an incised wound of the heart, and Dr. C. L. Ford, in the *New York Medical Record* (1875, p. 173), cites a case of buckshot injury with recovery. From these statistics, and they are only a partial list of those recorded, it seems that the heart is capable of resisting traumatic interference to a certain degree and of fulfilling its function in spite of more or less injury.



X. Wound of exit.

If this be so under such unfavorable circumstances as in neglected wounds, why should not the parallel hold good in surgery, when every advantage is seized and little left to chance?

There are three main objections to surgical interference with the heart: 1. The danger of stopping the cardiac action. 2. The question as to the possibility of starting pulsation if it cease; and 3. The danger of the entrance of air into the circulation.

In the first place it remains to be seen whether the application of sutures would check the heart's action. If it would, which is not proved, the question of restarting the heart would have to be settled. As for the third objection, it has been shown experimentally that this is not so great a factor as has been supposed. Drs. Hare and De Schweinitz, of Philadelphia, have done much work along the line of experimental cardiac surgery. Whether their results have been published I do not know, but they have demonstrated that the intravenous injection of large quantities of air is not necessarily fatal.

If, then, a heart may sustain a grave injury and perform its function for so long a period as five days, or even five hours, why should not some remedial measures be possible and allowable, as the present view is that all direct wounds of the heart are necessarily fatal sooner or later, and that no hope, or practically none, lies in a policy of non-interference.

In view of the statistics quoted, it might at least be open to discussion whether a surgeon might not open the pericardium, clean out the clots, close the wound in the heart-wall, and give his patient a chance of recovery. It is no more improbable now than was the removal of a tumor from the motor area of the brain in the recent past.

THERAPEUTIC NOTE.

FORMALIN IN THE TREATMENT OF CHANCROIDS AND VENEREAL WARTS.

By H. R. GAYLORD, M.D.,
RESIDENT PHYSICIAN IN THE PHILADELPHIA HOSPITAL.

In a paper read before the Microscopical Society, in Washington, January 9, 1894, Dr. W. W. Alleger speaks of having tried formalin in the treatment of chancroids, but gives no particulars other than that the lesions healed rapidly after one application of the full-strength solution. There were no bad results except pain, which, however, he considered more severe than necessary, and he intended using a weaker solution in the future.

I have had the opportunity of trying the drug in several cases of chancroids in the venereal wards of the Philadelphia Hospital. In four cases which were under observation sufficiently long to be certain that they did not relapse, the results were uniformly favorable.

Case I was a male, twenty-eight years of age. He had an active, well-defined chancroid on the dorsal surface of the inner aspect of his prepuce, which was touched with formalin, full strength, on a cotton swab. One day later a thick, brown crust had formed over the sore, and on the fourth day this separated, leaving a healthy ulcer that healed rapidly under antiseptic dressings. The pain in this case was not severe, and no anesthetic was used.

Case II was a male, forty-six years of age. He had multiple chancroids on the inner aspect of the prepuce, varying in size from a pin-point to a quarter of an inch in diameter. These were carefully touched with the full-strength solution, which produced severe pain, lasting several minutes. One week from the institution of the treatment the entire prepuce was free from chancroids, except two small areas which had been overlooked. These were then treated in a similar manner,

with the result that they, too, entirely disappeared by the end of the following week.

CASE III was a female, twenty years of age. She had a chancroid the size of a penny on the inner aspect of the left thigh, one inch from the labium. This was treated with formalin, in a 20 per cent. solution, and the application was repeated in twenty-four hours. The patient complained greatly of the pain of the first application. The second was preceded by the application of a 10 per cent. solution of cocain, with the effect of decreasing, though not entirely relieving the pain. Five days from the first treatment the chancroid had decreased in size to that of a pea, but the center was still active, and was again touched with a 10 per cent. solution. Ten days from the first treatment there was nothing left but a scar.

CASE IV was a male, twenty-four years of age. He had fifteen chancroids distributed over the penis, the scrotum, and pubic eminence. He had been in the hospital two months, had had his prepuce laid open, and two buboes were open and suppurating. This mass of infection had made but slight progress under the usual antiseptic treatment, and he was in a deplorable condition.

On September 13 the chancroids on the penis were dressed with a 10 per cent. solution of formalin, and the buboes had gauze saturated with a 1 per cent. solution laid over them.

On September 14 I dressed the buboes with a 5 per cent. solution; on the 15th and 16th, with a 5 per cent. solution; and on the 17th with a 3 per cent. solution. The pain had become so severe at this point that treatment was discontinued.

On September 20 the buboes were again dressed with a 5 per cent. solution of formalin. The pain produced by this dressing was so acute that I reduced the strength of the solution to ½ per cent., and used this for three days more, when I found it necessary to discontinue the dressings entirely.

During this treatment the improvement of the chancroids on the penis and of one of the buboes was most marked. Two large chancroidal areas healed entirely, and the bubo mentioned formed a superficial slough, which came away, leaving a healthy granulating surface, which is now nearly healed. The extreme sensitiveness which the patient developed to the pain produced by the drug was very unusual, and was so marked toward the end that a ½ per cent. solution could not be borne without the use of opiates.

CASE V was a male, forty-two years of age. The penis was covered with venereal warts arising from the preputial fold and glans. These were touched with formalin, full strength, and on account of the large surface covered produced intense pain.

In four days the warts were reduced to less than half their original size, and on a second application of a full-strength solution they disappeared entirely in five days more.

The results in these cases show that the best results are obtained when full-strength solutions can be used, and then one application is usually sufficient.

The pain produced by the full-strength (40 per cent.) is not markedly greater than that produced by solutions above 10 per cent. Pain, while excessive, can be deadened by cocain, when it is probably not more severe than that caused by nitric acid. The drug should not be applied over large surfaces except in weak solution. When continued for a protracted period of time it tends to lead to an intolerance on account of the pain produced.

Formalin recommends itself for office-use when the patient is anxious for speedy relief and is willing to endure the pain. The fact that the active principle of formalin is a gas would seem to indicate its use in buboes which are open, as it acts on the deepest recesses of the wound. The formation of the crust, however, which it produces, in one case, at least, prevented drainage, and in this way delayed the result.

MEDICAL PROGRESS.

The Bacterio pathology of the Tooth-pulp.—As the outcome of a study of the pulps of 250 diseased teeth, MILLER (*Verhandl. d. deutsch. Odontolog. Gesell.*, Bd. vi, H. 1, 2; *Centralbl. f. Bakteriol. u. Parasit.*, Bd. xvi, No. 10, 11, p. 447) formulates the following conclusions: The infectious processes of the tooth-pulp are associated, with but few exceptions, with mixed infection, cocci and bacilli being almost equally represented. Somewhat less frequently long, thin threads and spirals are found. Bacilli and threads with spores are also sometimes present, but not frequently. The microscopic examination of cover-glass preparations alone justifies the assumption that micrococci especially participate in the suppurative process. The bacteria find their way to the pulp principally through carious dentine, even a thin layer of which suffices to protect the pulp from infection. Infection of the pulp through the circulation, while conceivable, is scarcely capable of direct demonstration. The pulp is predisposed to infection by the action of the products formed in the carious dentine, such as acids and ptomains. Forms of bacteria, particularly spirals, not capable of cultivation, play a prominent part in the production of disease of the pulp. A considerable number of cultivable bacilli have been found in connection with disease of the pulp; but, as a rule, they possess no special pathogenic activity. The typical pyogenic cocci, the staphylococcus pyogenes aureus and albus, and the streptococcus pyogenes, are but rarely found in pus in the pulp. On the other hand, a number of cocci, particularly a closely related group that induce suppuration in mice, are found. In spite of careful search the presence of the pneumonia-coccus could not be detected. The activity of the cocci found in the pulp is increased by co-existence of putrefactive processes. A putrid condition of the pulp, whether the presence of bacteria in the body be demonstrable in pure culture or not, is always a dangerous source of infection. The putrefactive processes in the tooth-pulp are to be ascribed to various forms of bacteria. The putrefactive products are not always the same. In addition to gaseous substances there occur others whose nature is deserving of further study.

Fatal Poisoning by Sewer-Air.—WEBBER (*Lancet*, No. 3708, p. 686) has reported the case of a girl four years old, who for two days had complained of sore-throat and difficulty in breathing. Immediately previous to

this the child, in common with the other children of the family, had suffered from what the parents described as mumps, during recovery from which the other symptoms appeared. The parents complained of constant bad smells, and on inspection the origin of these was found in a small court-yard in the back of the house in which the cesspit of the adjoining house was situated. This was furnished with an inspection-hole, the cover of which, a flat stone, fitted badly, and from which sewer-air escaped. It was stated that when the cesspit became very full the sewage forced its way beneath the cover into the court-yard. Several members of the family in the adjacent houses had for some time suffered from anemia and occasional sore-throat. The little patient appeared anemic and ill. On examination the tonsils, faucial interspace, and pharynx were found covered with muco-pus. The tongue was thickly coated with a creamy-white fur and a purulent discharge oozed from the anterior nares. The submaxillary glands were slightly enlarged. The temperature was 102° and the pulse 110. The local condition improved upon the administration of four minims of tincture of ferric chlorid every four hours and the application to the throat and nose of a boric-acid solution. The child, however, continued weak and anemic. In the course of a week she made complaint of pain in the abdomen, which on examination was found to be moderately full. The liver was uniformly enlarged, smooth, and slightly tender, the edge rounded and reaching downward to a level of two inches above the umbilicus; the dulness commenced above at the sixth rib, and tenderness was complained of on percussion over the lower ribs. The area of splenic dulness was not increased. The child continued in this collapsed condition and albumin appeared in the urine. Amid symptoms of profound asthenia death took place two weeks after the onset of the first symptoms. An autopsy was not permitted.

Syphilitic Cerebral Arteritis.—As a result of an anatomico-pathologic and clinical study, Charrier and Klippel (*Revue de Médecine*, 1894, No. 9, p. 792) arrive at the conclusion that syphilitic cerebral arteritis is the most frequent of the specific arteriopathies. Anatomically the process may be an obliterative or an aneurysmal one. When the obliteration or the aneurysm involves a large artery at the base of the brain there may result apoplexy and death, by thrombosis of the basilar artery or meningeal hemorrhage. When the arteries affected are of moderate size or when the obliteration is incomplete grave and often incurable hemiplegia may result. When the morbid process is not extensive and involves the small arteries the symptoms are not alarming, although so-called syphilitic aphasia may occur. When the morbid processes is widely distributed over the arterial system there may be present both specific lesions and those of a diffuse peri-encephalitis. Clinically these lesions give rise to paralyses of hemiplegic type analogous to those observed when the affected arteries are of moderate size, or the obliteration is incomplete, or when the alteration is less extensive and involves the smaller vessels; but the symptoms approach in character those of general paralysis. This last condition, however, must not be confounded with the pseudo-general paralysis resulting from the existence of an insular meningitis of gummous nature. Whatever the form of lesion, the treatment should be prompt and energetic. As soon as syphilis is suspected mixed treatment should be instituted, including the use of inunctions of mercurial ointment in quantities of from 60 to 90 grains daily, the administration of potassium iodid in doses of 90 grains the first day, 130 the second, and gradually increasing until 240 or 260 grains are taken in the course of twenty hours. Tolerance is more readily established when large doses are administered then when small ones are given.

The Treatment of Rupture of the Uterus during Labor.—Wasten (*Bolnitschnaia gaseta Botkina*, No 24; *St. Petersburger med. Woch.*, 1894, No. 36, Supplement No. 8, p. 46) has reported the case of a nonipara in which, following the delivery of a stillborn child with the forceps, a rupture of the uterus was found. The woman was in a condition of collapse, the abdomen distended, the fundus uteri two-fingers' breadth above the umbilicus. The ligated umbilical cord protruded from the vulva. Digital examination disclosed a laceration of the anterior wall of the uterus, through which the placenta had gained entrance into the abdominal cavity. Celiotomy was at once undertaken, and some liquid blood and the placenta surrounded by clots were removed, while the ligated umbilical cord was withdrawn from the vagina. As evidences of septic infection were present, and it would have proved difficult to suture the margins of the wound in the uterus, supra-vaginal amputation of the viscus was decided upon. The stump was returned to the abdominal cavity, and a drainage-tube was passed through Douglas' cul-de-sac into the vagina. The abdominal wound was sutured. The laceration was 6.5 cm. long and extended obliquely downward and to the left upon the anterior aspect of the uterus from near the fundus.

The general condition following the operation was satisfactory, although for two weeks the temperature was elevated and remittent in character, gradually, however, subsiding to the normal. On the sixth day after the operation a malodorous vaginal discharge set in, which was found to depend upon an endocervicitis. The drainage-tube was removed on the eighth day, the sutures on the eleventh, and the wound was found healed by first intention. The patient ultimately recovered perfectly.

A Case of Akromegaly with Autopsy.—Bonardi (*Arch. Ital. di clin. Med.*, 1893, Punt. ii; *Centralblatt f. Chirurgie*, 1894, No. 34, p. 816) has reported the case of a man seventy-five years old, in whom the head, hands, and feet had from youth undergone progressive enlargement, and who stated that his father had suffered similarly. The eyelids were thickened, the nose was large and broad, the lips thick and muscular, the tongue immensely large and with difficulty protruded, the lower jaw greatly increased in size, measuring 30 cm. (11.79 in.) from one angle to the other; the circumference of the head was 61 cm. (24 in.); the larynx was also greatly enlarged; the vertebral column was markedly kyphotic. The enlargement of the right hand was greater than that of the left. That of the feet appeared to involve particularly the soft parts. There was dulness on percussion over the manubrium sterni.

Death took place as a result of cardiac asthenia. The sella turcica was found to be of normal size and the hypophysis cerebri not enlarged. The tongue was 7 cm. (2.75 in.) thick and weighed 210 grams (6.75 oz.). The thyroid gland was atrophic; the retrosternal lymphatic glands were found to be enlarged. The entire arterial system was in a high degree atheromatous.

THERAPEUTIC NOTES.

Bone-marrow in the Treatment of Leukemia.—BIGGER (*The Lancet*, No. 3708, p. 682) has reported the case of a lad, twelve years old, who came under observation at the age of six years, suffering from splenic enlargement and anemia. During a period of six years he had from time to time had courses of arsenic and iron iodid. Under this treatment the anemia had always improved, but until recently the enlargement of the spleen had not varied. Within a period of some two months the disease had manifested a more active character, and the boy was rapidly sinking into a critical condition. The spleen became much larger than before, and completely filled the left half of the abdomen, extending into the iliac fossa and across the middle line for two or three inches. Associated with this enlargement there were very rapid emaciation and marked anemia, accompanied by an icteric tinge of the surface. To these symptoms were added diarrhea, pyrexia, and frequent attacks of epistaxis. The pulse was rapid, and there were dyspnea and palpitation on the slightest movement. There was no enlargement of the lymphatic glands. In spite of full doses of arsenic and iron the anemia and wasting progressed, and the case assumed an almost hopeless aspect. The boy was now provided with a supply of bone-marrow, which he ate spread upon thin slices of bread. For the first two or three days the result did not appear to be satisfactory, as the spleen became more tender and complaint was made of acute pain over the splenic area. The pain was relieved by hot fomentations and soon passed away, and the spleen became less tender. By the end of the first week of the new treatment the patient looked and felt so much better that there was no doubt of the advisability of continuing it. At first there was some repugnance toward the raw marrow, but this soon passed off, and there was no difficulty in getting down two or three slices of bread thickly spread with marrow, three or four times a day. The improvement in the boy's condition after the first week was little short of marvellous. The anemia and jaundice disappeared, and the skin and mucous membranes acquired a healthy color. The symptoms due to the anemia at the same time passed off, and in three weeks the boy was able to walk about without shortness of breath or palpitation. The temperature also became normal. The spleen diminished in size, and at the end of two weeks the lower edge had receded to a level with the anterior spine of the ileum, and the inner edge did not extend beyond the middle line. After a month of treatment the boy was better than for a long time, and the spleen continued to diminish in size. Some ten weeks later the boy appeared perfectly well, and the spleen had become normal in size.

Bone-marrow in the Treatment of Pernicious Anemia.—DANFORTH (*Chicago Clinical Review*, vol. iv, No. 1, p. 1) has reported a case of pernicious anemia in which recovery seemed hardly possible, but in which excellent results were brought about by the administration of bone-marrow. This substance was at first administered in capsules, and subsequently with the food, but later the following mode of preparation was pursued: The anterior extremities of calves' ribs were comminuted, so as to thoroughly expose the cancellated tissue, and the fragments were placed in a jar and covered with glycerin, to the influence of which they were exposed for three or four days, being occasionally agitated. At the end of this time the liquid was strained through flannel, and the resulting fluid presented a reddish, syrupy appearance without pronounced odor and with very little modification of the ordinary sweetish taste of the solvent. This preparation was administered in doses of a teaspoonful three times a day, together with five drops of the official solution of potassium arsenite. As in the course of a few days the sweetish, sickly taste of the glycerin extract became disagreeable, and the stomach began to rebel, the following combination was employed:

Solution of potassium arsenite .	2½ drams.
Acid sodium phosphate . .	3 ounces.
Extract of bone-marrow . .	8 "

Of this a dessertspoonful was given after each meal. This combination proved entirely satisfactory, and the patient steadily gained in health, strength, and spirits, and in a short time presented every indication of restoration to former vigorous health. The hemoglobin rose from 35 to 80 per cent., and the red blood-corpuscles underwent a corresponding increase in number.

Lactophenin as an Antipyretic.—JAQUET (*Correspondenzblatt für Schweizer Aerzte*, May 1, 1894) has employed lactophenin in forty-two cases of various kinds, including pneumonia, influenza, erysipelas, typhoid fever and florid pulmonary tuberculosis. In all the drug acted as a reliable and agreeable antipyretic; in doses of from 50 to 75 cg. (7.7 to 11.5 gr.) it caused a fall of temperature, even in the case of erysipelas. In one case a dose of 1 gram induced a fall of temperature from 104.3° to 98° F., its action being continued for eight hours. A certain amount of stupor followed the administration of the drug, but this did not persist for any considerable length of time. In addition to its antipyretic action lactophenin is a sedative and hypnotic in doses of from 80 centigrams to 1 gram (12 to 15 gr.).

Idiosyncrasy to Topical Applications of Tannic Acid.—KRUGER (*Deutsche med. Woch.*, 1894, No. 18; *St. Petersburger med. Woch.*, No. 36, p. 331) has reported a case in which the employment of a 1 per cent. solution of tannic acid as a nasal douche was followed by the appearance of redness of the face, injection of the conjunctivæ, increased lachrymal and nasal secretion, redness of the fauces, of the soft palate, and of the epiglottis and entrance to the larynx. There was besides complaint of occipital headache, ringing in the ears, ocular pressure, tension of the gums, and a sense of dyspnea. The symptoms receded spontaneously in the course of two hours.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, OCTOBER 27, 1894.

THE DUTY AND PRIVILEGE OF MEDICAL EXAMINING BOARDS.

DURING the past few years there has been a marked extension of the method of State examination for license to practise medicine. This must be encouraged by the commendation of every physician. But it may not be amiss to warn the examiners that they are likely to fall into a grave error. The examinations are, so far as we can learn, entirely written. This seems right and proper for the protection of the examiners and the safety of the applicant. But these written examinations are also, so far as we can learn, conducted from written questions requiring nothing of the applicant except his pen and the correct answer. The questions entail no examination of anatomic material, no physiologic examination of the living body, no chemic or microscopic examination of the excretions or secretions, and no clinical or pathologic examination of actual diseased conditions.

The effect of this Chinese-like method of examination at the writing-table alone is beginning to be felt by medical educators. The text-book system of study is increasing in medical schools. Cramming is becoming as virulent a malady in them as it was in our literary colleges when the sciences were first made an obligatory part of their courses. As we look over the field of medical education we cannot help admitting the evident benefit which examining boards have conferred in whipping the poorer schools into line. But they have a duty also in encouraging the better schools. Now they measure and record the low-water mark of medical education. It would be equally salutary if they would measure and reward superiority.

In a recent conversation with a prominent examiner upon the method of these examinations, he seemed to appreciate the desirability of examination by means of actual physical and chemic diagnosis with all the appliances of the consulting-room, but he feared the expense. This expense ought not to be considerable. If a hundred students were to be examined, ten small rooms could be provided in addition to the writing-room. In the first, a healthy man should be placed with the necessary appliances for examination as for life-insurance. A blank should be at hand leading to the required examination, and the first applicant should be allowed such time as this examination ought reasonably to consume. The examination finished and the report written, the applicant should pass to the second room and write the result of his examination of such clinical case as he finds there. This case and other cases should be selected from the hospital or dispensary. They would be willing to submit to these examinations for the fee which every State can well afford to pay. Some care must of course be used in the selection of these cases, but no more than ought to be used in selecting the questions presented. In each clinical examination-room should be at hand the material and apparatus for the examination and a suitable blank to be filled out, with the result of the examination, the diagnosis, the prognosis, and the indications for treatment. It is evident that all kinds of medical and surgical cases are not adapted to the purposes of this examination; and it is equally obvious that the patient must be protected by an attendant from any careless, rough, or dangerous methods of examination at the hands of the student. We regret to say that lately, presumably through conscious or unconscious imitation of our German neighbors in their clinics, many students in American medical colleges have seen rough and almost inhuman, certainly unchristian and undemocratic treatment of hospital and dispensary patients at the hands of their teachers.

In the second, third, fourth, fifth, and sixth rooms also, the applicant would perhaps find in succession

heart-disease, tuberculous pneumonia, dilatation of the stomach, and lead-poisoning. In the seventh room he would find a basin containing a pathologic lung on which a written description and diagnosis with illustrative drawings would be required. In the eighth, ninth, and tenth rooms other means of testing the ability of the applicant to diagnosticate, say, carcinoma, from the mounted specimen, and again two or more forms of nephritis from the urine and the accompanying written histories. The reader will at once see what an impetus to correct medical education such an examination would surely give. It would rebuke, through the failure of its students, those schools that have no laboratories and no clinical teaching in the true sense of teaching. It would bring into prominence the value of biologic study as a preparation for medicine. It would put before the medical student real acquirements, instead of parrot-like memory, as the essential for a license to practise medicine, and it would give true pedagogic methods in medical schools an ascendency over the traditional methods of the past century.

This much surely the medical examining board ought to do. It is a duty to the citizens of the State; it is justice to the better class of medical colleges; it is a privilege which no other body possesses.

WAR MADE UPON MEDICAL AND HYGIENIC BARBARISM IN OHIO.

STRANGE and wonderful as it may seem, the cause of medical civilization is being upheld by Ohio. The State cannot get a Medical Practice Act passed by the State Legislature out there, but by some hook or crook it seems that a law has been put on the statute-books prohibiting the adulteration of food, beverages, and medicine. We suppose the quack aristocracy that stuck their tongues into their cheeks and roared derision at the medical profession never suspected that this law could be applied to their infamous cure-alls, "patent medicines," "bitters," and whiskeys. But the Ohio Dairy and Food Commission, with headquarters at Cincinnati, discovered the applicability of the general terms of the law, and also—*mirabile dictu*—discovered some moral courage, and putting both to use they are marching to the courts of justice the grocers and druggists who are the distributing-agents for the concocters of fraudulent drugs and articles of food. It is noteworthy that these local grocers and druggists, instead of throwing the blame upon the manufacturers, seem inclined to espouse their cause and to fight the commissioners. So far has corruption come! The law and its execution is plainly directed against the manufacturer, and only secondarily against the distributer, and because in no other way can the State reach the rascals. One of the commissioners is reported as saying some time ago:

"We have brought about ninety cases, and not one of them has been decided against us. That is the record for the last six months, but it is likely to be eclipsed by the results of the next half-year. Our work is only fairly begun."

The arrests have been for selling as pure, or without proper notices, according to law, such articles as vinegar, oleomargarin, fruit-jellies, preserves, lemonade, milk, grape-juice, Vin Mariani, Paskola. The commissioners' expert in chemic analysis first buys these articles, analyzes them, then prosecutes the clerk or proprietor of the store who sold them to him.

Massachusetts, we believe, has a similar law, but we have not heard of any serious attempt to execute it in the case of such things as the vile compounds foisted upon the gullible public as the great promoters of health and curers of all diseases. It is a somewhat curious psychologic puzzle to understand how it is that in Massachusetts, where a learned (?) professor in Harvard College joins hands in upholding the quacks and helps them to succeed in killing a proposed medical-practice act, and in Ohio, where a similar delectable set rules the Legislature—in these two States, there should be such laws against the scoundrels, and that in Ohio they should, as CARLYLE would say, succeed in getting themselves executed. The rest of us are bound down in abject slavery. The law of libel, or the absurd fear of it, holds over the heads of publishers and editors a sword that, it is said, would chop heads clean off "with neatness and dispatch," should a word be whispered in objection to the ring-rule of the patent-medicine syndicates and the manufacturers of secret nostrums. If a suggestion of the law of libel were not sufficient to throw us into "conniption fits" of fright, the threat of a cessation of advertisements is quite enough to make us scuttle to our holes like frightened chipmunks. Thank heaven for one man and one journal that will speak out fearlessly and welcome the threatened lawsuits. We do not always agree with the brave editor of the Cincinnati *Lancet-Clinic*, but in this crusade we cry him Godspeed with all our heart and with all our lungs.

EDITORIAL COMMENTS.

Ophthalmologic Tricks.—Even the oculists are mortal and peccable! We do not know how many times it has come to us very directly that patients with cataract, well advanced, incipient, or even only imagined, have been "treated" for it systematically and locally, in expectation of its absorption, the treatment extending over months, or even years, with constant payment of fees. This is the homeopathic trick *par excellence*. We have never except once heard of an "allopath" doing it. It is psychologically interesting to see that the mind has sectarian "lines of cleavage" in its scoundrelisms as well as in its therapeutics. In ophthalmic tricks the "allopath" can certainly rival his erring homeopathic brother. His is the far more common attempt to cure a case of reflex conjunctivitis or blepharitis, due to eye-strain, by the local application of astringents, etc., or by aqua destillata (and the applications always must be made by the physician), continued until the patient's purse or patience are one or both exhausted. Another "money-maker" is humoring the popular mistake in nomenclature which supposes the "scales" along the lid-edges in certain forms of blepharitis to be "granular lids," and the long-continued treatment of trachoma is instituted when there is not the slightest sign of the disease present.

But the wiliest and perhaps the most common, as it is the most profitable, stroke is that of treating *muscæ volitantes*. Many patients are frightened by the "dark spot before their eyes," get to watching it, and think it is the beginning of blindness or of some dire disease of the eyes. If they fall into the hands of a fellow whose motto is "*Medicine is Business*" he will humor their error, and, systematically or locally, pretend to treat this little symptom until some honest man will brush the morbid fear away with a laugh. We are glad to believe the ophthalmic tricksters are few and the honest men are many, but we are sorry to be compelled to confess that the few sneaks do exist. And they are much better known than they themselves suppose. Hospital positions, long tails to names, even professorships, do not hide the facts or lessen the disgrace. Patients will travel and will talk—sometimes maliciously, sometimes errorfully, but sometimes also truthfully.

Examination of the Eyes of Motormen, Engineers, etc., is a suggestion well worthy of commendation. Without such a safeguard it is more than possible that some of the accidents occurring may be due to a defect of vision on the part of the men in charge of the trolley-cars. A high degree of ametropia would certainly lessen the precision and quickness with which the cars should be stopped in order to avoid accidents. Leaving out of consideration the direct danger in any specific instance, it is beyond question that such an ocular defect has the effect of dulling the general sensibility of the mind and making the entire man as a nervous mechanism less prompt in perception and reaction. The speed with which these cars are run, and the need of lightning-like accuracy and certainty in controlling them, demand the most perfect nervous mechanism possible.

In the case of railway locomotive-engineers and brakemen there is prevalent to-day a widespread mistake or superstition that is endangering the lives of many people. We allude not to the admitted need of testing the color-sense of such men, but to the non-admitted and despised need, on the part of higher railway officers, of ametropic tests for the men. Ametropia both directly and indirectly, especially of high degree and if coupled with presbyopia, greatly lessens the accuracy of perception, both ocular and mental, of engineers and of brakemen. Glasses would greatly increase this accuracy in many cases, but however atrocious the defect, the men do not dare to wear glasses while on duty, because of the knowledge that if they do so they will be discharged because of poor eyes. Officials stupidly prefer them to continue work with poor vision rather than with glasses that make the vision practically normal.

Midwifery among the Somalis.—The *Indian Medical Record* (Vol. vii, No 5, p. 145) cites as an instance of barbarous midwifery, without a parallel, the practice in vogue among the Somalis of Africa. When a Somali woman in labor experiences any difficulty, such as obstruction to the passage of the fetus, her relatives call in the assistance of their Wadad, or priest, who is a kind of Jack-of-all-trades, and exercises a universal sway over the tribe. To assist the delivery the priestly doctor thrusts into the vaginal canal a knife, which, being of local manufacture, is rough and black, and is never overclean, and with a rapid sawing movement cuts anteriorly until the blade comes in contact with the arch of the pubes. This obstetric operation is expected to give instantaneous relief; and the hemorrhage necessarily entailed is considered to be a "good sign," according to the explanation vouchsafed by the "learned doctor" to the elderly relatives. If this fails to effect the delivery, as it always does, the poor patient is blamed for the result as being the possessor of an impure soul. She is now gotten ready for a second and the last operation of relief. The priest-surgeon then thrusts the knife again into the vagina and cuts backward until the posterior wall of the pelvic cavity resists the knife. This is really and truly the finishing stroke, as it finishes off both the mother, to whom death must be undeniably a relief from such brutal interference, and the child, mutilated, though yet unborn.

Unilateral Fibrinous Rhinitis.—While it has been shown that many, if not the majority, of cases of so-called fibrinous rhinitis are due to the presence and activity of diphtheria-bacilli, it is equally admitted that this affection may arise in the absence of such bacilli. Even fibrinous rhinitis due to the presence of diphtheria-bacilli is to be differentiated from true nasal diphtheria. The latter invariably arises by extension of the diphtheric process from contiguous parts, while the former may develop as a primary and independent condition, although it too may follow in the sequence of pharyngeal diphtheria. On the other hand, fibrinous rhinitis is not characterized by extension of the exudative process to the pharynx; and the constitutional phenomena are less pronounced in rhinitis than in diphtheria. In illustration of the fact that the mere presence of microörganisms is not sufficient to generate disease, it is interesting in this connection to refer to a case of fibrinous rhinitis in a nine-year old boy who had not had diphtheria, but whose

mother had suffered from an attack of the laryngeal variety, reported by ABEL (*Deutsche medicinische Wochenschrift*, 1894, No. 35, p. 693), and in which diphtheria-bacilli were found in both nares, although false membrane formed in but one.

Who are the Editors, the Publishers, etc.?—We wish to protest against the custom of some English medical journals (we suppose they are English) of leaving contributors and correspondents in entire ignorance not only as to who their editors are, but also as to who their publishers may be, and even as to where the journal itself is published. In our prized contemporary whose only fault is excessive urbanity, good nature, and remarkable scholarship in reference to what it calls "American spelling"—the *Medical Press and Circular*—there is not a line from beginning to end to tell us where it is published or by whom it is published and edited. This excessive modesty is complimentary to the hidden and nameless divinities that preside over the destinies of medicine and of the medical press. It forms a delightful contrast, perhaps, to some of our American examples of medical journalism in which the editor's name and that of his journal are the chief or only prized thing in the valueless journal; but, seriously, *omne ignotum pro magnifico* is about as ridiculous a blunder—at least for perplexed correspondents. It may be characteristical, and even scientifical—perhaps our charming contemporary would prefer us to spell *characteristickal* and *scientifickal*.'—but it is not sympathetical or hygienical.

The Medical Department of Tulane University requires, as we are glad to learn, an attendance upon "three courses of lectures of not less than six months each in three separate years." The implication in a recent editorial comment that it is "a two-year college" was an error, based upon misinformation, which we are happy to correct.

SELECTION.

THE ENCOURAGEMENT OF PAUPERISM ILLUSTRATED BY THE TOWN OF WATERBURY, CONN.

From 1869 to 1893, inclusive, the disbursements for official alms in Waterbury, Conn., aggregated $483,043. If the expenses of administration and the cost of new almshouses were included in these figures the rotund total for the quarter of a century would approximate $600,000. The increment in alms during the twenty-five years has strikingly outstripped the increment in population and in the grand list. In 1869 the total relief amounted to $6,799, while in 1893 it was $38,452, an increase of 462 per cent. The population of the town is estimated to have been 12,834 in 1869 and 35,500 in 1893, the growth being 176 per cent. The grand list on which the tax of 1869 was levied was $6,900,005, while twenty-five years later it was $10,819,836, the expansion being a laggard 56 per cent. In other words, while the pauper expenditures in Waterbury during the twenty-five years bounded forward 462 per cent. the census increased but 176 per cent., and the grand list, striking a leisurely pace, grew but 56 per cent. Your committee are not convinced that changes in the character of our population or in the condition of our industries justified a *per capita* pauper tax of $1.08 in 1893, as against 52 cents in 1869.

A comparison with other communities serves still further to emphasize the lavish nature of Waterbury's distribution of public revenues among the poor. It is, in sooth, lamentably true that several large Connecticut towns jauntily jump over Waterbury's too high standard; but Prof. McCook has cleverly and conclusively demonstrated that Connecticut—a State famed for its inventive skill and its industrial genius—leads the world in its dispensation of public alms. But venturing beyond the borders of this Commonwealth, we find that while the annual cost of poor relief (exclusive of $7,147.84 for hospitals) was 88 cents *per capita* in Waterbury last year, it was only 20 cents in the city of Providence in 1892. The figures for the manufacturing city of Pawtucket, R. I., are 37 cents as against our 86. The *per capita* tax for the support of outdoor and indoor paupers in Springfield was 51 cents in 1892. In most other New England cities (outside of Connecticut) whose population, like our own, is distinctly industrial, the burden of pauperism falls lightly on the shoulders of the taxpayers, if Waterbury's rate be taken as a basis of comparison.

Passing from municipalities to commonwealths, we find that the *per capita* cost of poor relief was 67.8 cents in Massachusetts in 1891; 55.3 cents in New York in 1890; 33.4 cents in Pennsylvania in 1890; 32.1 cents in Ohio in 1891; 35.9 cents in Michigan in 1889; 36.7 cents in Indiana in 1890-91; 35.9 cents in Illinois in 1889; 24.2 cents in Wisconsin in 1889; and 23.7 cents in Minnesota in 1891. Our own pauper tax towers loftily above these modest figures.

The names of eighteen families which were the recipients of aid in 1893 appeared on the town-records for the first time ten years ago. Nineteen families in last year's immortal 396 poured profuse and profitable petitions for assistance into the ears of the Selectmen nine years ago. Two families began their career of permanent pauperism eight years ago, and sixteen families seven years ago. Not less than 105 families, representing 367 persons, were aided continuously through the fiscal year of 1893, while sixty-two were relieved from six to eleven months.

It is a recognized principle that "people who have once drunk from the fountain of public relief acquire an insatiable appetite for its waters." Age cannot wither nor custom stale their infinite importunity. The step from temporary to permanent pauperism is short and alluring, and it is easier than the traditionally easy descent into Avernus.

It is unreasonable to suppose that under a plan of personal examination into the character and condition of the applicants, three proprietors of resorts of ill-fame could, between February, 1893, and January, 1894, have made victorious raids on the Selectmen's office. It is a matter of regret to your committee that Waterbury's system of public poor-relief is so elastic that under it the public revenues have several times been diverted to promote the practice, prosperity, and profits of prostitution.

At the first conference which we had with the Selectmen we were informed, with engaging frankness, that the recipients of orders could buy ice-cream with them if they chose. We heard of a woman in January who, having obtained a $2 grocery-order, desired to use it exclusively for sugar. When the grocer conscientiously advised her to get only 50 cents worth of sugar and to expend the remaining $1.50 on other articles she waxed indignant and threatened to transfer her future patronage to some less critical merchant. As several of the dealers on whom orders are drawn are licensed liquor-sellers it is not an improbable assumption that Waterbury occasionally furnishes some of its outside poor with a brand of groceries which can best be carried home in a jug, and which, if consumed in sufficient quantities, is less liable to cheer than to inebriate.

The local public expenses for the support of patients at hospitals for the sick are steadily increasing. Each patient sent to the Waterbury hospital by the Selectmen involves a weekly tax of $6, while the New Haven hospital charges $5. For that reason, in cases in which hospital-treatment will be required for a protacted period, the town finds it cheaper to send its patients to New Haven.

During the past ten years the disbursements for the hospitals-account have expanded 133 per cent., but we are advised that the Selectmen encounter considerable difficulty in keeping them down to the present figure. The requests for admission to the sick-hospitals at the expense of the taxpayers are constant and numerous, and eternal vigilance, supplemented by a discriminating judgment, is necessary to prevent the development of costly abuses. We think that, except in emergency cases, no patient should be admitted to a hospital for the sick without the written approval of the town-physician.

The fact that not less than forty-eight of the inmates are victims of inebriety challenges attention. In fact, the superintendent informs us that in reality intemperance is the cause of pauperism in a larger number of cases than the records indicate. Many of those who have tarried at the wine have tarried very long and very industriously. A majority of these forty-eight too bibulous persons are not old as age is reckoned by the calendar. Five of them are between twenty and thirty years of age; seven between thirty and forty; twelve between forty and fifty; fifteen between fifty and sixty; seven between sixty and seventy; while only two are on the sunset side of threescore years and ten. Their average age is forty-nine years. Many of these chronic drunkards will, in the natural course of events under existing conditions, become permanent and expensive public burdens. Looking at the problem exclusively from the standpoint of taxation and of public economy, we inquire whether it is not worth while for the town to test the value of medical treatment for inebriety on a few of these slaves of dipsomania. If a reasonable probability exists that some of them can be reclaimed to independence and to productive citizenship, the dictates of dollars and cents suggest the propriety of making the experiment.

The problem of women who, in the last stages of pregnancy, go to the almshouse to be delivered of their children, usually illegitimate, is not easily solved. Several such cases occurred last year. The women usually leave the institution when they are able to work. The almshouse is thus converted into a lying-in hospital for the convenience of indigent women whose virtue is not stable and continuous, and licentiousness is indirectly promoted. The question is a delicate one, and we have no specific recommendation to offer, although we venture to inquire whether the detention of such mothers in the almshouse for at least six months, during which time they might develop a permanent affection for their children and also by hard work reimburse the town for the expense incurred by their admission, would not be advisable.

The superintendent when asked if opportunity was provided for the employment of the able-bodied inmates when the weather was unsuitable for outdoor labor, replied in the negative.

The number of capable workers at the institution is, as we understand, and as is the case in most almshouses, larger in winter than in summer; for not infrequently men who are not inclined to have much commerce with hard work find the almshouse an agreeable place for hibernation and for obtaining the maximum of winter comforts in exchange for a minimum expenditure of energy. In the spring they migrate.

We have considered at length the operations and the results of Waterbury's system of official relief. Under that system the support of the public poor is imperiously exacting from taxpaying pockets large levies of money which might otherwise be employed in productive industries. That system has created in the community a vast amount of hereditary and chronic pauperism. It has encouraged the spirit of mendicancy and dulled the sense of personal responsibility. It has taught scores of people who, under ordinary conditions, ought to be self-supporting, confidently to rely on official bounties and to give their independence and ambition in exchange for the gratuities that are distributed from the City Hall. It has, in many cases, filched from the industrious and independent for the benefit of the idle and thriftless, and it has not infrequently rendered the condition of the pauper easier than that of the self-supporting taxpayer. It has naturally engendered certain administrative defects which have fostered the general evil and conduced to unnecessarily large expenditures. Under that system and, indeed, under any system of public relief, that delicate personal ministration on the part of the almoner and that feeling of gratitude on the part of the recipient, which are the most helpful features of true charity, are absent: for the dispensation of public relief is a contest in which the applicant battles to get a large grant while the official fights to make the dole small.

We are profoundly convinced that Waterbury should aim to secure the ultimate abolition of outdoor relief. Brooklyn has abolished it. Baltimore has abolished it. Philadelphia has abolished it except for medicine and medical attendance. Other progressive cities, appreciating the grave social diseases that are caused by the microbe of liberal official charity, are rigorously curtailing their outdoor alms.

The dictates of civilization demand that the impotent poor who are not able to earn their own subsistence shall not be permitted to starve. But, as Prof. Francis A. Walker has pointed out, "it is of the highest impor-

tance that pauperism shall not be made inviting; that, on the contrary, the laborer shall be stimulated to the utmost possible exertions, only accepting relief as an alternative to actual starvation." Churches, voluntary charitable organizations, relatives, and private benevolence are, in general terms, competent to relieve the distress of the provident and deserving poor of Waterbury, while, in our opinion, the worthless indigent ought not to be assisted outside of the almshouse. This goal, although it cannot be reached by a short cut, ought to be kept steadily in view. We are confident that many outside paupers, if they were required either to go to the almshouse or be deprived of further relief altogether, would decline to accept the hospitalities of the institution and would find unsuspected resources by which an independent living could be obtained. Indeed, we do not believe that, in the long run, a general reduction of outdoor aid would largely increase the population of the poorhouse. Dr. Gladden, an authority on scientific philanthropy, says: "The abolition of outdoor relief involves a moral change in the community, upon the whole subject of dependence, which finds expression not only in the homes of the poor but also in the almshouses. If you want to reduce the number of dependents in your institutions, cut off the distribution of outdoor relief."

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Eleventh Annual Meeting, held in New York, October 9, 10, and 11, 1894.

FIRST DAY—OCTOBER 9TH.

DR. ZERA J. LUSK, of Wyoming County, reported a case of lateral lithotomy for the removal of a large wire nail, which was alleged to have been in the bladder for four years. The nail was exhibited.

Dr. Lusk also reported a case of traumatic epilepsy, which was of interest because by trephining over the speech-center and removing an epidural clot the man was restored to health.

DR. E. D. FERGUSON, of Rensselaer County, in discussing this case, cautioned against expecting to find the lesion exactly where the anatomic or physiologic center was located, and reported a case from his own practice in illustration.

DR. DARWIN COLVIN, of Wayne County, said that cases of gunshot wound causing epilepsy were quite rare, according to the *Medical and Surgical History of the War of the Rebellion*, and that the case in which he had trepanned a soldier for this condition was the only one there reported as having recovered.

DR. EDEN V. DELPHEY, of New York County, exhibited a new non-conducting speculum made of hard rubber, which he had found useful for giving a post-partum intra-uterine douch. It resembled a very large one-bladed Sims speculum, the handle of which was in the form of a gutter, through which the fluid drained off into a pail suspended from the end of this handle. With it very hot water could be used without discomfort to the patient from the speculum becoming too hot.

Dr. Delphey also narrated some of the interesting points in a lawsuit in which he had been made one of the defendants. He had been asked by Dr. A. H. Goelet to give an anesthetic to a man of fifty-two years, who had a gangrenous finger that required amputation. The patient had refused consent to the operation unless an anesthetic were given. The urine had been examined and found to be normal. With the Esmarch inhaler not more than one dram of Squibb's chloroform was given, and then ether was substituted, being administered in a paper cone and towel in the usual way. Shortly after beginning the ether, the patient without any warning suddenly stopped breathing. Artificial respiration by the Sylvester method was at once begun, and kept up for half an hour, and only abandoned after the heart had ceased to beat. The autopsy was made by the deputy coroner, who reported finding pulmonary edema, pachymeningitis, old adhesions of the lungs on the left side, and incipient disease of the kidneys. The medical expert for the plaintiff alleged that no conscientious physician would administer chloroform to a patient having incipient disease of the kidney. It is important to note that the Judge, Judge C. H. Truax, in his charge, instructed the jury to take no notice of the fact that the family of the patient had objected to the giving of an anesthetic, for he held that they had no right to do so, especially as the patient was competent to decide that matter for himself. A verdict was rendered for the defence.

In the course of the discustion, DR. E. D. FERGUSON called attention to the fact that it had been held, at least in Pennsylvania, that the physicians who are present at an operation merely as witnesses could be made co-defendants in a suit of this kind, and DR. D. COLVIN asserted that the previous signing of a contract by the patient releasing the physician from damages in case of an untoward result would not save him if it could be shown that he had not taken all ordinary precautions or had not pursued the usual treatment.

DR. J. W. S. GOULEY, of New York County, presented a communication, in which he gave his reasons for offering the word "typhlenteritis" as a substitute for "appendicitis."

DR. JOSEPH D. BRYANT, of New York County, reported four "Interesting Cases of Appendicitis," all of them secondary, and each illustrating a certain type of the disease.

In discussing the paper, DR. F. W. GOODALL, of Vermont, said that from a recent short experience in palpating the appendix, as advocated by Dr. G. M. Edebohls, he had become convinced that it was a method of examination that was both easy and useful.

DR. J. G. TRUAX, of New York County, said that, in his opinion, if the first attack of appendicitis were properly treated, not one case in a thousand would have a second attack. By proper treatment he meant placing the patient in bed, applying an ice-bag over the ileo-cecal region until all induration had disappeared, keeping the patient all this time, and for two or three weeks

longer, on an exclusively milk diet, and then for five or six weeks more on farinaceous food.

Dr. H. O. Marcy, of Boston, defined appendicitis as a proliferation of the bacillus coli communis locked up in a small process of the bowel. In a large experience, he said, he had never felt sorry for having operated for appendicitis, but he had frequently had occasion to regret the opposite course. He had been the first to operate in recurrent cases during the interval, and he still favored this practice.

Dr. E. D. Ferguson reiterated a statement made a year ago, to the effect that in his experience the vast majority of cases had only had a single attack.

Dr. Bryant replied that from 60 to 80 per cent. of those having appendicitis primarily would recover without operation. The mortality in the operative cases was about two per cent. In ordinary primary attacks, in the absence of symptoms distinctly demanding operation, he would, before operating, wait for about forty-eight hours, or until the fever indicated the possibility of suppuration.

Dr. W. H. Park, of New York County, read a paper entitled "Recent Studies on Diphtheria and Pseudo-diphtheria." He explained the methods now in vogue by the Board of Health for determining by bacteriologic examinations whether cases reported are true or false diphtheria. Cases were also cited to show that healthy persons could carry the bacilli and infect others with the disease without themselves succumbing to it. It had been found that if care were taken to keep the throats of persons exposed to pseudo-diphtheria in a healthy condition there was little risk of contracting this disease. Experiments carried on at the Willard Parker Hospital had shown that warm salt solution was one of the very best solutions for irrigating the nose and throat of diphtheric patients—even better than hydrogen dioxid solution. Calomel-sublimations had not been found antiseptic in the nasal passages. A short account was then given of the new method of treating diphtheria by the antitoxin, and it was stated that competent observers were well agreed as to the excellent therapeutic results obtained from it and as to its furnishing immunity from the disease to healthy persons for a period of a few weeks.

Dr. John Cronyn, of Erie County, followed with a short paper on diphtheria, in which he presented his reasons for believing the disease to be in the first instance a constitutional disease.

Dr. Herman M. Biggs, of New York County, said that he had recently talked with the able men who were studying the antitoxin treatment in Berlin, and they were of the unanimous opinion that the treatment had already passed beyond the experimental stage. In their last series of tracheotomy-cases treated in this way they had had over 75 per cent. recover. It had been found that the dose of antitoxin must be graduated according to the weight, age, and size of the patient.

Dr. A. Palmer Dudley, of New York County, exhibited three patients on whom he had performed Cesarean section, and described the technique he had employed.

Dr. Joseph Taber Johnson, of Washington, D. C., read a paper on "Hysterectomy for Uterine Fibroma by Baer's Method," and reported nine successful cases treated by this method. They had all had a remarkably rapid and easy convalescence. Other similar methods required more time for their performance.

Dr. W. R. Pryor, of New York County, read a paper on "Hysterectomy in Pus cases," in which he advocated the removal of the uterus as well as the pus-tubes, claiming that unless this were done in the more severe cases a large percentage would be only temporarily relieved of the symptoms for which the salpingo-oophorectomy had been done. The removal of the uterus added but little to the shock and danger of the operation.

Dr. H. O. Marcy, of Boston, made some remarks on "The Anatomy and Surgical Treatment of Inguinal Hernia in the Male," and illustrated them profusely by means of the stereopticon. He emphasized especially the importance of restoring the obliquity of the inguinal canal if one would effect a permanent cure.

Second Day—October 10th.

Dr. Douglas Ayres, of Montgomery County, read a paper on "Fractures of the Inferior Extremity of the Humerus, involving the Articulating Surface," and reported two cases occurring in children. He advised elevation of the limb, cold applications, careful immobilization of the limb in the bent position, and an early resort to passive motion.

Dr. A. J. Van Vraken, of Albany County, emphasized the importance of basing the diagnosis on an examination made under an anesthetic, and also the advisability of confining children to bed as the only way of properly controlling them.

Dr. John Cronyn said that injuries of this class were especially likely to lead to suits for malpractice. For this reason he had been in the habit in such cases of telling the family at the outset in the presence of witnesses that it was rare to get a perfect result, and that consequently if they knew of any surgeon whom they thought might be able to treat the case more skilfully than he he wished they would send for him at once.

Dr. Joseph S. Gibb, of Philadelphia, read a paper on "The Stearate of Zinc Compounds in Atrophic Rhinitis," which will be published in a future number of The Medical News.

Dr. Dwight L. Hubbard, of New York County, said that while he could from personal experience vouch for the value of stearate of zinc, he felt that the chief factor in the treatment described in the paper was the efficient cleansing of the parts.

Dr. William H. Robb, of Montgomery County, reported a case of suppurative cellulitis following an injury of the hand, in which in spite of antiseptic dressings, and later on amputation of the arm, the cellulitis spread rapidly upward, and the patient finally died. He attributed the peculiar behavior of this case to the fact that the injured hand had been wrapped up in germ-laden woolen rags for nearly four hours before he had seen it, and that in this way the microbes of suppuration had had time to penetrate deeply into the lymphatics before the application of the first antiseptic dressing. The moral was obvious.

Dr. Herman M. Biggs, of New York County, opened the formal "Discussion on the Prevention of Tuberculosis." He said that for the past eight months the New York City Board of Health had treated tuberculosis as a

communicable disease, and had compelled notification when tuberculosis had developed in public institutions. The chief means of prevention were: (1) notification; (2) advice against marriage of tuberculous individuals; (3) destruction of tuberculous matter, and limiting its dissemination; (4) improvement of sanitation generally; (5) removal of delicate children from families in which tuberculosis had already developed; (6) governmental inspection of dairy cows, and of animals slaughtered for food, and the sterilization of milk from doubtful sources; (7) the maintenance of a proper sanitary condition in all public conveyances; (8) the establishment of special hospitals for the advanced cases of tuberculosis.

DR. LAWRENCE FLICK, of Philadelphia, continued the discussion, illustrating his remarks by lantern views. He exhibited statistical maps showing plainly that health-resorts had been an important factor in propagating tuberculosis. His photographs of small alleys and the interiors of tenements showed very well the overcrowding and the unsanitary nature of the ordinary home-life of these people. He dwelt with emphasis on the influence of hospitals for tuberculous patients on the mortality from tuberculosis. Thus, since such hospitals had been in vogue in England, there had been a noteworthy diminution in this mortality-rate—an argument at once powerful as regards the contagiousness of tuberculosis, and in favor of the more general erection of such special hospitals. In the city of Philadelphia, since 1884, there had been a reduction of 6 per cent. in the mortality, or a saving of nearly one thousand lives a year. There had been a reduction of nearly one-third in the mortality in Berlin since the discovery of the contagious nature of tuberculosis. About one hundred years ago in Naples tuberculosis had been extremely common and malignant, but owing to the enactment of very stringent measures looking to the compulsory isolation of tuberculous patients, the mortality had been wonderfully reduced, until at the present day it was only about one-tenth per thousand in the cities, and practically *nil* in the rural districts.

DR. J. H. HUDDLESTON, of New York County, spoke of the technique of examining the sputum for tubercle-bacilli, and dwelt on the importance of concentrating the sputum.

DR. JOSEPH D. BRYANT, of New York, recounted the preliminary steps that had been taken since 1887 by the Board of Health in connection with the prevention of tuberculosis, and how these efforts had finally culminated in the recent and now well-known action of the board in declaring tuberculosis a contagious disease, and requiring it to be reported as such by the authorities of all public institutions.

DR. E. G. JANEWAY, of New York County, sent a communication, in which he pointed out that examination of the sputum for tubercle-bacilli was not always a reliable guide in diagnosis. He also suggested having separate rooms and distinctive bed clothing in hotels for the use of tuberculous patients only.

DR. J. G. TRUAX, of New York County, said that he did not consider it quite safe to employ tuberculin as a diagnostic test.

DR. BIGGS, in closing the discussion, said that Professor Koch had recently told him that tuberculin was used as a routine measure in the Berlin hospitals in all doubtful cases, and that if properly used it was perfectly harmless. If used in *pure* tuberculosis it appeared to be curative, whereas, it was harmless if used in cases of mixed infection.

DR. J. BLAKE WHITE, of New York County, in a paper on "The Diagnosis and Treatment of Pleurisy," expressed the opinion that strapping the chest in this disease would be likely to result in permanent changes in the lungs and pleura. He had not found the salicylates especially useful except when there was a rheumatic element present. Aspiration should be performed as soon as serous effusion was detected. The open incision without resection of the rib was ample in empyema.

DR. FRANK VAN FLEET, of New York County, in a paper entitled the "Treatment of Retinitis Albuminurica in Pregnancy, from an Ethical Standpoint," presented quite fully both the legal and the moral aspect. Quoting from the Penal Code, he showed that the law did not justify the performance of abortion, except when it was necessary to save the mother's life; but he argued that as marked retinitis did not occur until nephritis was quite advanced, many would contend that the mother's life was really in jeopardy by reason of the renal complication.

THIRD DAY—OCTOBER 11TH.

DR. JOHN G. TRUAX, of New York County, in a paper entitled "Some Facts About the Treatment of Typhoid Fever," put forward as the best of many methods he had tried, the administration of mercury and salol, in conjunction with the persistent application of an ice-bag to the ileo-cecal region.

DR. FREDERICK HOLME WIGGIN, of New York County, read a paper on "Intestinal Anastomosis," in which he reported a clinical case and also results of twenty experiments on dogs. He objects to the Murphy button (1) because a foreign body is left in the intestine, which is sometimes retained, necessitating a secondary celiotomy for its removal; (2) the spring of the buttom may be made so strong as to cut through the coats of the bowel; (3) the weight of the button may anchor the intestine in a flexed position, and so cause obstruction, as in a case narrated; (4) there was some danger of the lumen of the button becoming plugged with hard fecal matter; and (5) the sharp edges of the lateral openings in the button are very liable to cut through the bowel. Dr. Wiggin prefers Maunsell's method, which he says is suitable for any portion of the canal, and can be safely and easily performed by an experienced surgeon.

DR. PARKER SYMS, of New York County, read a paper on "The Arthropathies of Locomotor Ataxia," and exhibited some patients. The pathologic changes, he said, involved both the bone and the soft parts. The joint-disease appears very suddenly, and the movements are abnormally great, and are associated with some of the early symptoms of locomotor ataxia.

DR. J. R. JANVRIN, of New York County, in a paper on "The Early Diagnosis of Tubal Pregnancy, and Primary Laparotomy in such Cases," enumerated, among the important signs, the patulous condition of the os; a tipping of the uterus laterally away from the side on which the fetal sac is located; an elastic swelling corre-

sponding to the location of the ovum; and an exquisite tenderness in this locality.

Dr. Austin Flint, of New York County, was elected President of the Association for the ensuing year.

CORRESPONDENCE.

MID-SYSTOLIC MITRAL MURMURS.

To the Editor of The Medical News,

Sir: I have just finished reading the interesting note by Dr. J. N. Hall, of Denver, upon an "Undescribed Heart-murmur." He is undoubtedly correct, that the murmur occurring in the middle of the cardiac systole is rare; but it is not undescribed. In 1892 I read a paper before the Association of American Physicians upon "Mid-systolic and Late-systolic Mitral Murmurs," and published it later in the *American Journal of the Medical Sciences* for September, 1892. In this I described three cases, in one of which the murmur occurred immediately before the occurrence of the second sound; so close to it, in fact, that it at first seemed almost coincident with it. It could properly be called a late-systolic murmur, analogous to the mitral diastolic murmur which occurs immediately before the first sound in many cases of mitral stenosis. In the other two cases the murmur was of longer duration, and was more properly mid-systolic in nature.

I hardly think Dr. Hall's explanation, that there was a separate action of the right and left ventricles, explains my cases. It seems much more probable that the condition is exactly analogous to that which obtains in the mitral diastolic murmurs. As Bristowe aptly puts it, there is often a "potential presystolic murmur," *i. e.*, the vibrations caused by stenosis occur during the whole of the diastole; but they do not always reach the ear, or they reach it at different times on different occasions, consequently a case may one day exhibit a murmur which occupies only the first part of the diastole, while upon the next day it may fill the whole period of it, or only become audible during the latter part. The actual condition of the valve is, of course, the same on all occasions. So in the mitral regurgitant murmur also. The regurgitation is taking place during the whole of systole, with the exception of the very short "persistence-time" at the very end of it, described by Martius. The vibrations, however, do not always reach the ear, as is well known. Consequently, on some days or under some conditions the mitral murmur is not audible, although the regurgitation is undoubtedly going on. Similarly there is no reason why we should not fail, for some unknown reason, to hear the first part of the regurgitation, although we do hear the later portions of it. It is true that this seldom occurs, while in the murmur of mitral stenosis it is common.

That this is the most plausible explanation of the mid-systolic mitral murmur seems indicated by Dr. Hall's own case. When his patient was first examined she presented a mitral murmur which had nothing unusual about it as to its time, while at the second examination the peculiar rhythm was noticeable. In two of my own cases this same variability was a very prominent feature, and was, in fact, one of the chief reasons for the explanation I have proposed.

Yours truly,

J. P Crozer Griffith.

123 S. Eighteenth Street, Philadelphia.

NEWS ITEMS.

Foot-ball Casualties.—"On the 22d ult., in a match at Watford between the West Herts and Royal Engineers teams, a player (a forward) fractured his knee, and another player (a center forward) also sustained an injury to his knee. On Saturday last, during a match on the recreation ground, Driffield, between the Driffield and Selby Mispah teams, the Driffield full-back fractured his leg. On the same day in a match at Kinver between the Kinver and Kingswinford Clubs a player received injuries from which he died on Monday last. While playing a match on Wednesday last at Brunham between the Reading and Brunham Clubs a player fractured his right leg."—*Lancet*, October 6, 1894, p. 831.

From a few New York and Philadelphia papers that have come to our notice we gather the following:

"On Saturday, October 20th, at Philadelphia, in a game between teams of the Drexel Institute and Hamilton School, O. F. Knight, a student of the Drexel Institute, a man twenty-five years old, of fine physique and prominent in athletic sports, collided with another player and fractured his skull so badly that he will probably die."

"Of the men who have been hurt, five are undoubtedly laid up for good. They are Connor, Richardson, and Dunlop, all of whom had their collar-bones broken; Gray, who broke his leg, and Acton, who dislocated his arm. Hallowell got into a hard scrimmage, and was taken from the field. It was found that he had sprung a cartilage over his rib."

"E. Bennett, of the Harvard School eleven, fractured his left leg while playing in Central Park, and W. McGahey, of the Brooklyn Polytechnic, broke his thigh in a game at Eastern Park."

"Lehigh's foot-ball eleven is in a deplorable state from having played Princeton, Yale, and Pennsylvania within twelve days. The work was too much for them, and the whole truth of the matter is, several of the players show signs of growing stale."

"Houston and Budd, the tackles, are laid up with injuries. Yates, who played such a good game at end in the second half of the Pennsylvania game, will be unable to play again this year on account of a broken collar-bone received in the game on Saturday; Saltzman, the quarter-back, is still laid up, and Keys at center is also in a bad condition. Fitzgerald at full-back has been unable to play since the Pennsylvania game."

"Mr. Deland said Saturday that Mackie, the veteran guard, would also be in harness later, but the big fellow himself says differently.

"He thinks he has played long enough with the team, and says that even if he wanted to play his father would not let him."

"For over a week, Brown, the stocky little half-back from Newton High, has been laying off on account of an injury to his knee. Yesterday he started in again with the 'varsity, only to be taken from the field before the

practice was half over, having again badly hurt his leg. Besides these two accidents, Weld strained his knee so badly that he too had to leave the game and be carried to the club-house."

"The eleven of Stevens Institute has disbanded for the season owing to injuries received by its best players."

The Tri-State Medical Society of Iowa, Illinois, and Missouri held its third annual meeting at Jacksonville, Ill., October 2d and 3d. Papers were read by Drs. J. H. Etheridge, Bayard Holmes, Boerne Bettman, Robert H. Babcock, F. Henrotin, and W. F Hubbard, of Chicago; John Punton, Kansas City; James A. Close and Emory Lanphear, of St. Louis; W. B. LaForce, of Ottumwa, Iowa; E. O. Sisson and F. B. Dorsey, of Keokuk, Iowa; Frank B. Norbury, Anne H. McFarland, Carl E. Black, and L. A. Malone, of Jacksonville, Ill.; Alfred Meyer, of Kankee, Ill.; W. M. Catto, of Decatur, Ill., and Charles W. Rook, of Quincy, Ill.

The following officers were elected:

President: Dr. James Moores Ball, of St. Louis.

Senior Vice-President: Dr. Bayard Holmes, of Chicago.

Junior Vice President: Dr. L. A. Malone, of Jacksonville, Ill.

Treasurer: Dr. C. S. Chase, of Waterloo, Iowa.

Secretary: Dr. Frank P. Norbury, of Jacksonville, Ill.

St. Louis was selected as the next place of meeting, which is to be held April 2 to 4, 1895.

Dr. John A. Wyeth, of New York, has consented to deliver the address on Surgery.

Dr. Fred. Byron Robinson, of Chicago, will deliver the address on Gynecology, and Dr. David Cerna, of Galveston, Texas, will speak on "Recent Advances in Therapeutics."

Monument to Charcot.—The pupils and former associates of Charcot in Paris and throughout France are engaged in raising a fund for the erection of a bronze statue of him in the Salpêtrière. This movement is now receiving cordial and material support in Germany, in England, and in Italy.

It has therefore seemed desirable to the New York Neurological Society that the profession in America join in this testimonial.

For this purpose the Society has appointed a committee consisting of Drs. Edward D. Fisher, E. C. Seguin, M. Allen Starr, Charles L. Dana, and C. A. Herter, to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowleged and forwarded to the Central Committee in Paris.

New Medical, Pharmaceutical, and Dental Directory.—George Keil, 1715 Willington street, Philadelphia, has now in press the third edition of the *Medical and Dental Registry-Directory and Intelligencer* of Pennsylvania, New York, New Jersey, Maryland, Delaware, and the District of Columbia. It will present a complete list of the medical, pharmaceutical, and dental practitioners in the States named, with place and date of graduation; also professional educational institutions, hospitals, societies, etc. Medical men who have just located or removed are requested to forward their addresses, with desired information, to the publisher.

The Treatment of Appendicitis.—At the last meeting of the Board of Managers of the University Hospital the Director was authorized to set aside certain beds to be used by Professors William Pepper and J. William White for cases of appendicitis, those gentlemen being engaged in a special investigation of the symptoms, treatment, and pathology of that disease. Each case admitted to these beds will thus be studied from the outset with reference to both its medical and its surgical features. It is hoped that the results may aid in clearing up the prevalent differences of opinion as to this malady.

The Serum-Treatment of Diphtheria.—According to dispatches in the daily newspapers the Budget Committee of the French Parliament has resolved upon an appropriation of 100,000 francs with which to test the efficacy of the new diphtheria-serum.

A dispatch from Berlin says that Professor Virchow has expressed his opinion that the blood-serum prepared by Dr. Behring has the effect to protect the person taking it from the diphtheria for weeks, and possibly a few months, but says that it remains to be demonstrated whether the effect is permanent or really curative.

Medico-Legal Society.—A joint session of the Medico-Legal Society and the Section of Medico-Legal Surgery will be held at the Academy of Medicine, New York City, on November 15, 1894, at 8 o'clock P.M. precisely. The following papers will be read: "Hygienic Training of Men in Charge of Railway Trains," by Dr. Granville P. Conn; "Expert Examination of Plaintiff in Damage Cases, when Ordered by the Court,' by Dr. George Chaffee; "The True Line of Duty of the Railway Surgeon," by Clark Bell, Esq.; "Medical Witnesses," by Dr. R. S. Harnden.

Prof. Carl Fraenkel, of Marburg, has been elected to the Chair of Hygiene in the University of Halle, rendered vacant by the transfer of Prof. Renk to Dresden. Prof. Fraenkel will not assume the duties of his new position until some time next year, his place in the interim being occupied by Prof. Behring, of the Institute for Infectious Diseases in Berlin.

Prof. Oscar Fraentzel, a distinguished pupil of Traube, died at Berlin on September 18th, after a protracted illness, at the age of fifty-six. He contributed generously to medical literature, more particularly in the department of internal medicine.

Dr. Hunter Robb, late assistant in gynecology at the Johns Hopkins Hospital, has been elected to the chair of gynecology in the medical department of the Western Reserve University.

The American Academy of Railway Surgeons will hold its first meeting in the parlors of the Grand Pacific Hotel, Chicago, Ill., on Friday and Saturday, November 9 and 10, 1894.

Dr. John M. Fisher has been elected one of the gynecologists to the Philadelphia Hospital, in succession to Dr. E. E. Montgomery, who resigned after a long term of service.

ORIGINAL ARTICLES.

ABORTIVE AND AFEBRILE TYPHOID FEVER.[1]

BY SAMUEL A. FISK, A.M., M.D.,
OF DENVER, COL.

IN introducing, for discussion, the possibility of the existence of a condition which may be spoken of as "abortive" typhoid fever, or a condition presenting the symptoms of typhoid fever without the existence of the fever itself, or even with a subnormal temperature, I am well aware that I am opening a wide range for discussion, and one that may be seriously questioned. At the outset, however, I wish to urge the necessity in medicine of ever keeping one's eyes open to existing facts, and endeavoring to find an explanation for them, rather than accepting as law and gospel statements which however backed by authority, are not necessarily final.

The books describe a *prodromal* stage of typhoid fever of greater or less length, succeeded by from five to seven days of *invasion* with its gradually ascending temperature, two weeks of *fastigium*, then the *crisis*, and the decline by *lysis*. While we all recognize that this stands as a fair representation of a type, we see every day, in actual experience, variations from this type. We are coming to learn that nothing is so fixed in medicine that it cannot be changed. We have seen hydrogen sulphid and tuberculin throned and dethroned. The years are not far past since drainage was a *sine qua non* in all surgical dressings. The theory of self-limitation of disease is itself becoming limited. There are not many of us who, suffering from an attack of acute articular rheumatism, would willingly twirl our thumbs and philosophize with Flint that the duration must necessarily be twenty-six days. We have all seen cases that had the initial symptoms of croupous pneumonia that did not go on to fruition. We have even seen wide variations in the course of diphtheria. And so with typhoid fever, we are coming to learn that there are wide variances in its manifestations; that a condition may occur without the presence of any elevation of temperature, which in other respects must be dignified by the name of "typhoid" or "enteric" fever. This fact is now being recognized in the text-books. Osler, in his *Practice of Medicine*, p. 15, says:

"There are cases decribed in which the general features of the disease have been present without the existence of fever. They are extremely rare in this country. No instance of the kind has come under my observation."

In Pepper's *System of Medicine*, vol. i, p. 299, we find reference to a description of afebrile typhoid by Liebermeister, which says:

"Many of them never show during the entire course any rise of temperature, or occasionally a slight elevation only. Enlargement of the spleen could generally be detected and occasionally an unmistakable rose-colored eruption. The action of the bowels was usually irregular; sometimes there was diarrhea; sometimes, on the other hand, obstinate constipation. The other symptoms are prostration, pain throughout the body, often headache, persistent loss of appetite with more or less swollen, furred tongue, and marked diminished frequency of the pulse, which disappeared with convalescence, while its quality was not appreciably altered."

The long duration of an apparently trifling indisposition is considered as especially characteristic.

Strube writes of an outbreak during the siege of Paris in 1870: "In many cases the temperature was subnormal."

The existence of abortive typhoid is perhaps more generally recognized. We find ample authority for believing in its existence. Strümpell, for instance, writes:

"The name belongs to cases which begin with severe symptoms and high fever, as if they were going to be grave, but in which these violent symptoms disappear after a few days and give place to a rapid convalescence."

Niemeyer, Lebert, Osler, J. C. Wilson and Fagge all recognize the existence of abortive typhoid. It seems singular to meet with such a general acquiesence in this condition when formerly it was thought that typhoid or enteric fever must necessarily run a well-defined course of invasion, fastigium, crisis, and decline, and when we had the theories of self-limitation so thoroughly dinned into us. Our ideas with reference to this affection are likely to be still further modified; for there are those who are advancing the belief, supported by pathologic evidence, that typhoid fever may exist without the presence of intestinal lesions. Karlinski cites three cases of this kind and DuCazel reports another. The last was that of a patient who for three weeks presented the symptoms of

[1] Read before the Colorado State Medical Society, at Denver, June 20, 1894.

classic typhoid fever—headache, epistaxis, meteorism, rose-spots, congestion, fever, albuminuria, with a development of bilateral pneumonia. The case terminated fatally. Upon post-mortem examination the lungs were found almost completely hepatized and the spleen enlarged, while the intestines and the mesenteric glands were perfectly uninvolved. Bacteriologic examination of the spleen, however, demonstrated the presence of typhoid-bacilli in pure culture. The case suggests the query, as pointed out by one of our medical journals, whether some more accurately descriptive name than that of "typhoid" or "enteric" fever is not needed.

We all recognize that a diagnosis in disease is based upon a grouping of the symptoms, and that by a process of careful elimination we arrive at the condition we think to be most probable, to which we give a name, and which condition we assume to represent some pathologic change. We further recognize the fact that the chain of evidence is not invariably complete, and that we do not always have all the symptoms present that are given in the text-books as belonging to a given affection. So it is with typhoid fever. We are coming to learn that diarrhea is not an invariable accompaniment of the affection; that in fact we frequently find a condition of constipation, or something akin to it. The enlarged spleen is not always to be determined. Conditions may exist to mask its detection. If it be present skilful manipulation may fail to determine its existence.

We know that great variations exist with regard to the element of temperature, and opinions may differ with reference to the presence or absence of rose spots, though in my own experience I have seldom found them wanting, even if not invariably in large numbers. Thus we see that if our diagnosis must be squared by the four so-called cardinal symptoms of "pea-soup" stools, temperature, enlarged spleen, and rose-spots we may be in error, especially with reference to the cases of afebrile typhoid. Our opinion, then, must be based upon a broad consideration of the case. We must give due weight to the presence or absence of typhoid in the community. This is a factor of no little moment, as in epidemic seasons we see wider variations from the normal. We should consider the prodromal symptoms, the method of invasion, the feeling of malaise, indisposition to work, the furred tongue, the loss of appetite, the headache, the pains in the back and throughout the body, the recurrent nose-bleed. And here it does not seem to me that we should insist upon a torrent of blood. "It may not be so deep as a well nor so wide as a church-door, but 'tis enough—'twill serve." We do not always insist that a person shall bleed a pint or a quart from the lungs in order to say that he has had hemoptysis. And so if we inquire carefully with reference to these typhoid cases I think we shall frequently find that they have had stains on their handkerchiefs sufficient to attract attention, even though they may not have had a full and free epistaxis. The appearance of the tongue, too, is significant. The furred center, not necessarily brownish, the peculiar beefsteak-red border, this coloration at the tip often taking a pyramidal shape. Wakefulness at night, with mild delirium, coupled with other symptoms, is often suggestive. The facial aspect is peculiar and sometimes diagnostic. The tympanites and tenderness in the right iliac fossa must be looked for, and in due season the rose-spots and enlarged spleen. One swallow does not necessarily make a summer, and one rose-spot does make a diagnosis of typhoid, but taken in conjunction with other symptoms its significance should never be underestimated. Furthermore, by way of confirmation, the convalescence should be considered. It has seemed to me that the convalescence from typhoid fever is somewhat diagnostic in itself. The brightness of expression, the peculiar luster of the eyes, the relish for food, the hunger, the rapid putting on of flesh, the loss of hair; the grouping of these conditions conducing to give a general appearance of convalescence which, it seems to me, is somewhat peculiar to this affection and which should help confirm our opinion.

My point then is that a careful diagnosis should be based on a well-considered grouping of the conditions and symptoms, and we should never exact too close a compliance with so-called cardinal rules. Autopsy, moreover, sometimes shows ulceration of Peyer's patches, with enlargement of the spleen, when typhoid has never been thought to exist. Such pathologic specimens have been presented to our medical societies.

It is to be noticed that I have used the term "abortive" typhoid, and not "aborted" typhoid. Whether the course of treatment has an influence in producing the result, or whether the attack is a natural sequence, I am incapable of saying.

A case that came forcibly to my attentiou in the summer of 1888 was one of the early ones that brought this condition to my notice. I was called to see two young men of equal age, living together in a small house in the upper end of California street. The symptoms were identical, their illnesses were synchronous, the treatment was the same. In a day or two one was dismissed as well, the temperature having come to normal and the other symptoms having cleared up. He returned to his work but was urged to be cautious. The second one ran an attack of well-defined typhoid of moderate intensity. Later on I was told that my first patient was not feeling so well, and I took the precaution to

go to his place of business and inquire, but was assured that he never felt better in his life. I was surprised a week or ten days later to be called to his bedside and to find him genuinely sick with typhoid fever. He died a few weeks later after repeated hemorrhage from the bowel. My conviction has always been that had he rested and taken care of himself at the time he was dismissed he would probably have avoided any further trouble. Such cases are not infrequent, especially in hospital-service.

I am reminded of a somewhat similar case at the County Hospital occurring in a man who came in with what was considered to be typhoid fever in the early stage and, after a week, was dismissed as well. He returned three or four weeks later to pass through a regular course of typhoid.

It is not these cases, however, that I have especially in mind. I have cited them to note the tendency. The cases that I have spoken of as abortive are such as are described by Strümpell in the quotation just given, in which he speaks of the violent symptoms disappearing after a few days and giving place to a rapid convalescence.

In making the diagnosis care must be taken to note the previous history of the case, and not to confound it with ambulatory typhoid going on to convalesence.

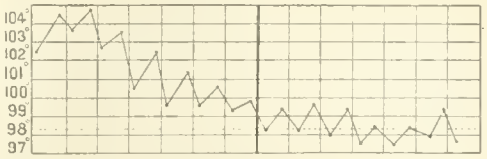
The chart that I now present (No. I) is that of a young woman, a school-teacher, who, in the fall of 1890, when typhoid was prevalent, having some prodromal symptoms, took to her bed and called me at once. The chart dates from the beginning of my attendance. The attack was probably near the end of the first week,

Chart I.

as rose-spots soon appeared. It was one of undoubted typhoid, the diagnosis being backed by the prodromes, the symptoms at the time and those of convalescence. She lost all her hair, which was a great privation, as it was her pride; she became quite stout; it was evidently a case of abortive typhoid.

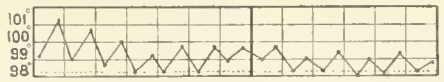
The third case (No. V), however, is one that was under my observation from the start. It is that of a young man with a tuberculous tendency, who came to this country because of his pulmonary affection. He complained

Chart III.



of malaise and symptoms that are usually defined as "biliousness." He had lived in a malarial region, and his case made me suspicious of a malarial outcropping, so that I purged him pretty vigorously and put him on

Chart IV.



Warburg's tincture, which simply aggravated his condition. After a few days he went to bed with a temperature as indicated, soon developing rose-spots and other well-

Chart V.

marked typhoid symptoms; but the subsidence of the fever, and the general improvement coincident therewith, justified the diagnosis of abortive typhoid.

From the foregoing condition it is but a step to the so-called *typhus levissimus*, or very mild typhoid, of which I introduce two charts.

The first is that of a young lady (No IV), occurring also in the fall of 1890, when typhoid was so prevalent, showing well-defined typhoid symptoms; the second (No. II) that of a man who a few years previously had had an attack of typhoid, and who was one of three cases, occurring at the same time, in the same house, one of which proved fatal with repeated hemorrhage from the bowel; the second running a well-defined course of typhoid.

These two cases are illustrative of conditions justly called *typhus levissimus*, occurring as they did

Chart II.

The second one (No. III) is also that of a school-teacher, about the same age as the first, and occurring the same season. She had undoubted typhoid, with a rapid convalescence. She was under my care from the time of going to bed. The temperature-chart here given represents the course of the illness while under observation. Some doubts may exist, however, with reference to this case, whether she may not have had the ambulatory form before going to bed, as she had been feeling poorly for some weeks before giving up.

in typhoid seasons, with typhoid surroundings, having typhoid symptoms, though mild, and the convalescence characteristic of the affection.

It is but a step further from *typhus levissimus* to a febrile typhoid. I recollect several such cases, two of them occurring in the fall of 1890.

One was in a prominent business-man of this town, who went to bed with typhoid symptoms, even to the rose-

spots. He had one or two slight hemorrhages from the bowel, and his condition was aggravated by stimulating food even as mild as beef-tea. He was kept in bed by his attack for the usual time, and never once did I find him with a normal temperature, but with a temperature somewhat subnormal and the pulse somewhat depressed.

A few months later I had another man under my care with typhoid symptoms. This attack was not attended with fever; indeed, the convalescence was exceedingly slow, and the nervous symptoms were particularly pronounced.

In the fall of 1892 I had under observation another man, who went into the mountains, where he subjected himself to considerable hardship, riding horseback, fishing, wading streams, sleeping out at night, and taking long journeys. He came back complaining of loss of appetite, of feeling tired, of lack of energy, and then went off on another trip to the southwestern portion of the State, and, while out driving one afternoon, was attacked with a severe chill, and hurried to Denver the following morning. He complained, in addition to the symptoms that I have mentioned, of loss of energy, loss of appetite, of fatigue, and of being sleepless. One thing that he noticed particularly was that for a week or so he had not been able to sleep; that he also had persistent pain in the small of his back of which he could not rid himself. His eyes were heavy and lusterless and his tongue furred. He had some diarrhea, and had been blowing some clots of blood out of his nostrils. There was tenderness in the right iliac fossa. His temperature, so far as I know, was never above the normal, and his pulse was subnormal, going as low as forty-two, forty-eight and fifty-two beats per minute. He had rose-spots in successive groups, and his spleen was enlarged.

I have repeatedly noticed in typhoid seasons patients with normal or subnormal temperatures whose condition I could only describe as typhoid upon whom treatment, at my hands, would make but little impression. These conditions I have come to regard as a species of afebrile typhoid and am learning to put the cases to bed at once and treat them as such, in which way I acquire the speediest and surest results.

Unquestionably, we shall have to divest ourselves of the belief that the typhoid state is invariably accompanied by the typhoid temperature, and we are learning that the condition to which we have given the name of "enteric" or "typhoid" fever is one that admits of wide variations from that which has been regarded as the type.

URIC-ACID LEUKOMAINS AS FACTORS IN THE ETIOLOGY OF MIGRAINE AND KINDRED NERVOUS DISEASES.

By B. K. RACHFORD, M.D.,
of Cincinnati, Ohio.

In The Medical News of May 26, 1894, I published a paper on "Paraxanthin as a Factor in the Etiology of Certain Obscure Nervous Conditions." That paper was based on the study of a patient who had had migraine all her life till she was past sixty years of age, at which time the migrainous attacks were superseded by epileptoid paroxysms, which came at about the same interval of time as the migrainous attacks had previously occurred, and produced no bad effect on the intellectual faculties. I showed, by a careful study of this case, that it belonged to the class of cases which were formerly thought to be due to an excess of uric acid in the blood, but which at the present time, since we know that uric acid is non-toxic, are left without any very definite pathology. I found that the urine of this patient passed during and just after a paroxysm contained not only an excess of uric acid, but also a *very great excess of paraxanthin*, a poisonous leukomain of the uric-acid group. I also found that the paraxanthin-solution taken from the urine of this patient, when injected into mice, produced symptoms like those from which my patient suffered. From this study I drew the conclusion that paraxanthin-poisoning, rather than uric-acid poisoning, is an important etiologic factor in producing these epileptoid attacks.

A subsequent study of this and other so-called uric-acid cases not only confirms me in the foregoing conclusion, but it has led me to believe that the uric-acid leukomains, of which paraxanthin is the most poisonous, are important etiologic factors in producing the nervous symptoms which have heretofore been attributed to uric acid. I believe that classic migraine is a leukomain-poisoning, and that there is a form of so-called epilepsy coming on late in life, often taking the place of the migrainous attacks of previous years, which has as its most important etiologic factor the very poisonous leukomain, paraxanthin. The foregoing conclusions will, if correct, be of much clinical importance. I wish, therefore, to afford an opportunity of judging of their value by presenting herewith, in connection with my previous paper already referred to, the evidence upon which they are based.

In the beginning I must express my obligations to Mr. Otto F. Bange for the assistance he has given me in this work; the investigations by him were conducted in his private laboratory and at his own expense, his only incentive being his love of science and his desire to assist me in the study of a question that not only required a great deal of time, but also much technical knowledge.

I am also indebted to Mr. Stuart Wallingford for assisting me in my private laboratory in making a number of urine-examinations. In my previous paper I gave the technique of the urinalysis and many other important facts which here have a direct bearing, but cannot be repeated.

Specimen No. 1. Two gallons of normal urine were obtained from soldiers at the Newport Barracks. This specimen was a portion of the morning urine passed by a large number of strong, healthy men.

It may, therefore, be taken to represent an average normal urine. The examination was made by Mr. Bange. The final fluid was evaporated to 8 c.c. Result: Paraxanthin was not present in sufficient quantity to be detected, and the final fluid was not poisonous to mice.

Specimen No. 2. Two gallons of normal urine were obtained as noted, and were examined by Mr. Wallingford under my direction. The final fluid was evaporated to 8 c.c. Result: No paraxanthin or other leukomains could be detected, and the resulting fluid was not poisonous to mice.

Specimen No. 3. Normal urine obtained as noted. Boric acid was added, and the fluid allowed to stand three days, and then examined by myself. The final fluid was evaporated to 8 c.c. Result: No paraxanthin or other leukomains could be detected, and the resulting fluid was not poisonous to mice.

Specimen No. 4. One quart of urine was obtained from a case of epilepsy—*grand mal.* The secretion was passed between and just after a series of severe epileptic convulsions. The patient was a boy, fifteen years of age, with a tuberculous family history. His mother attributed his sickness to a fright which he received when five years of age. For some years he has had one or more severe epileptic convulsions a day, usually occurring at night. At short intervals a large number of violent convulsions will occur during the same day, and following these severe attacks he will be quite unmanageable for several days. He cannot dress or undress himself, and his mind is hopelessly diseased. To be brief, I may say the boy is a typical case of very severe *grand mal.*

The urine was examined by Mr. Bange, the final fluid evaporated to 4 c.c. Result: No paraxanthin or other poisonous leukomains could be found, and the resulting fluid was not poisonous to mice.

Specimen No. 5. Two quarts of urine were obtained from a case of epilepsy—*petit mal.* This case was under observation at my clinic at the Medical College of Ohio for some months. The patient, a boy of ten years, had a bad tuberculous and nervous history; he was anemic and poorly nourished, and had had epilepsy for "four or five years." When he came to the clinic for treatment he was having on an average one attack a day. In these attacks the boy would lose consciousness for a few moments, and then complain of being sleepy. His mother said that at all times he was nervous and irritable, and much changed in his disposition. This boy was very much improved by treatment; so much so that when I sent him to the country (in June) he had had only one attack during the previous month. The improvement in his epilepsy was no doubt due to the improvement in his general health and strength. The treatment consisted in systematic exercise in the open air, good food, including one quart of milk each day, and syrup of iron iodid and cod-liver oil. The specimen of urine examined was obtained from this boy between and after two nervous attacks, and was examined by Mr. Wallingford under my direction. The final fluid was evaporated to 6 c.c. Result: No paraxanthin or other leukomain was found, and the resulting fluid was not poisonous to mice.

Specimen No. 6. Four quarts of urine were obtained from a case of acute mania following influenza. This patient was an overworked business man, fifty years of age. He had had a very severe attack of mania following influenza. The maniacal symptoms lasted some weeks, and then passed off. During the eighteen months following this first attack he had a number of attacks of acute mania; they would be accompanied by intense pain in the back, and would always follow symptoms of influenza. The last attack of this kind lasted two days, and it was during this time that the specimen of urine was obtained.

The urine was examined by myself. The final fluid was evaporated to 6 c.c. Result: No paraxanthin or other leukomains of the xanthin-group could be found. The resulting fluid was not poisonous to mice.

Specimen No. 7. Four quarts of urine passed by a patient during and after a severe attack of migraine. This patient was a German woman, thirty-three years of age, whom I had known for many years as a sick-headache sufferer. Her mother and one of her sisters also have the same disease. During the many years that I have known her she has often come to me hoping to get relief from these migrainous attacks, which came every two or three weeks and utterly prostrated her, confining her to bed for from twelve to twenty-four hours. At these times her stomach would reject all food, and she would suffer from intense headache. She was a great meat-eater and beer-drinker. A number of times I succeeded in making her quite comfortable and free from headaches for months at a time. The treatment at these times consisted in stopping the beer and fresh meat, giving her instead vegetables, fruit, eggs, and milk, *ad libitum.* The medicinal treatment was a dose of Carlsbad salts each morning and five drops of tincture of veratrum viride when the patient suspected an attack was coming on. When she would adhere to this treatment she suffered very much less from migraine. But always after some months of caretaking she would lapse into her old habits of eating and drinking, and the migrainous attacks would take on their former severity.

The urine was examined by Mr. Bange, and the final fluid evaporated to 10 c.c. Results: Paraxanthin and other leukomains of the xanthin-group were found in considerable quantities. The resulting fluid responded to the chemic tests for paraxanthin, and a drop of the fluid evaporated on a glass slide showed under the microscope paraxanthin-crystals, and when injected into mice this fluid produced poisonous symptoms resembling paraxanthin-poisoning. In this way the resulting fluid was shown to contain a substance which responded to the chemic, microscopic, and physiologic tests for paraxanthin. In the evaporation, other xanthin-leukomains crystallized out, but the fluid was not sufficiently evaporated to get rid of these leukomains and give a pure solution of paraxanthin, as was done in the case reported in my previous paper. The resulting fluid in this case was, therefore, a solution of the

leukomains of the xanthin-group, the most important of which is paraxanthin.

First experiment. Five minims of this fluid were injected into a full-grown house-mouse. In five minutes the mouse was very nervous, its breathing very rapid, its muscles twitching. The muscular twitching gave way to convulsive movements, and the mouse died fifteen minutes after the injection.

Second experiment. A second mouse was injected with two and a half minims of the same fluid. In fifteen minutes it did not resist handling, was apathetic, and its breathing rapid and labored. After the mouse had remained in this condition for a half-hour a second injection of two-and-one-half minims was given; three minutes later convulsive movements came on and continued till the mouse died, fifteen minutes after the last injection.

Specimen No. 8. Two gallons of urine were obtained from a patient in whom migrainous attacks were superseded by epileptoid attacks after she was sixty years of age. This is the same case so fully described in my previous paper, already referred to. The urine was passed between and for some days after two very severe attacks which occurred the same day. The urine was examined by Mr. Bange, and the final fluid evaporated to 8 c.c. Result: Paraxanthin and other leukomains of the xanthin-group were found in considerable quantities, and the resulting fluid was very poisonous to mice. From the resulting fluid hypoxanthin, xanthin, and other leukomains were eliminated, so as to have as pure a solution of paraxanthin as possible; this solution responded to the chemic, microscopic, and physiologic tests for paraxanthin.

The concentration and strength of this 8 c.c. of paraxanthin-solution is shown by its very poisonous effects on mice. If one minim of this solution was injected into the peritoneal cavity of a mouse it produced increased nervous excitability and convulsions, followed by general tetanic muscular contractions, which always terminated in death. The small quantity of the paraxanthin-solution (one minim) required to produce this effect, when compared with the non-poisonous effect of ten or twenty minims of the "resultant fluid" from normal urine, shows that in this case paraxanthin was enormously increased in quantity in the urine passed by this patient during or just after an epileptoid attack.

From the foregoing examinations and experiments the following summary may be made:

1. Two gallons of normal urine do not, by the method used, yield an appreciable quantity of paraxanthin or other leukomains of the xanthin-group.

2. One quart of *grand mal* epileptic urine passed between and after severe epileptic convulsions did not yield an appreciable quantity of paraxanthin or other leukomains of the xanthin-group.

3. Two quarts of *petit mal* epileptic urine, passed just before and after an attack, did not yield an appreciable quantity of paraxanthin or other leukomains of the xanthin-group.

4. Four quarts of urine from a case of influenza-mania, passed during the attack, did not contain an appreciable quantity of paraxanthin or other leukomains of the xanthin-group.

5. Four quarts of urine, passed during and after a severe migrainous attack, yielded considerable quantities of paraxanthin and other leukomains of the xanthin-group.

6. Eight quarts of urine, passed during and after a migrainous epileptoid attack, yielded comparatively large quantities of paraxanthin and other leukomains of the xanthin-group.

Upon the above investigations here summarized I base the following conclusions:

1. Normal urine contains such a small quantity of uric-acid leukomains that they cannot be detected in such quantities of urine as can conveniently be obtained from one person for urinalysis.

2. Many pathologic urines, including the urines in *grand mal*, *petit mal*, and influenza-mania, contain so small a quantity of the poisonous uric-acid leukomains that it is highly improbable that they act as etiologic factors in the production of these diseases.

3. Urine passed during an attack of migraine or migrainous epilepsy contains such comparatively large quantities of paraxanthin and other leukomains of the xanthin-group as to make it highly probable that they act as important etiologic factors in the production of these diseases.

At the present time there is probably no fallacy more deeply rooted in the medical mind than that uric acid and its compounds are toxic, and that they produce by their direct action on the nervous system a number of nervous diseases. The uric-acid theory of nervous disorders has never been supported by chemic or physiologic experiment. But it has been such a convenient theory to cloak our ignorance concerning the etiology of so many diseased conditions, that now we are loath to give it up, even in the light of the experiments which in recent years have demonstrated that it is non-toxic, and that it can only produce disease in a mechanical or reflex way by reason of its insolubility in the body-media. But the time has now come for us to discard, once and for all, the idea that uric acid and its compounds, by their presence in solution in the blood, can produce nervous symptoms. In accepting the non-toxicity of uric acid and its compounds we are compelled to seek another explanation for the nervous disorders which have heretofore been thought to be due to the toxicity of these substances. But in doing so we must not forget that uric acid and its compounds, by reason of their insolubility, may be pathologic factors in gravel, gout, and other diseased conditions, and that the term uric-acid diathesis is rightfully used to describe the condition in which, either from increased production or defi-

cient elimination, there is an excess of uric acid or its compounds either in the blood or in the tissues.

In some diseases, such, for example, as gout, which belong to the uric-acid diathesis, the distressing symptoms are no doubt due to the precipitation in the tissues or elsewhere of the comparatively insoluble urates; but in other diseases, such for example as migraine, which may also be classed as coming under the uric-acid diathesis, the uric acid, although it may occur in excess in the blood and urine of these cases, has nothing whatever to do with producing the constitutional symptoms. It is a sign, but not a cause of these diseases. The extensive and valuable studies of Haig and others have clearly demonstrated that there is a form of migraine and a form of epilepsy in which the excretion of uric acid and the proportion of uric acid to urea in the urine are greatly increased during the paroxysm of these diseases, but these carefully-made observations were misinterpreted to mean that uric acid in the blood was the cause of these diseases. My investigations show that in a case of migraine and in a case of migrainous epilepsy there was in the urine passed by these patients during their attacks, not only an increase of uric acid and an increase in the ratio of uric acid to urea, but there was also found a very great increase of the poisonous leukomains of the uric-acid group, and the paraxanthin-solution from the migrainous-epilepsy case produced in mice symptoms very like those from which my patient suffered.

These obervations tempt me to offer the following substitute for the uric-acid hypothesis in explaining the etiology of migraine and kindred nervous disorders.

First. Typical migraine is due to the action on the nervous centers of soluble, poisonous uric-acid leukomains. The presence of an excess of these leukomains in the blood precipitates an attack of migrane, which is terminated by their elimination through the stomach and kidneys.

Second. Leukomain-epilepsy is a form of epilepsy etiologically quite distinct from the other forms of epilepsy. It is caused by the action on the nervous centers of paraxanthin and other poisonous leukomains of the uric-acid group, which by their presence in the blood precipitate an attack. Leukomain-epilepsy usually supersedes migraine; it commonly comes on after middle life, and does not, as a rule, impair the intellect.

The foregoing is offered only as a working hypothesis, to be confirmed or disproved by subsequent work in this field.

NOTES ON TREATMENT.

In the case of migraine I got, as noted, fairly good results from Haig's dietetic treatment. No wine or malt liquors and no fresh meat were allowed, but milk, eggs, fruits, and vegetables, *ad libitum*. But in the case of leukomain-epilepsy very little good was accomplished by this treatment; however, when sodium phosphate, Carlsbad salts, or sodium salicylate was added to the treatment the patient was benefited. After some weeks without medicinal treatment this patient was placed upon potassium permanganate, one grain three times a day. At the present writing (August 12th) she has been taking the permanganate for two-and-one-half months, and has apparently derived more benefit from it than from the other medicines named. She passed a longer interval (seven weeks) without having an attack under the permanganate treatment than after any other. I am not at all sanguine about the therapeutic value of potassium permanganate in leukomain-poisoning, but only mention it here because it was suggested by the fact that I found it to be a good antidote for paraxanthin-poisoning in the mouse.

In my studies I was struck by the fact (as noted in my previous paper) that the most poisonous leukomains of the uric-acid group, viz., paraxanthin, xanthin, and gerontin, each have two atoms of O, while uric acid has three. Uric acid is, therefore, a more highly oxidized body than these poisonous leukomains. These facts suggested the use of potassium permanganate in leukomain-poisoning, because of its well-known oxidizing properties. I do not wish to offer the foregoing observations as an explanation of the action of the permanganate in paraxanthin-poisoning, but only mention them because they suggested its use in this condition. Before using the drug in the case of leukomain-epilepsy, as already narrated, the following experiments were made.

Experiment No. 1. One minim of the paraxanthin-solution obtained from the leukomain-epilepsy case + one minim of distilled water, was injected into the peritoneal cavity of a house-mouse; the mouse died from paraxanthin-poisoning with the symptoms previously detailed (control-experiment).

Experiment No. 2. One minim of the same paraxanthin-solution + one minim of a one per cent. solution of potassium permanganate was injected into the peritoneal cavity of a mouse. This mouse, although quite sick, did not have the characteristic symptoms of paraxanthin-poisoning, and, after a time, entirely recovered.

These and other experiments convinced me that the permanganate is a fairly good antidote for paraxanthin-poisoning in the mouse, and led me to try its use in the case of leukomain-poisoning from which the paraxanthin-solution was obtained. But I must say that my experience thus far does not promise any great things from the use of the drug in this condition.

I believe that in this paper I have touched upon

a field ripe for clinical research, and my only excuse for publishing observations so incomplete is that it is almost impossible for a busy practitioner to find the time to carry to anything like satisfactory completion a work that requires so much time and labor as this one does.

117 BROADWAY.

TEA-INTOXICATION.

BY JAMES WOOD, M.D.,

ATTENDING PHYSICIAN TO THE BROOKLYN CENTRAL DISPENSARY, BROOKLYN, N. Y.

THE intoxicating effects of tea are not appreciated so fully as they should be, either by the indulger in its infusion or by the physician who is later called upon to combat its untoward influence on the system and to give advice in regard to its further continuation. So very little is to be found in our text-books on the subject of tea-poisoning that, unless the facilities have been such as to make a study of it possible, a recognition of the condition is far from likely. That it is a potent factor in causing functional derangements of the gravest character is well known to those who have given its physiologic action serious attention.

Of 1000 consecutive cases applying for general treatment at our largest dispensary, 100, or 10 per cent., were found to be liberal indulgers in tea, and suffering from its deleterious effects, and no one of which came for treatment of the tea-habit, but for various other complaints. They were loath, when apprised of the cause of their illness, to believe that such a harmless household commodity ever produced any bad effects.

Of these 100 cases reported,[1] 20 per cent complained of persistent dizziness, 19 per cent. of indigestion, 45 per cent. of headache, 20 per cent. of despondency, 19 per cent. of palpitation of the heart, and 15 per cent. of insomnia. Truly the foregoing is an array of troublesome symptoms of which any pernicious drug should be proud.

A much more careful and exhaustive study was made of the next twenty-five cases, which furnish us with the following report of symptoms and the percentage of their frequency:

	Years.
Oldest tea-drinker	76
Youngest tea-drinker	18
Average age of the twenty-five cases	34¾
	Per cent.
Nationality—United States	60
" Irish	32
" English	8
	Pints.
Amount drunk in 24 hours—largest quantity	15
" " " smallest "	1½
" " " average "	5

Rheumatism	16

At first glance there is apparently a great difference in the percentages of the frequency of certain symptoms in the first one-hundred cases and the subsequent twenty-five. The explanation is that the study of the twenty-five cases commenced on July 1st, and during the hot weather people drink more tea than in the colder seasons of the year, hence the higher per cent. of evil symptoms.

That we may better appreciate the power which tea is capable of exerting, a brief outline of its physiologic action on the system would not be out of place, and is as follows: No nervous depression follows its use; the action of the skin is increased while that of the bowels is decreased; it is not narcotic; it is anesthetic hypodermatically; it decreases bodily temperature; it affects the sensory system; is a general excitant of the circulation; it dilates the capillaries of the splenic arcade; it retards digestion; it is mildly diuretic; it causes irregular and feeble cardiac action; it rouses and clears the mind and stimulates the imagination; it is an antidote to alcoholism; it lessens tissue-metamorphosis; it opposes active nutrition; it is astringent; it causes a sinking sensation in the epigastrium.

There is a great difference between physiologic and poisonous effects of a drug on the system. When tea has been used for a considerable period in excess and its detrimental action has been constant, we have well-defined symptoms supervene, a few of which are such as vertigo, mental confusion, sensible palpitation of the heart, restlessness, insomnia,

hallucinations, "nightmare," nausea, neuralgia, anorexia, constipation, prostration, and anxiety, and a peculiar kind of intoxication ending after hours of vigil in a sopor from exhaustion.

What worse line of symptoms could follow the use of a beverage so commonly employed it is hard to imagine, and that many people use it to excess is unquestionable. Many have confessed to an inability to "get through the day" without copious imbibitions of what is, in many cases, a strong decoction. Some drink every twenty-four hours as much as fifteen pints, and some there are who are unable to judge of how much they consume. Whether a confession would be considered a matter of shame, it is hard to say; the general lack of moral tone and the total perverseness are so great. They are nothing more or less than genuine inebriates, and look upon tea as the same agent of support as an alcoholic does upon alcohol. It is high time that physicians should recognize these cases of dipsomania and study a method for their amelioration.

The following cases are reported, necessarily very briefly, as typical tea-inebriates. Such symptoms as are due to other complaints have been abscinded, and great care has been taken to avoid confusion between effects caused by too free tea-drinking and those of other agents.

CASE 33.—Female, was exceedingly nervous and easily startled at every noise; suffered much from insomnia, and when able to get any sleep it was greatly disturbed by terrible "nightmare." During the day her mind was very prone to wander, and she had difficulty in concentrating her attention on her work. Palpitation of the heart was constant. She used the tea for its stimulating action alone, and drank eight pints in twenty-four hours.

CASE 101.—Male, was much excited and sleepless, and after drinking tea was troubled with severe abdominal pains and nausea. The bowels were constipated. He drank, besides three pints of tea, fifteen pints of coffee every day.

This case illustrates the antagonizing effects of coffee when it and tea are drunk together. This is a very common occurrence, and patients seem to be able to drink a great deal of both, with few bad symptoms, except the cerebral stimulating effects and the insomnia.

CASE 148.—Female, twelve years of age. Her bowels were constipated. She was subject to bad attacks of dyspepsia and nervous headache. She had no appetite for general food, and was content with tea and toast. She drank about four pints of strong tea a day.

This is the youngest inebriate that has come under my notice, and in her method of living represents a large number of young women working in our large stores and places of business. The food-value of a meal of tea and toast may be designated as *nil*, and a sure consequence of such living is sickness and days of enforced idleness. To ameliorate such a state of affairs would be of economic value to the working class. In the domain of tea-drinking, at least, this class does not appreciate one's efforts in their behalf.

CASE 228.—Female, suffered greatly from conscious palpitation of the heart, especially at night, and from dyspnea. The pupils were widely dilated; indigestion was troublesome, and also insomnia. She used four pints of tea a day.

CASE 838.—Male, had pains all over the body, insomnia, conscious palpitation of the heart, dizziness, muscular tremor, headache, constipation, and sinking sensation in the epigastrium. He often contemplated suicide. He drank five pints of strong tea a day.

CASE 839.—Female, was very despondent and weak, had no appetite, had occipital cephalalgia, sinking sensation in pit of stomach, and palpitation of the heart. She had a very strong desire to "do away with herself." She depended largely on toast, and drank daily three pints of the strongest decoction of tea she could make.

CASE 966.—Female, aged twenty-five years, has suffered for several months from intestinal catarrh. She is dizzy and complains much of general headache, insomnia, nausea, and muscular twitchings. The usual meal is tea and pie. When she does not have an opportunity of making tea she will eat the dry leaves. She has attempted suicide. She drank ten pints of strong tea a day.

These three cases, Nos. 838, 839, and 966, contain an element of interest. They are the only ones met with so far in our study of tea-drinking which have had suicidal tendencies. They also well illustrate the dietetic perversity already referred to.

CASE 935.—Female, had constant headache, muscular tremor, dyspepsia, and palpitation of the heart. Her sleep was restless and much troubled by dreams. She screamed at night and was very despondent. The menses were irregular and painful. She was anemic, with a most pronounced hemic murmur present. Twitching of the mouth and conscious pulsation of the epigastrium were perceptible. She drank four pints of tea a day.

This case was one of the most obstinate to treat, and for awhile seemed to defy the heretofore efficacious medication. Persistence gave its own reward, and she is now in excellent health.

CASE 1017.—Female, had severe pain in the epigastrium, nausea, constipation, vertigo, pain in the back and side, sinking spells, muscular tremor, very weak eyes, and loss of appetite. She had a constant dread of going to sleep for fear she would never wake up. Her usual amount of tea was nine pints per day.

CASE 1083.—Female, thirty-eight years old, had irregular menses, was very nervous and forgetful,

had distress in the stomach after imbibition of tea, dizziness, despondency, and muscular tremor. She drank six pints, and often more, a day.

Case 1134.—Female, sixteen years old, gave a history of severe intercostal neuralgia, nausea, indigestion, headache, cramps in the bowels, and diarrhea. She was very nervous, and muscular tremor was marked. She had an hallucination that she was soon to be killed or meet with some bad accident. She has never menstruated. She drinks six pints a day.

This case and Case No. 1017 are illustrative of quite a common hallucination among these people. They are either fearful of impending death or some accident which will leave them crippled or deformed, and often beg piteously for relief.

Case 1177.—Male, was unable to regulate his bowels for several months, and suffered much from headache, vertigo, mental confusion, palpitation of the heart, insomnia, nausea, muscular trembling, dyspnea, dyspepsia, despondency, and a feeling of vacuity in pit of stomach. He had various delusions. He used about four pints a day.

Case 1274.—Male, was very nervous, had vertigo, mental confusion, horrible dreams, despondency, anxiety, palpitation of the heart, dyspnea, sinking sensation in the pit of stomach, and constant pain at top of head. He also had hallucinations, but of no constant character; in speaking he became very much excited, and stammered. This soon became so bad that he was unable to talk and had a strong desire to do violence to the one with whom he was speaking. He drank four pints of tea a day.

Case 1292.—Female, forty-five years old, had some rheumatism in the ankle and slight pain in the side, and was constipated. She drank ten pints of the strongest tea a day.

This case is a noted one on account of the large amount of tea drunk and for the length of time that she has maintained the amount taken. The method of making the infusion which she used was the same as that employed by the others.

These are a few cases selected at random to illustrate the symptoms one is most likely to meet with and their severity in tea-dipsomania.

The method employed in making the infusion of tea by nearly all of the cases which have come under my observation is as follows: An unmeasured quantity of the leaves is thrown into the teapot and an unmeasured quantity of boiling water added. In any time from ten to thirty minutes this infusion is used. In the preparation of the second infusion the new leaves are thrown in with the old, which have been left to soak, and the procedure given is repeated. This continued throughout the twenty-four hours assures, after the first infusion, a decoction heavily loaded with tannin (from 7 to 17 per cent.) and thein, and in fact with all the constituents of the leaf soluble in either hot or cold water. A method more pernicious and sure to give its own reward could hardly be devised That tea is an agent capable of producing the most untoward effects upon the system, our cases fully substantiate.

In reports just received from the lunatic asylums of Ireland the excessive drinking of tea is given a prominent place as an etiologic factor in causing insanity. This fact and the adscititious data of the increase in the amount of tea imported yearly makes a more thorough study of tea-inebriety desirable. There are many economic questions involved which it would be well for scientific sociologists to recognize and place at their proper status. To the physician there is revealed a field for research in mental diseases which promises good results. Nor must the power of tea as a causative factor in disease be lost sight of. The safest advice would be to interdict its use as unquestionably as one would the excessive indulgence in alcohol.

162 St. John's Place.

ARE LIGATURE-FISTULÆ AFTER CELIOTOMIES AVOIDABLE?

By FRANCIS L. HAYNES, M.D.
of Los Angeles, California.

Text: "Dr. Jones reported the following case: A young woman came into Christ's Hospital with an abscess three inches above the pubes. Why it was there was a puzzle. She had been operated on eighteen months prior for an ovarian tumor by Dr. Reed. The probe passed down behind the pubes for a considerable distance. With the curet this portion of the ligature (shown), which had been put on the stump, was fished up.

"Dr. Reed: The silk is manifestly impure. I have had this same thing to happen to me several times. Generally there is some infection, followed by an abscess or sinus. Sometimes, these ligatures, when once contaminated, will feed a sinus indefinitely."—*Cincinnati Obstetrical Soc.; Journ. Am. Med. Association, June 23, 1894.*

Comment: The foregoing text will recall to almost every surgeon one or more similar cases, too many of which may fairly be considered incurable.

Are such failures in technique avoidable? I know of but one certain means to avoid them: to use catgut instead of silk or other unabsorbable material for ligatures which are to remain in the tissues. For intestinal sutures we should still retain silk.

The use of catgut in the abdominal cavity is no longer experimental. Many hundreds of cases carried to a successful termination attest its safety. In my last hundred celiotomies, including nephrectomy, pan-hysterectomy, myomectomy during pregnancy, and extra-uterine pregnancy, I have used catgut exclusively, except for intestinal suture, in which fine silk is used, for hysterorrhaphy and for suturing the abdominal incision, in both of which wormgut is used. All have fully recovered except a case of colotomy for enormous sloughing carcinoma of the rectum and one of ectopic gestation

in which a fetid placenta was removed from the abdominal cavity.

Catgut is a little more difficult to handle than silk, but with a few hours' practice on dogs all difficulties may be readily overcome.

Preparation of Catgut: It is best to buy the raw material from dealers in silk-mill supplies, as gut must be strong and fresh to be used by manufacturers. The gut is bought in long skeins. The surgeon disinfects his hands, and with strong boiled scissors divides the skein into pieces about twenty-five inches long. The individual pieces are then made into coils and loosely secured by loops, after which they are dropped into a boiled preserving-jar, soaked in Squibb's ether for forty-eight hours, then in ethereal sublimate solution 1:200 for forty-eight hours, and finally in absolute alcohol. Just before the operation the surgeon, or his first assistant, with boiled forceps picks from the jar a sufficient number of loops, with which he threads a number of boiled needles, which are arranged in a boiled platter, from which they are picked by the surgeon (not by a nurse) as he needs them. The rule is never to return a piece of catgut to the jar after it has been once removed. It is better to use small storage jars, rather than large; in fact, I take to the operating-room about enough gut for two operations.

Silk and silkworm-gut are boiled for two hours and stored in alcohol. Just before the operation, the needles are threaded and then are basted into a towel and placed in a copper boiler and boiled for half an hour, after which the water is poured off. As needles are needed during the operation, they are picked from the towel by the operator himself, the nurse holding near at hand the boiler containing the towel in which the threaded needles are basted. As the threaded needles are not touched after boiling by anything but the disinfected hands of the operator, it follows that the chances for infection are reduced to a minimum.

Summary: 1. Ligatures and sutures will occasionally produce fistulæ if non-absorbable or slowly absorbable thread is used.

2. Silk is readily sterilized, but is likely to become infected by the hands during the operation, or by the tubal mucosa or other sources or through the drainage-tube after operation.

3. Catgut carefully prepared is in most cases a very satisfactory ligature-material. Should it become infected, it would disappear too soon to produce permanent fistulæ.

4. Operators should pay more attention to the preparation of ligature-thread. After ligatures are sterilized they should not be handled by any one but the operator.

CLINICAL MEMORANDA.

A CASE OF EXSTROPHY OF THE BLADDER.[1]

By H. C. MASLAND, A.M., M.D.,
of Bethlehem, Pa.

Because of its comparative rarity, the following case of exstrophy of the bladder, I think, justifies a report. The following is the history:

Maud M., born August 16, 1893, was the third child of healthy, well-developed parents. The other two children were healthy and well formed. The mother stated that nothing unusual had happened during the period of gestation that might account for the deformity. Labor was easy and natural. When I was called in, about six weeks after birth, the child presented a healthy appearance, with an excessive development of adipose tissue, which is well shown in the appended illustrations.

In the hypogastric region there was found absence of the abdominal walls extending as high as the umbilicus. The anterior half of the bladder was also absent, and the posterior wall presented a red, papillated surface, protruding to a greater or lesser degree, according to the degree of intra-abdominal tension. The line of union of the bladder with the abdominal wall was well defined by a smooth, glossy strip of mucous membrane. At the lower aspect the orifices of the ureters were noted at the summit of little papillæ. The vulvar parts were medianly divided as far down as the anterior wall of the vagina. A very slight groove was present on the superior surface of the vaginal wall, which represented the normal urethra. The pubic symphysis was also absent. The hymen was normal. There was no hernia found on either side. This condition, so frequent in males suffering from this deformity, we would not expect to find as frequent in females, due, of course, to the different anatomic construction.

Fig. 1.

The parts were kept as clean as possible, but some excoriation of the tissues surrounding the bladder unavoidably ensued. This is shown in Fig. 1, which represents the condition prior to the operation.

I advised postponement of operative procedure until the parts had more nearly approached the adult position, as the bladder of the infant extends well into the ab-

[1] Read before the Northampton County Medical Society.

dominal cavity, receding to the pelvic cavity as the child grows older.

The child is less able to bear the strain of the summer months and the teething period with this continual irritation, but statistics show that a good percentage pass these trying periods safely, and considering the fact, too, that operation has never perfectly restored the parts—incontinence of urine persisting, I believed on the whole, that it was better to wait until the child was at least two years old before attempting operative relief. The mother was anxious, however, to have the operation performed, and I acceded to her request.

After all preliminary attention had been given to the bowels and the parts to be operated upon, on March 6, 1894, assisted by Drs. A. R. Wilson and F. H. Erwin, the operation was performed. I considered the method of procedure as advised by Prof. Wood, of London, to be the best adapted to cases of this nature, and it was carried out.

According to this plan, a middle flap was measured on the abdominal wall superior to the bladder. This was separated from the abdominal wall, hanging by its inferior border. A groove of good depth was then made around the border of the bladder to allow thorough coaptation of the flap. Next, the two lateral flaps were outlined and separated from their deeper structures, the pedicle of these also being the inferior border of the flap. All the flaps were cut a little larger than strict measurement, to allow for contraction.

A considerable amount of adipose tissue was included in the flaps, that we might secure a good circulation and better insure the vitality of the parts.

Having dissected the flaps in a satisfactory manner, I proceeded to fit the inverted superior flap into the groove prepared for it. To accomplish this the silk was threaded in two needles and passed in an outward direction, first through the inner edge of the groove, then through the flap, piercing first the dermal surface of the flap, then through the outer edge of the groove, where the two ends were tied. These so-called tongue and groove sutures were repeated till the first flap was completely attached. This was the tedious part of the operation, and occupied some little time.[1]

The two lateral flaps were then twisted at right angles on their pedicles and sutured end-to-end over the first flap. Sutures were also introduced uniting them to the subjacent flap.

The elasticity of the skin, due to the large amount of fat present, rendered it easier to draw together the edges of the wounds made, making it possible to almost completely cover the raw surfaces.

Silk sutures were used in both the buried and superficial stitches.

It was the original intention to catheterize the ureters. This necessitated the use of catheters of very small caliber, and after watching them awhile and believing there was a damming back of urine, they were discarded, and I used an ordinary rubber tube placed in the vesical cavity. Rubber dam was used to protect the dressings. Notwithstanding the great caution that was taken, we were unable to perfectly protect the lower parts of the flaps from being contaminated with urine. We did not, as a consequence, get complete primary union between the lateral flaps. The parts united, however, without any ill effect. Save the two tongue and groove sutures mentioned later, the other buried sutures were not seen till May 25, when two were passed in the urine.

Chloroform was used in this case, as I believe it preferable in children, when there are none of the special contra-indications to this anesthetic.

The temperature after the operation was 101.4°; the child reacted nicely, during the evening the temperature coming down to 99.6°. At no time subsequently did the temperature reach the initial height.

Opium was administered to quiet the child, as, of course, restlessness and crying would increase the abdominal pressure, and so tend to separate the flaps.

For the first ten days the child was kept on a broad splint projecting beyond the head and the feet, and well padded so as to produce a slight flexion of the thighs on the abdomen.

During the second week the child contracted a slight bronchitis, but responded kindly to treatment.

On July 6, four months after operation, I was called to see the patient and found her with a temperature of 101.8° and presenting considerable swelling over the right lateral flap. Fluctuation was detected, and we attributed the condition to an irritating suture. The knot of this suture was expelled on July 7th along with a considerable quantity of pus. The parts quickly healed, and have given no further trouble. Fig. 2 shows very well the parts as they appear at the present time.

FIG. 2.

The child was not weighed before and after the operation, but it did not apparently lose flesh. Owing to the pulling out of a tongue and groove suture on either side, attributed to some unavoidable restlessness, the parts separated somewhat, leaving an opening at the present time capable of admitting the end of the finger.

In conclusion, I might say I expect at some future

[1] In connection with this part of the operation I might draw attention to a condition that interested us. In order to prevent the sutures from pulling through the unresisting adipose tissue we found it necessary to leave a small strip of skin tissue on the outer edge of the groove. This was completely covered in by the lateral flaps in a later part of the operation. The question was as to the result that would follow burying this strip of skin by the lateral flap, leaving the skin in contact with the adipose tissue. As far as we can see no harm has resulted. None of the text-books to which I have had access makes any mention of this little point.

time to endeavor to find the ends of the sphincter vesicæ and unite them, at the same time endeavoring to form a normal urethra. Ashhurst states that this has not yet been accomplished so as to give control of the bladder. I am not sanguine as to the result, but no harm can be done, and the attempt is well worth making.

In regard to the statistics concerning this condition, Prof. Ashhurst informs me that, including this case, he has collected 115 cases, with 87 recoveries, 6 failures, and 22 deaths—a mortality of 19 per cent. As far as I can learn, this is the youngest case that has been operated upon for this interesting condition. The child was six months and eighteen days old at the time of operation.

CONTUSION OF THE ABDOMEN, WITH RUPTURE OF THE THORACIC DUCT.

By THOMAS H. MANLEY, M.D.,
VISITING SURGEON TO HARLEM HOSPITAL, NEW YORK.

Serious abdominal contusions always constitute an interesting class of cases, and the one here presented was, from several standpoints, of a unique and unusual character. I can find no parallel case in the annals of American surgery, nor in the older foreign works any one possessing all the features of this.

It has been a debatable point whether, in visceral, central disorganization from contusive violence, the viscera suffer by *contre coup*, or whether the injury results from force coming from before, the structure being crushed between it and the resisting spinal column behind. In this instance the quality of force was dual; almost simultaneously both contusive and compressive. The case was a typical one, too, as illustrating the obscure symptomatology which, as a rule, attends abdominal contusions in their early stages. Clinical phenomena in their usual order succeeded in this case which are witnessed in all grave abdominal injuries. But, notwithstanding the extent of injury, recovery has been complete, and no evidence exists that any structural changes remain that in any way diminish bodily strength.

In all serious abdominal injuries of a contusive or compressive character, one of three things must necessarily happen: (*a*) hemorrhage; (*b*) laceration of a fixed, solid organ; (*c*) rupture of some part of the alimentary canal or of some of the tubular structures within the abdomen. But as the patient is invariably in a condition of shock of a severe degree, it may be quite impossible immediately after injury to make a correct diagnosis for the purpose of guiding us in a rational therapy or in forecasting prognosis. This was the condition in the following case; it was only after several days that I was able to determine what organs were injured and what escaped.

The patient, a man, thirty-five years old, of medium height and spare build, was admitted to Harlem Hospital, July 3, 1893. On the morning of that day, about one hour after he had eaten a hearty breakfast, while crossing a street, he was struck with great force over the epigastrium by the pole of a brewery-wagon and knocked down on his back. Before the driver could stop his horses the front wheel passed over the center of the abdomen. An ambulance was called, and the injured man was immediately admitted to the hospital. At this time he was in a state of great shock. Hypodermatic injections of brandy and strychnin were administered and artificial heat applied. The man complained of intense pain in the abdomen on the slightest motion. There were no marks of injury on the integument, except on the right side near the crest of the ilium, where a slight erosion of the integument was discovered. The pulse was 70, the temperature 98°, and the respirations 20.

As reaction set in, the abdomen commenced to distend and everywhere was exquisitely sensitive. On the day after admission the patient complained of pain in the hypogastrium and required catheterization. Except for a slight tinge of blood in the urine its analysis was negative. There was no vomiting. Opium was freely given, and hot stupes applied locally. On the third day (July 5th) peritonitis with entero-paresis was unmistakable. The eyes were sunken, the nose pinched, and the lips and ears cool and blanched. The man was in great mental distress and constant suffering, which it required large doses of opium to assuage. He was nourished altogether by enemata, and was allowed bits of ice to suck to relieve thirst, which now was excessive. The abdomen was hard, sensitive, and flattened, the knees extremely flexed to relieve muscular tension. The temperature on this date was 100.4°, the pulse 86, and the respirations 32. On July 8th and 9th the patient was about the same, except that he was becoming somewhat weaker. On July 10th the symptoms commenced to ameliorate; the abdomen was less tender, and he began to demand food. The pulse was 80, the temperature 100°, and the respirations 21.

At this time, on the right side, over the right iliac fossa, low down over the course of Poupart's ligament, there was a distinct bulging forward of the abdominal wall; this enlarged and diminished in volume, according to the position which the body took, being much the largest when the patient lay on the right side.

It was well defined, and transmitted a distinct fluctuating sensation on pressure. The surface of the integument over it was not reddened, and not hotter than elsewhere. On percussion, it was evident that whatever its nature, it had pressed the intestinal coils away from it; for it everywhere emitted a dull sound. It was nowhere sensitive, and on firm pressure could be made to quickly disappear. From its general character it was supposed that it was a hematoma. To definitely determine the question, an exploratory needle was introduced and the syringe filled. It was found that the collection was a fluid of a milky color and consistence. An incision was now made into the tumor, when a little more than sixteen ounces of a lactiferous fluid was discharged and secured as it came through the incision. The tumor was lodged immediately behind the peritoneum, over the sheath of the muscles. A drainage-tube was passed into the opening, its free end being engaged in a perforated cork in a pint-bottle. In the next twenty-four hours eight ounces of the same fluid were collected through the tube, but a large quantity had made its way out beside the tube and saturated everything in near contact. In the next four days the daily quantity collected averaged from five to six ounces. In the meantime, there was much that made its way out into the

clothing. It continued to drop, more or less, for ten days, when it finally ceased. All the time that this discharge took place the appetite was good, but the man became steadily weaker until the discharge ceased. He constantly complained of a feeling of emptiness in the stomach, and, particularly during the night, he clamored for food. On the fifteenth day the wound had healed and he was up.

A careful microscopic and chemic examination was made of the specimens of fluid evacuated at various times on the same day and on successive days, and was demonstrated to consist of pure chyle. The color was a bluish-white, very much like that of woman's milk. Its taste was slightly salty. Its odor was feeble, giving off an aroma very much like that from fresh, warm milk. Its specific gravity varied from 10.10 to 10.19; under the microscope it was found to contain an abundance of characteristic lymph-corpuscles, granules of fat, broken-down endothelium, and flakes of an ill-defined substance, probably coagulated protoplasm. On some days its specific gravity was less than on others, and it was always noted that it flowed most abundantly after eating. The man left the hospital August 31st, quite restored to health.

As this accident must have produced ulceration of some part of the chylous system within the abdomen, it is interesting to speculate on its *modus operandi* and where the brunt of force was sustained. I believe that it was the reservoir of the chyle which was ruptured while distended early after breakfast. The viscus is lodged behind the peritoneum, resting on the body of the second lumbar vertebra. It was violently crushed by the wagon-pole against the bony wall of the spine. The fluid, in response to gravitation, the same as in hemorrhage, gravitated into the flank, making its way around through the loose retro-peritoneal tissues, following the course of the psoas muscle over the iliac fascia till its further descent was arrested at the crural arch.

It certainly does seem extraordinary that a structure so well protected as the thoracic duct can sustain damage, while overlying, more exposed parts escape. This is difficult to explain; but, that it does occur is beyond question, as, for instance, when the aorta is torn open, or the deeply protected ureters, and various vessels in the abdominal viscera. A case of rupture of the common bile-duct with an enormous leakage into the peritoneal cavity was under my care three years ago which conclusively proved this. The young man had been run over by a heavily laden wagon. Shortly after (three days) he was tapped, when two gallons of bile were removed. On autopsy, a laceration four centimeters below the cystic conduit was discovered. None of the overlying organs was damaged.

The obscurity of diagnosis here was an interesting feature, and in this instance it is evident that an exploratory celiotomy would have accomplished no good, but on the contrary, would probably have very much diminished the patient's chances of recovery.

The Alvarenga Prize of the College of Physicians of Philadelphia, for 1894, has been awarded to Dr. G. E. De Schweinitz, for an essay entitled "The Toxic Amblyopias: their Pathology and Treatment."

SUPPURATIVE SACRO-ILIAC DISEASE DUE TO INDIRECT VIOLENCE, WITH NERVOUS SYMPTOMS.

BY A. H. P. LEUF, M.D.,
OF PHILADELPHIA.

THE following case is of interest in being a deviation from the rule. Ordinarily if the body has momentum from locomotion, and the lower extremities are suddenly arrested, there is likely to result a strain of the ligaments of the ankle or knee, or a dislocation of the ankle, or a fracture of the lower end of the leg. In the subjoined case, however, although the conditions named existed, the result was very different from what was to have been expected.

On February 28, 1891, I was requested by her legal adviser to see a lady with a view to determining her existing status, resulting from an injury due to negligence on the part of the city authorities, against whom she had entered suit for damages. I found a widowed lady of education, culture, and refinement, fifty years of age, American by birth, and rather stout. While out on the evening of June 22, 1890, mailing a letter, and as she stepped upon the sidewalk from the street-crossing, her left foot, instead of landing upon solid ground, passed down into a hole from twelve to fifteen inches deep, and large enough to readily admit the foot. She fell forward upon her hands. With a little aid she limped back to her home, only a short block away. At the time of the fall she experienced a "sudden, sharp, deep, burning pain" in the left hip and in the region of the back of the left sacro-iliac joint. Until August 20th of the same year she had almost constant pain, with occasional remissions lasting from half a day to two days at a time. During this period she used the common "liniments" and "pain-relievers" advertised by manufacturers and the simple remedies generally depended upon under similar circumstances. On August 20th, however, the pain became so severe that she took to bed. The pain was aggravated by motion. No other parts were affected, except the left knee and ankle to a slight extent. The woman remained in bed three weeks under homeopathic treatment, suffering pain all the time. She continued under the same medical care for fourteen weeks longer. During the first three weeks in bed she had "beating, throbbing pain, at times like labor-pains," at the site of the left sacro-iliac joint posteriorly. A hard ridge crossed the line of this articulation; it was three-and-one-half inches in length, with a depressed spot in the center, the size of a half-dime. During these three weeks this ridge, and especially the spot, were excruciatingly tender. The woman became rapidly emaciated, until she was "very thin." It was only in the middle of January, 1891, that she began to get around alone, with the aid of a cane.

When I called, she still had pain, at times severe and at others not. That in the knee and ankle continued from the beginning to the present, recurring every few days. Walking caused pain to appear, if absent during rest, and increased it if it already existed. To sit steadily, or to maintain any fixed position for ten or fifteen minutes, caused pain that constantly increased if her position was not changed. The pain was deep-seated. The woman complained of a very uncomfortable surface-

numbness at the lower end of the spine and back of the left hip. When she first sat up she had perfect numbness of both lower limbs and the buttocks. She could not use either leg for a long time while in bed, nor for a time after she began getting up. There was marked hyperesthesia of the left leg for eight weeks from August 20, 1890. Simply touching the skin would at times elicit screams. For seven weeks she was obliged to sleep upon her abdomen. After the three weeks in bed she could only leave the bed by being carefully lifted out, and then the most delicate handling caused excruciating pain. She was as helpless as a child.

About the third day in bed she developed a very free vaginal discharge, lasting more than three weeks. "The discharge was thick, greenish-yellow, and very offensive, the odor so penetrating as to make the room almost unbearable." She said "toothache is heaven to the pain I suffered that time."

During the December holidays she dismissed the homeopath and secured the services of a regular physician. The diagnosis of the former had been typhoid fever; that of the latter rheumatism, or at least a chronic congestion of the fibrous structures of the hip and vicinity, possibly caused by the injury. She improved rapidly during January and February, so that when I saw her she had regained her former weight, looked well, and could walk alone with care and effort. Some of her trouble in getting about was undoubtedly mental.

After a careful consideration of her history I concluded as follows: The sudden arrest of her foot while walking, and its fixation in the hole in the ground, against the edge of which her leg was fixed, as evidenced by a deep abrasion and subsequent scar, caused the momentum of her trunk, head and arms to continue these forward. While her foot was wedged in the bottom of the hole the leg at the junction of its middle and upper thirds pressed against the edge. The greatest strain was at the point of contact with the edge of the opening, but the contact being so high up on the leg prevented a fracture, for the double reason that at this point the tibia is much stronger than at its lower end, and because the leverage was less—*i. e.*, there was greater resistance and less power. At the moment of strain the knee was promptly fixed by its musculature, and so was the hip. The least protected parts were the two sacro-iliac joints, which have very little muscular protection, this being almost entirely fibrous. The keystone character of the sacrum in the posterior pelvic arch, with the forward tilting of its superincumbent weight and added momentum, the force of which this bone was so suddenly called upon to arrest, proved too much for its unsupported ligaments and its spongy tissue. The strain was sufficient to wrench or crush the cartilaginous face of the joint, and perhaps to tear the attachment of the fibers passing into the bone at the back of the articulation.

Had this condition been recognized at once, had counter-irritation, or local depletion by leeches been applied, and had absolute rest been steadily enforced until a day or two after subsidence of all pain, I believe that the woman would have made a complete and uneventful recovery. But the condition was not even suspected. The parts were compelled to do their work while attempting repair. The conditions were too severe; congestion increased, inflammation supervened, there was necrosis of cartilage, accompanied and followed by suppuration. The effort at repair while the joint was taxed with its normal work was marked by the two months after the injury, during which the patient kept about, but when destruction had fully set in she took to bed. The tension of the accumulating pus confined within the narrow limits of the sacro-iliac joint, with bony walls on each side, and ligamentous bands all around, was so great as to cause pain almost unbearable. Extension was in the direction of least resistance, which was anteriorly, though progress had been made behind, as evidenced by the tender, bulging ridge. Its anterior progress irritated the sacral plexus, causing hyperesthesia over its area of distribution, and subsequently, through pressure upon this plexus, paralysis and numbness of both lower limbs occurred, especially of the left, that of the right probably being largely reflex or sympathetic.

The possibility of extension of the pus through the auricular surface of the sacrum into the sacral canal, and thence upon the roots of the sacral plexus of each side, must not be overlooked. The slow and gradual mode of improvement is most readily accounted for on this supposition. Of course, evidence either way concerning this possibility was no longer available with any certainty when I saw her. No history had been kept by either attendant.

Eventually the abscess discharged into the vagina. The pus was characteristically greenish and horribly and penetratingly fetid. The discharge continued until the recuperative powers of the patient had completed the repair. As this progressed the symptoms waned, the patient felt better, her appetite returned, her nutrition improved, and she became convalescent. Tenderness of the parts naturally remained for awhile, as is the rule, but it gradually wore away.

If correct in my supposition, verification should be certain and easy through the vagina. An examination was, therefore, made with her attending physician. A small nodular scar, about one-quarter inch in diameter, was found in the upper end of the vagina, on the patient's left side. It was very markedly drawn directly toward the left sacro-iliac joint by a cylindrical band of scar-tissue.

I may also add that there were no local spinal symptoms indicating disease of the cord.

The case went to trial, and the woman recovered damages.

AMPUTATION AT THE HIP-JOINT BY WYETH'S METHOD.

By ROBERT T. MORRIS, M.D.,
of Houston, Texas.

Some months ago, while an interne in the Charity Hospital, New Orleans, through the courtesy of Drs. Souchon and Matas, I performed a disarticulation at the hip-joint by the Wyeth method.

The history of this operation and the statistics to sustain it, and its advantages over allied operations have been so completely investigated and reported by Wyeth, Lanphear, Parham, and others, that it would be superfluous to attempt to make any additions. Suffice it to say that the mortality in civil practice has been reduced

from 64.1 per cent. to about 22 per cent. by this method, and that the two great sources of danger—shock and hemorrhage—have been materially diminished; in fact when the needles and tourniquet have been properly applied the hemorrhage is under complete control.

The case which I operated upon is as follows:

J. B., aged nineteen years, entered the Charity Hospital, March 16, 1894. His brothers and sisters are all healthy, and he is without tuberculous or syphilitic history. He had spent all of his life in the country on a farm. About December 3, 1893, while at work, he was hit on the external condyle of the femur with a "dolley," the blow producing considerable pain and incapacitating him for work for several days. About one month later a horse fell upon the same limb, injuring it to such an extent that he was compelled to use a crutch while walking. A tumor appeared soon after the last accident, and increased rapidly in size.

The patient is a tall negro, slightly narrow-chested, and of a cachectic appearance. His evening temperature registered between 99° and 100°. An examination disclosed a large spindle-shaped tumor, involving the thigh and leg of the right side, the greatest circumference of which, twenty-seven inches, was at the lower third of the shaft of the femur. The upper visual limit of the growth was about five inches below the anterior inferior spine of the ilium, the lower about four inches below the lower border of the patella. By aspiration a small quantity of dark, sanious fluid was removed from the joint-cavity. The inguinal glands were enlarged.

After explaining to the patient the gravity of the operation and the necessity of removing the focus of infection, he submitted to treatment.

The night previous to and the morning of the operation ten minims of the tincture of digitalis were administered. Chloroform was the anesthetic used. Mattress-needles were used to support the tourniquet. On April 3, 1894, the limb was disarticulated, observing closely the directions given in Wyeth's article in THE MEDICAL NEWS of December 9, 1893. After the limb had been elevated and an Esmarch bandage applied, the needles were inserted. While making the skin-incision it was noticed that the limb was not completely exsanguinated, and the tourniquet was retightened, after which no bleeding resulted.

The ideal flap was made; the circular muscular incision was on a level with the trochanter minor; the limb was then disarticulated and the vessels ligated.

The condition of the patient after the operation was satisfactory; shock was slight, and the man soon reacted. The day after the operation the temperature ran up to 101°, and continued above normal until his death, eleven days later. Six days after the operation nausea and vomiting supervened, which were the forerunners of peritonitis of a tuberculous nature.

The *autopsy* showed tuberculous enlargement of the internal iliac, lumbar, and mesenteric glands. There was also a tuberculous peritonitis.

It will be noticed that there were a few variations from Wyeth's original operation. It is recommended to remove the soft parts some inches below the muscular incision to facilitate the search for the vessels. This seems to be a needless complication, and unnecessarily prolongs the operation, and in consequence aggravates the shock. If the tourniquet is properly applied and supported there is no danger of disarticulating previously to the ligation. This, of course, pre-supposes the application of the needles sufficiently high to permit of disarticulation without their removal. Murdoch's suggestion of leaving the limb intact to use as a lever in disarticulating was utilized.

I think an observance of these modifications would remove the only serious objection to the operation—that the delay by this method and the double operation, amputation and disarticulation, greatly increase the shock.

A CASE OF SUBDURAL HEMORRHAGE.

BY J. SHELTON HORSLEY, M.D.,
OF STAUNTON, VA.

A. B., colored, about forty-three years of age, was a man who had not for some time enjoyed good health. About twenty years ago he contracted syphilis, which continued to trouble him to the time of his death. He had also been a very hard drinker, from which habit he was never completely free. He was not, however, subject to epileptic seizures or troubled in any way with cerebral symptoms so far as the knowledge of his physician extends.

On the afternoon of August 6, 1894, while sitting in a wagon, which was being driven slowly, he said the "hand he was holding on with slipped," and he fell, striking the left parietal eminence against the edge of the curbing. The wound inflicted was slight, being about one-and-a-half inches in length and not extending to the bone. He got up and seemed to have a slight convulsion of the left arm. Dr. Catlett was sent for, and after giving the wound proper attention he had the man sent home, a few blocks distant. The man was perfectly conscious at this time (4.30 P. M.), and as he complained of being nervous, Dr. Catlett gave him ammonium bromid. At 5 o'clock the Doctor was again sent for, and found the patient conscious, but having general convulsions. He then gave him a hypodermatic injection of morphin and atropin, which seemed to afford relief, and the spasm was then confined to his left arm.

At 6.30 P.M. the man was completely unconscious, his pulse full and rather slow. His respirations were stertorous, his body covered with sweat, and the temperature slightly elevated. At 10.30 of the same morning I saw the patient in consultation with Dr. Catlett. His condition was much worse; the respirations were shallow, difficult, and stertorous; the abdomen was very tympanitic; the pupils slightly dilated; the pulse about 125 per minute and weak. The spasm was confined to the left arm, the rest of the body being quiet, and consisted in eight or ten rapid partial flexions and extensions of the forearm upon the arm, the wrist and fingers not being involved. This happened every two or three minutes. The head was turned to the left side, and the eyes were also rotated in the same direction.

We thought of operating then. Weisemann's series of 257 cases of intra-cranial hemorrhage, 147 of which were treated expectantly, 131 dying; while of 110 operated on, only thirty died, would alone establish the justification of operating in cases of this kind, even in the most desperate conditions. However, the surroundings, which

were filthy, and many adverse circumstances deterred us so we gave a hypodermatic injection of ergotin, and left, feeling certain that the issue must shortly be fatal. The man died at 12.30 A. M., eight hours after receiving the injury.

The case being a peculiar one, we held an autopsy and procured the brain. The bone beneath the scalp-wound was sound and apparently uninjured, but had a slightly reddish tinge. The dura and the brain beneath presented nothing peculiar, but all the cortical blood-vessels were injected and engorged throughout the entire surface. We took out the brain and found an irregularly shaped clot on the outer surface of the right temporo-sphenoidal lobe, which proceeded apparently from the artery between the inferior and middle temporo-sphenoidal convolutions. This clot covered a portion of the outer surfaces of the three temporo-sphenoidal convolutions, the middle and inferior being chiefly affected. It was about two inches at its broadest diameter, an inch at its narrowest, and not more than one-sixth of an inch deep at its thickest point.

Feeling that there must be some other lesion to account for the arm-symptoms, we examined further and found a small clot just below the margin on the anterior portion of the inner surface of the upper end of the ascending frontal convolution. Further dissection revealed nothing of interest.

Among the points worthy of note are: 1. The main clot was found about diametrically opposite to the seat of the external injury, where the force-waves met. 2. There was another small clot nearer the original wound, which alone could account for the arm-symptoms. 3. Rapid death, hastened, I suppose, by a debilitated constitution, as the lesions found did not seem to be sufficient to cause death in a healthy individual, in such a short time. 4. The walls of all the bloodvessels seemed degenerated, the result, most probably, of syphilis and alcohol. I feel confident that if they had been normal, no such hemorrhage would have occurred.

MEDICAL PROGRESS.

Castration for Rupture of the Vas Deferens.—CARLESS (*Lancet*, No. 3708, p. 687) has reported the case of a strong, healthy-looking man, about forty-seven years old, who while lifting a piano was crushed, the whole weight of the instrument falling upon the patient, who at once felt a severe pain in the left side of the scrotum and in the left testicle, which became swollen and tender. No special notice was taken of this, as the pain passed away, but on attempting intercourse with his wife a few days later the most severe pain was again experienced in the testicle, which also became enlarged, and blood was found to have passed per urethram. On examination, the epididymis was observed to be large and tender, the swelling being most marked in the neighborhood of the globus minor, the testicle itself being of normal size and shape. Sexual intercourse was then omitted for some months, and at the end of that time, when attempted, was accompanied by great and sickening pain, with enlargement of the testicle. The patient was lost sight of for three years, remaining in the same condition. At the end of this time examination disclosed a chronic thickening of the epididymis, the testicle being still of normal size and consistence. There was also a definite varicocele, and a good deal of dragging pain was experienced. Sexual connection had been but little attempted during the interval, but was still excessively painful. Evidently the case was one of rupture of the vas deferens and castration was recommended. After the lapse of three months the left testicle was removed through an incision over the situation of the spermatic cord and not encroaching on the scrotum. The operation was a very simple one, as no adhesions existed, the cord being tied with silk in several pieces and divided close to the external abdominal ring. The wound healed by first intention in eight days, and the patient left the hospital in twelve days.

Vasomotor Rhinitis of Malarial Origin.—CHAPPELL (*New York Medical Journal*, No. 826, p. 403) has reported the case of a girl, eighteen years old, who was awakened early one morning by a chilly sensation, followed in half an hour by violent sneezing and a copious watery discharge from the nose. In the course of three hours the attack began to subside, and disappeared completely in three hours more. Later in the day considerable languor and drowsiness were experienced. On the following morning the attack was repeated at the same hour, and the symptoms recurred thus daily for a week. Various local remedies and internal medication were employed, with no relief until quinin was given. Three other cases of similar character are reported—one in a male of fifty, the second in a female of thirty-one, and the third in a female of forty-two. Ten others of a similar character have been observed, and it is believed that many such cases escape accurate diagnosis. In some of the patients the symptoms yielded to the administration of quinin, while in others they were favorably modified.

A Case of Traumatic Diphtheria with the Demonstration of Diphtheria-Bacilli.—ABEL (*Deut. med. Woch.*, 1894, No. 26, p. 548; *Centralbl. f. Bakteriol. u. Parasit.*, Bd. xvi, Nos. 10, 11, p. 455) has reported the case of a girl suffering with an attack of faucial diphtheria, in which, on the tenth day of the disease, a croupous deposit formed on a small wound on the ring-finger of the left hand, in which diphtheria-bacilli were found in pure culture. The wound healed in the course of twelve days under treatment by local applications of an iron solution. The diphtheria-bacilli, both from the wound as well as those obtained from the membrane in the pharynx, proved feebly virulent for guinea-pigs. The case demonstrates, in so far as experiment can, that diphtheria-bacilli alone, without the aid of other microörganisms, may infect wounds and give rise to the formation of false membrane.

Triple Births.—MIRABEAU (*Ueber Drillingsgeburten*, München, 1894; *St. Petersburger med. Woch.*, 1894, No. 36, p. 329) has found that triple births are most common (1 to 6500) in multiparous women between thirty and thirty-four years of age, the pregnancy being usually preceded by a long interval of sterility. Women who bear triplets usually come of families in which plural pregnancies are hereditary. Uterus duplex is believed to be a predisposing factor. The more fertile a community—that is, the larger the number of multiparous

women, the more common are triple births. In Russia the number of these is 1 : 4054; in Sweden, 1 : 4400: in England, 1 : 4600; in Germany, 1 : 7129; in France, 1 : 8256.

The Prevention of Recurrence of Volvulus.—On the hypothesis that volvulus of the sigmoid flexure of the colon is due to a shrinking of the mesocolon at its parietal attachment, which brings the arms of the S more nearly together, and which then, filled with scybala, swing to and fro, until finally torsion results, Roux (*Centralbl. f. Chirurgie*, No. 37) recommends fixing of the mesocolon to the abdominal wall, in order to hinder the excursions of this long-pedicled, offending loop, and thus prevent the recurrence of torsion. After releasing the volvulus he fixes the entire mesocolon laterally to the parietal peritoneum by means of a continuous catgut suture extending nearly to the linea alba.

THERAPEUTIC NOTES.

For Pulmonary Tuberculosis.—S. Solis-Cohen (*Philadelphia Polyclinic*, vol. iii, No. 28, p. 276 and No. 39, p. 386) recommends the following formula in cases of pulmonary tuberculosis presenting evidences of breaking down of tissue, or in which signs or symptoms of catarrhal processes in any portion of the air-passages are present, or in which there is continuous elevation of temperature or intermittent or remittent fever, exceeding 99.5 F.°:

℞.—Creosoti (beechwood) . . . ♏xxx–lxxx.
Tinct. cardamomi . . . f ℥iv.
Glycerini . . . . . f ℥ij.
Alcoholis . . . q. s. ad. f ℥ iv.—M.

S.—Two teaspoonfuls in water after meals.

Note.—To the glycerin add the creosote, then the tincture of cardamom and alcohol. The smaller dose of creosote is used at first, and the quantity gradually increased until five drops, four times a day, is reached as a maximum.

In certain cases of pulmonary tuberculosis, in which it is desired to act upon the heart in order to improve the pulmonary and general circulation and to stimulate the bronchial mucous membrane and respiratory tract in general, the following combination will prove useful:

℞.—Benzoyl guaiacol . . . . ℥j.
Powder of digitalis . . . gr. iij.
Eucalyptol . . . . . ♏xxiv.
Extract of gentian . . . q. s.—M.

Make twelve capsules.

S.—One capsule four times a day.

The following formula is of much benefit as a tonic nutrient in the early stages of pulmonary tuberculosis in anemic and scrofulous subjects, and in the prevention of the development of tuberculosis in predisposed persons worn out by nursing relatives in the last stage of this disease or otherwise run down in health.

℞.—Tincture of ferric chlorid . . f ℥ij.
Dilute phosphoric acid . . . f ℥iij.
Churchill's syrup of the hypophosphites . . . . . q. s. f ℥iij.—M.

S.—Two teaspoonfuls in a tablespoonful of water, after meals, thrice daily.

If softening have already taken place a few drops of creosote may be added to the dose. Inhalations of compressed air and systematic over-feeding must likewise be employed if it is desired to bring about a recovery.

Intravenous Injections of Mercuric Chlorid in the Treatment of Venous Septic Infection in the Puerperal State.—Kézmársky (*Centralbl. f. Gynäk.*, No. 38, p. 906) has reported the case of a quintipara who came under observation nine-and-a-half hours after the onset of labor. A deeply asphyxiated child was born that lived but a few minutes. On the third day the puerpera became feverish and had a chill, with pronounced elevation of temperature; this was followed by repeated chills on subsequent days. Examination revealed nothing other than transient sensitiveness and a sense of doughy resistance in the right vaginal vault. The condition was ascribed to a pyemic process in consequence of venous septic infection. On the eighteenth day gr. $\frac{1}{5}$ of mercuric chlorid was injected subcutaneously, and the injection was repeated on each of the following twenty-six days. This treatment was without influence upon the course of the illness. The patient finally died on the forty-fourth day in consequence of the rupture of a gangrenous metastatic abscess into the pleural cavity. Two other cases of similar kind coming under observation, the treatment was modified by introducing the mercurial directly into the venous circulation, the amount injected being gradually increased from gr. $\frac{1}{60}$ to gr. $\frac{1}{12}$, and the injection being made into a vein of the arm. One patient received ten injections of a total of gr. $\frac{1}{2}$, between the sixteenth and the twenty-fifth days; and the second, eight injections of nearly the same amount. Within two or three days of the institution of the treatment striking improvement had taken place. The temperature progressively declined and the general condition became more satisfactory. Both cases went on to ultimate recovery.

In the Treatment of Oxyuris, Nicholson (*Rev. des Maladies de l'Enfance*, June, 1894; *Journal de Med. de Paris*, No. 40, vol. vi, p. 482) has obtained excellent results from the employment of santonin and quassia. Santonin is administered every two days in medicinal doses for a period of a week, and at night a suppository consisting of extract of quassia, 1 to 3 grs. and cocoa-butter sufficient to make a suppository, is introduced into the bowel. It is well, besides, to apply about the anus, morning and night, an ointment containing a small amount of calomel, as well as a little extract of quassia. An enema of the following composition, repeated from time to time, is also serviceable:

℞.—Menthol . . . . . gr. j.
Olive-oil . . . . . f ℥j.

The finger-nails of the child ought to be cut short and the extremities of its fingers frequently immersed in an infusion of quassia in order to avoid auto-infection. Constipation is to be overcome by the use of calomel.

For Eczema.—

℞.—Acidi salicylici . . . . ℥j.
Zinci oxidi . . . . . ℥iij.
Adipis lanæ hydrosi . . . ℥j.—M.

Fiat unguentum.

S.—To be applied daily.

A NOTEWORTHY BOOK.

THE translation into English of a Continental treatise on insanity is something of an event. After the translation of GRIESINGER, now almost thirty years ago, if we except the almost unknown rendition of SCHRŒDER VAN DER KOLK, there had been no occasion to note such an enterprise until the appearance of KIRCHOFF'S work in English a short time since. Hence as an enterprise it must be regarded as both laudable and not without risk. This is so because of the remarkable indifference with which, as it thus appears, English-speaking alienists have all along regarded the productions of French and German psychiatry. In this respect they have not kept pace with the other specialists. Whilst in all departments of the medical sciences contributions have been levied by translators upon the rich literature of the Continent, in mental science we have had for all these years only ESQUIROL from the French, in 1845, and GRIESINGER, from the German, in 1867.

The causes for this lack of literary enterprise are not to be found in any superior culture of American and English alienists which presupposes an intimate acquaintance with these foreign languages. Far from this, in America at least, the proportion among asylum-physicians who speak or read these tongues is small. The true cause must be a lack of interest in, a recluse indifference to, the masterpieces of European psychiatry. The tendency has been toward a narrow culture, if culture it can be called, which has consisted in turning over and over again the ideas which mainly were borrowed unconsciously from ESQUIROL two generations ago. As a consequence, until the recent rise of a pathologic school, represented by LEWIS, English psychiatry has been insular, and American psychiatry has been and still is provincial. Neither is the specialty in America relieved from this reproach by the fact that some authors freshly returned from Germany have occasionally fulminated Teutonized ideas under a thin guise of originality. It has been the voice of JACOB, but the hand of ESAU.

We have now to note and to commend the appearance of a translation of a modern French treatise on insanity.[1] It comes in good time to remind American readers of the famous country of PINEL and to let them not forget the debt which modern mental science owes to the long list of illustrious French writers who have molded and embellished it. There has been, in truth, some danger of such forgetfulness. The current in these later days has set toward Germany, and while we would not disparage the benefits derived from the Teutonic *cult*, we recall that PINEL had already established the moral and ESQUIROL the intellectual treatment of insanity, while Germany had as yet little more than the mystic tenets of the psychologic school of STAHL, of IDELER, and of HEINROTH. These latter were still teaching that insanity was only the perversion of the moral tendencies of the soul, produced by sin; that it had its source in the absence of morality, and that its best prevention and cure were to be found in the dogmas of religion, while already BAYLE, GEORGET, FOVILLE, and CALMEIL, at Charenton, were observing the symptoms and lesions of general paralysis, and, at the Salpêtrière, TRELAT was describing reasoning mania, VOISIN was studying idiocy, FALRET was correcting the errors of the partisans of monomania, and MOREL was preparing for his

[1] A Practical Manual of Mental Medicine, by Dr. E. Régis, formerly chief of Clinique of Mental Diseases, Faculty of Medicine, Paris, etc. With a preface by M. Benjamin Ball, Clinical Professor of Mental Diseases, Faculty of Medicine, Paris. 2d edition. Authorized translation by H. M. Bannister, A.M., M.D., etc. With introduction by the author. Utica, N. Y., 1894.

memoirs on degenerations, hereditary insanity and the etiologic classification.

DR. BANNISTER'S translation of RÉGIS' treatise ought to have a cordial welcome in America. The book reflects the best of the modern French school, and will infuse a distinctly new element into the studies and practice of the day. While not without some literary faults, the translation presents us with a noteworthy book both because of the conditions already stated and also because of many inherent qualities in the work itself.

The quality of a treatise on insanity is perhaps nowhere better shown than in the chapter on classification. This is likely to present the whole subject in epitome, because a wise author does not begin to classify until he has mastered the elements of his science. Hence he shows his defects on the one hand and his mastery on the other when he begins to marshal his morbid entities for classification. He exhibits then his mental grasp, and, what is more to the point, his knowledge. Judged by this standard, M. RÉGIS' book is one of marked originality and precision of thought. This chapter alone will be a contribution of inestimable value to the American alienist both for its clear philosophic method and for the fulness of its subject matter. It is obviously impossible to analyze this classification in this short space, but we may characterize it in brief as remarkably free from the *à priori* considerations which mar the scheme of KRAFFT-EBING —the best of the German school. This is shown especially by the skill with which it leaves space for new varieties, by its flexibility and adjustability and by its close adherence to clinical details. It takes progressive systematized insanity, for instance, out of the list of the degenerated types, for this disease, as MAGNAN has clearly shown, is not essentially an hereditary one in all cases; and it leaves an option for placing the periodic so-called psychoses, such as recurrent mania and circular insanity, among the hereditary or constitutional types, where they indubitably belong.

The mechanism of this notable book is not the least admirable thing about it. In his introduction to this translation, the author, with pardonable pride, points out the fact that this is "assuredly the first instance of a work treating of mental alienation, written by an alienist, translated by an alienist, and, under the direction of an alienist, printed and bound by the insane." It is published at the Utica Asylum, and deserves a cordial reception.

TO PREVENT THE SPREAD OF COMMUNICABLE DISEASES.

THE position taken by the New York Board of Health in its endeavors to prevent the spread of communicable diseases cannot be too highly commended, and is deserving of the warmest encouragement and intelligent imitation. Some of the measures proposed may have seemed unduly radical to conservative minds, but the salutary results brought about furnish the justification for the steps already taken. The stand of the Board in favor of the registration of tuberculosis, its watchful activity at the time of a threatened epidemic of cholera, its invaluable aid to the physician in the diagnosis of diphtheria, and its still more recent part in providing for the treatment of diphtheria by means of protective serum, are all matters of common knowledge. The Board, however, is not yet satisfied that it has exhausted its resources in the matter of checking the spread of communicable diseases. In a recent letter to the Sanitary Superintendent, DR. HERMAN M. BIGGS, Pathologist and Director of the Bacteriological Laboratory of the New York Board of Health directed attention to the inadequacy of the current methods of preventing the epidemic occurrence of contagious disease in tenement-houses and apartment-houses, and particularly for the enforcement of isolation of persons suffering with such disease. The methods which have been long employed in the Health Department, *i. e.*, frequent visitation and instruction by Department Inspectors, have been found to be only partially effective. It has been the custom for years in cases of contagious disease for the inspectors of the department to visit the families of the sick persons, inform them as to measures of disinfection and methods of isolation, and at the same time to notify other families in the house of the existence of a case of contagious disease in a given apartment. The notification of all of the inmates of a large tenement-house is a very difficult matter, and even when notified, experience has shown that they soon forget or ignore the existence of illness in the house.

In addition, such notification fails entirely to protect non-residents who may visit the house or apartment. Ladies in search of servants have been repeatedly found in houses or in apartments containing cases of contagious disease, and servants who have been living with families in which there are cases of contagious disease, on obtaining situations frequently go to their employers' houses, carrying

infection with them; or, when relieved from duty for an afternoon or evening, visit families in which there are cases of contagious disease, and not infrequently carry infection back to the houses in which they are employed. Very commonly washing or various kinds of sewing are secretly done by other members of the family in apartments containing such cases, and the garments thus infected on the premises are later returned to the owners. In small shops business is sometimes carried on during the prevalence of a contagious disease in the family, and in one instance recently a number of cases of diphtheria were directly traced to an infected candy-store. The mere notification of the inmates of a house is ineffectual further, because it has been found that, as a rule, families in tenement-houses do not come so much in contact with others in the same house as with families living in other houses, and the latter are entirely unprotected by the methods at present followed.

After careful consideration Dr. Biggs has reached the conclusion that the desired object would be best attained by the placarding of apartments in tenement-houses containing cases of contagious disease, and he has recommended that hereafter the Chief Inspector of Contagious Diseases be authorized, in his discretion, to placard apartments in tenement-houses containing cases of contagious disease; and his recommendation has received the ratification and endorsement of the Health-board.

In the case of diphtheria it is further pointed out that patients are often apparently well long before they are free from the infectious agency, and there is great danger that these patients, especially if children may mingle with other children, and thus transmit the disease. This mode of disseminating disease is of no less importance as regards scarlet fever and measles; in the latter diseases desquamation frequently continues many days after the patient has apparently quite recovered.

It is believed that the placing of placards announcing the existence of contagious disease in a house or apartment would have considerable moral influence both upon the inmates and upon strangers or visitors.

The procedure has for some months been employed in certain classes of tuberculosis, and has proved most satisfactory in the attainment of the object desired. The only objection apparently to be urged against this measure is that the inmates of the apartment may object to the publicity thus entailed. This is exactly the object which the measure is justly and properly designed to subserve, and is the strongest argument in favor of its adoption.

We congratulate the New York Board of Health on the courageous and advanced stand that it has taken and feel sure that its action will be followed by the most salutary results. The experiment, if the course of the Board may be so designated, will be an object-lesson for observation and study by all the large cities of the United States, and the principles involved may be applied to even the smallest community.

DR. WILLIAM GOODELL.

The announcement of the death of William Goodell will, perhaps, bring a sense of personal loss to a greater number of physicians than would the death of any other member of the profession in America. Dr. Goodell had hundreds of personal friends and admirers in all parts of the country, and there were thousands more who looked for his medical papers with interest and accepted his advice without question. His position in American gynecology was unique. He was one of the small group of pioneers who made the gynecology of this country what it is, and he alone among these men possessed the literary faculty to a high degree. Had he chosen he could have made his name famous by literary work pure and simple. He had but one equal in this respect among English-speaking physicians—the late Oliver Wendell Holmes. Consequently he was able to present the advances of the new science and art of gynecology in a manner that chained the attention of every reader. Moreover, his work bore such evident marks of keen perception, sound judgment, and a judicial fairness of mind, that what he wrote was not only read with interest and pleasure on account of its pure and attractive style, but it molded the thought and shaped the practice of an astonishing number of followers. A personal acquaintance with Dr. Goodell strengthened the liking and respect which his writings always inspired. His kindness and courtesy to younger men made him many a devoted friend. His instant and enthusiastic response to every worthy appeal for aid could be confidently expected. His presence united a simple kindliness of manner with an innate dignity that could scarcely fail to impress the most indifferent observer.

Highly gifted by nature with a powerful mind, a keen wit and the power of expression, Dr. Goodell

never presumed upon his natural advantages. His work of all kinds was of the most painstaking and methodical character. His case-book was a model of comprehensive and careful note-taking, and his literary work, in which he should have been conscious of masterly ability, was not regarded as completed till every sentence was read and re-read, written and re-written.

The main events of DR. GOODELL'S life are tolerably familiar to many medical men, and they have been described besides in the daily press. He was born in Malta, the son of a missionary. He received his collegiate and medical education in this country and began his medical career in Constantinople. He returned to this country after a few years, and settled in West Chester as a general physician. So unsatisfactory was his progress, however, that he determined to emigrate to the West. His books and furniture were actually packed and addressed to a small town in Kansas when, in 1865, he received the appointment to the Preston Retreat. Here he found congenial work in favorable surroundings, and during the twenty years of his residency he acquired a leading position in his branch of medicine, and this he maintained till failing health last summer forced him to retire. His strength failed steadily, and he died on the 27th of October, in the sixty-fifth year of his age. He was appointed Lecturer on Obstetrics and Diseases of Women in the University of Pennsylvania in 1870, and Clinical Professor of the Diseases of Women and Children in 1874, and he continued in this position until a little more than a year ago, when, on his resignation, he was made Honorary Professor.

There must be many who, like ourselves, mourn not only the disappearance of a distinguished figure from American medicine, whose place cannot be adequately filled, but the loss at the same time of a dear friend, a wise teacher and a safe leader.

EDITORIAL COMMENTS.

Religion and Medicine Among the American Negroes.—Some time ago we commented upon the urgent need of negro physicians, and in reply we receive from the Rev. J. W. Wright, of Independence, Kansas, a courteous letter, showing that 132 colored physicians have been graduated from the Meharry Medical College, at Nashville, Tenn., an institution supported by the Methodist Episcopal Church, and for the education of colored physicians exclusively.

In a pamphlet issued by the *Freedman's Aid and Southern Education Society*, church aid in supporting medical schools is urged on the following grounds:

"We have one medical school in U. S. Grant University, Tennessee, among the white people. This is self-supporting, and forms a nucleus of large influence on behalf of the Church, as well as enabling the Church to influence for Christ and humanity multitudes through those who are educated in this school. We have our Meharry Medical College, at Nashville, Tenn., from which 132 young negro physicians have been graduated. We are now establishing a second medical school in connection with New Orleans University. These are the only medical schools south of the Ohio River and west of the Carolinas in a population of nearly six millions of colored people, where a young colored man can be educated as a physician. The death-rate among the colored people is appalling, being nearly twice as large as among the whites. This is the result of poverty, ignorance, and lack of proper medical attendance and nursing. Christ cared for the bodies as well as the souls of men; so must the Church, especially among our poorer populations. It is the plan to establish nurse-training classes in all our leading schools, and to establish free dispensaries. No more Christly work can be done, and the marvellous results already achieved for the good of the people are beyond computation, or even expression in words."

We most gladly make mention of the foregoing facts, and as heartily commend the work. It is encouraging to find that the religious instinct in this unfortunate people is being used to further what is a true and genuine religious work. But we wish to urge that it be still tremendously more used. The medical aspect should be made primarily important instead of secondarily so. Instead of a hundred or more negro physicians there is the greatest need of many thousands. The use of the funds given for educational purposes by the benevolent should be more largely applied to medical education instead of to theological education. With this people religion is in no danger of suffering and needs no encouragement, whilst the medical need is a "bitterly crying" one. In this view of the case we know also we are in accord with the wisest minds of the colored race. The trustees of the Slater and Peabody funds should seriously consider this. Doctors are needed more than preachers a hundred times over. And we would also suggest to trustees, and to our colored brethren, that instead of establishing what must necessarily be poor-grade new medical colleges on racial lines, it would be far better to help students to secure their medical education at Northern or at other general medical institutions. Preparation for their work will thereby certainly be the better.

The Teaching of Medicine in Different Countries—There are in the twenty medical schools of Germany over 8000 medical students, 3507 of whom are foreigners. In England there are now but 532 students of medicine, extremely few of whom are non-English, and this number is smaller than for many previous years. We append the totals for recent years for the purpose of comparison:

1883 . .	605	1889 . .	620
1884 . .	587	1890 . .	614
1885 . .	647	1891 . .	662
1886 . .	623	1892 . .	596
1887 . .	683	1893 . .	598
1888 . .	688	1894 . .	552

It is no wonder that England sends up a "bitter cry," in view of this comparative preference of medical stu-

dents for German methods of teaching. Reasons have been sought to account for this remarkable condition, but all come back to the fundamental fact that the Germans are the more zealous, unselfish, and more scientific —in a word, they are the better teachers. It does not lie in the English character to be a good instructor. The Englishman commands rather than teaches. There is no question but that, as any other, he is as good and successful a practiser, as capable a healer of disease, but when he tries to tell young men what he knows, and to inspire them with the enthusiasm of his calling, he is a sad failure.

But we wish in no egotistic mood to call the attention of young Americans to the fact that there are no better medical teachers in the world than their own countrymen. With us teaching is natural, and no better facilities for post-graduate study exist anywhere than in the United States. They may not be quite the perfection of systemization, certainly not the remorseless and cruel use of "clinical material" to be found in German institutions, but we have in every one of our large cities, and in many small ones, hundreds of men who know their science, with as good intellects, and who practise their art with as perfect skill as are to be found in Teuton-land. Instead of running away thousands of miles, any student can find at home the most willing and capable teachers, an opulence of hospitals and laboratories, that await his demand. We have too long spurned our splendid opportunities. We advise none to go abroad for what can be found in abundance at home. We are producing as good text-books as are made in the world, and nowhere can be found a higher and purer enthusiasm for medical study and research than burns in the hearts of Americans. This matter of studying abroad is a fashion, a fad, we were about to say, that appeals to weak minds, but which is unscientific, unpatriotic, and to be discouraged on any ground of sense, common or uncommon.

Unsatisfactory Researches.—In a paper in the last year's volume of *Virchow's Archiv*, ADOLF GOTTSTEIN reviews the action of living organisms on hydrogen dioxid, and claims that this substance may be utilized as a means of estimating approximately the number of bacteria in water-samples. He states that if less than one-thousand living microbes exist in a cubic centimeter a scarcely appreciable evolution of oxygen occurs after fifteen minutes' action, while if many thousands are present a rapid action occurs. It is obvious that such a method would be of great value in sanitary chemistry. Gottstein gives no details of his experiments, except the method of making the test, and does not say whether the hydrogen dioxid was used in acid or alkaline solution, nor what strength was employed. These points are obviously of the greatest moment, as the tendency of the dioxid to decomposition is influenced by its strength and reaction. In a recent number of the *Centralbl. f. Bakt. und Parasitenk.*, H. Laser reviews Gottstein's work, and finds that the claims are not established. Laser's experiments indicate that the alleged simple relation between the number of living microbes and the evolution of oxygen does not exist. It is possible that differences in the quality of the hydrogen dioxid used may have caused some of the discrepancy, but it is probable that the first paper rested on insufficient work. The incident shows very clearly the danger that arises from the multitude of workers in the field of biologic chemistry, many of whom publish results without sufficient experimentation.

Water-Supplies in Pennsylvania. — The ninth annual (1893) report of the State Board of Health and Vital Statistics of Pennsylvania, lately issued, gives some analyses of waters from various parts of the State. The funds at the disposal of the Board do not permit of original research; the analyses are mostly made at the suggestion and expense of the local boards and in consequence of existing epidemics. Twenty-three analyses are given, which indicate five samples unfit for drinking-purposes and two suspicious. The number of analyses is too small to form a basis for a general inference as to the condition of the water-supplies over a territory so large and so varied as Pennsylvania; but in view of the frequency of local epidemics of typhoid fever, and of the liability of pollution of surface and subsoil waters, the necessity of more extended investigation and of devising of means of sewage-purification and stream-protection is evident. Legislation for the protection of water-courses is certainly wanted, and it is necessary also that some definite means of establishing sewage-disposal companies should be provided.

Ocular Ballottement.—The diagnosis of fluid vitreous with floating opacities may be aided by a little method that is not usually laid down in the text-books. The retinoscopic mirror is used in the same way as in indirect ophthalmoscopy. The patient has to be "trained" a little or carefully instructed in order to carry out the manipulation rightly, the essential point of which consists in halting a downward sweep of the eye suddenly and at such a point that the oculist can have a good view of the post-pupillary field. Direct the patient to look up to the ceiling and then to swiftly look at an object in front and on a line horizontal with the eyes, holding the gaze steadily there. If opacities floating in a fluid vitreous exist, this sudden "flip" of the vitreous chamber upward, followed by a sudden stoppage, flings the opacities upward, and with the ophthalmoscopic mirror they will be seen again to descend like snow-flakes falling outside of a window in the night. This method of diagnosis might appropriately be named *ocular ballottement.*

Effects of Poisonous Food.—An eruptive skin-disease now prevailing in London almost as an epidemic, mostly in workhouse-infirmaries, has been ascribed by some authorities to the milk-supply. Bacteriologic examinations of milk supplied to several infirmaries have been made, but no results indicative of a causal relation have been obtained. The disease has a death-rate of over 10 per cent. In the same number of the *British Medical Journal*, from which we condensed the foregoing account, is to be found some statistical information as to the effects of poisonous food. During the months of June, July, and August, nearly one hundred cases with five deaths have been reported. These were mostly from canned meats. The symptoms were vomiting, diarrhea, severe abdominal pains, cramps, and collapse. These symptoms might readily give rise to suspicions of criminal

poisoning. A case has recently been reported in which the greater part of the population of a village in Russian Poland was made sick by eating tainted herrings.

Hog-Cholera and Swine-Plague.—Veterinarians will be much interested in the results of a series of careful experiments conducted in the Pathological Laboratory of Johns Hopkins University on Hog-cholera and Swine-Plague, and presented in a recent brochure.[1]

These two swine-epizootics have been so commonly confused as to prevent the collation of reliable statistics concerning their relative frequency, virulence and treatment. Fortunately, this state of confusion has been finally disentangled by the clear presentation of the distinguishing characters of the microbes of the two diseases, as well as those of their peculiar lesions.

REVIEWS.

Microörganisms in Water: Their Significance, Identification, and Removal. By Percy Frankland, Ph.D., B.Sc., F.R.S., and Mrs. Percy Frankland. Octavo, pp. xi, 520, and index, with many illustrations. London and New York: Longmans, Green & Co., 1894.

Several features give unusual interest to this book. As a product of the joint authorship of husband and wife, both already well known in the field of original research, it is an earnest of the results of the higher education of women. The want of comprehensive information in a compact form in English has been seriously felt by sanitary chemists and engineers, particularly in America, where more attention seems to have been paid to the subject than in England. Percy Frankland has been engaged in investigation of microbic life in water and the effects of filtration, subsidence, etc., for many years. The present work republishes much of the matter that appeared in journals, but supplemented by later observations. Mrs. Frankland's most important work has been doubtless in the joint researches on the nitrifying microbes.

The work begins with the usual account of the methods of preparation and use of culture-media. The bacterial contents of various waters are treated of in about thirty pages; then follow one-hundred pages on the purification of water. This is especially Frankland's field, and much interesting matter is presented. It is, however, with surprise, and even irritation, that we note that no mention is made of the ingenious process of purification by metallic iron, reference to which was made in an editorial comment in The News some time ago. This process is operated on a large scale in several Continental cities, notably Antwerp, and it seems strange and unfair that it should not be noticed. Even if the authors of the book have doubts as to the method, these doubts should have been set forth, for other processes acknowledged to be of little value are given some space. Extended reference is made to the work of the Massachusetts State Board of Health. A long chapter on the influence of light on microörganisms in water is summarized by the statement that sunshine is to be recognized as a powerful bactericide, but the value of it is liable to be overrated. Anthrax-spores, for instance, resist the action of sunlight for many hours. The application of insolation has, however, but minor interest in the management of public water-supplies, as we know that filtration can be made to remove practically all the dangerous microbes from water. An appendix of over a hundred pages gives descriptions of each species of microbe which has been reported as occurring in water. No satisfactory system of classification for these organisms has yet been found. The present work does not add to the vividness of this department of biology by adopting an arrangement based on the similarity of the pigment produced, which is equivalent to describing in sequence all plants which produce red flowers.

In consulting a work of this character the sanitarian turns promptly to the description of the supposed specific bacillus of typhoid fever. Much space is given to the topic, and it is clearly shown that a large proportion of the published statements are unreliable, and that especially the *b. coli communis* has often been confounded with *b. typhosus*. Great is, however, our surprise to note an entire ignoring of Vaughan's important contributions to this field. The omission is a serious one, for if the authors had embodied the results that the American investigator published some years ago still greater doubt would have been thrown on the specific identity of the typhoid-fever germ. Enough is now known to show that no reliance should be placed on reports of finding of this microbe unless the methods of identification be given.

The work is well printed, and will find a wide acceptance.

Transactions of Societies:

Transactions of the American Gynecological Society. Vol. 19. For the year 1894.

Transactions of the Medical Society of the State of New York for the year 1894.

Transactions of the Medical Society of Virginia. Twenty-fourth session, Charlottesville, Va., October, 1893.

Transactions of the Texas State Medical Association. Twenty-sixth annual session, Austin, Texas, April, 1894.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Ninety-sixth annual session, Baltimore, Md., April, 1894.

Transactions of the South Carolina Medical Association. Forty-fourth annual meeting, Rock Hill, S. C., April, 1894.

Transactions of the Association of American Physicians. Ninth session, Washington, D. C., 1894.

Transactions of the Michigan State Medical Society for the year 1894.

Transactions of the Medical Society of the State of California. Session of 1894.

Transactions of the Vermont State Medical Society for the year 1893.

Transactions of the Indiana State Medical Society. Forty-fourth annual session, 1893.

The annual influx of society *Transactions* brings with it such a vast amount of literature that mere mention of

[1] Remarks on Hog-Cholera and Swine-Plague, by William H. Welch, M.D., Professor of Pathology Johns Hopkins University, and A. W. Clement, V.S. Pamph. 37 pp.

a few of the more prominent features of the various volumes is all that a limited amount of space will permit. While it is true that much that appears in volumes of this description is but a presentation of old material in new garb, there are always to be found therein valuable contributions to the medical knowledge of the day. Thus, in the *Transactions of the American Gynecological Society* among other meritorious papers there is a complete *résumé* of the accepted management of that difficult obstetric complication, face-presentation, together with an exposition of the present status of symphysiotomy in obstetric surgery. The discussion by eminent practitioners of abdominal surgery, menstruation and its abnormalities, and diphtheria, as recorded in the *Transactions of the New York Medical Society* is truly brilliant, and from a practical standpoint leaves untouched little of these vital questions that is worthy of consideration. The same may be said of the interesting series of papers on tuberculosis, to be found in the *Transactions of the Michigan Society*, and on chronic nephritis and the place of electricity in general practice in the *Transactions of the Medical Society of Virginia*. Of more than passing interest are the papers by George Dock on "Osteomalacia," and by J. P. Crozer Griffith on "Tetany in America," recorded in the *Transactions of the Association of American Physicians*. The *Texas State Medical Association* offers a truly valuable collection of papers which merits a more substantial binding than that provided by the society. The rich and varied medical botany of the far West is ably presented in the two papers by W. P. Gibbons on "Poisonous Plants of the Pacific Coast," and "Indigenous Botany," both to be found in the *Transactions of the California State Medical Society*. An instructive contribution to the history of medicine in the United States is contained in Dr. Wishard's paper on "Medical Men and Medical Practice in the Early Days of Indianapolis," in the *Indiana Transactions*. The dominant feature of the *Transactions of the South Carolina Medical Association* is the address by Howard Kelly on recent results in hystero-myomectomy; of the *Vermont Transactions*, the "Location of the Lesion in Paralysis," by M. R. Crain; and of the *Transactions of the Maryland Medical and Chirurgical Faculty*, the President's address on the extinction of tuberculosis.

Gonorrhea: Being the Translation of Blenorrhea of the Sexual Organs and its Complications. By Dr. Ernest Finger, Docent at the University of Vienna. Third revised and enlarged edition, with seven full-page plates in colors, and thirty-six wood-engravings in the text. 8vo. pp. 324. New York: William Wood & Company, 1894.

So far as we are aware, this third edition of Prof. Finger's work is the first to appear in English dress. The translator's name is not given, but he has discharged his task very creditably.

After an introductory historical chapter, an exposition of the anatomy and physiology of the urethra is presented, the important fact being especially insisted upon that the canal is divided by the compressor muscle into two sharply-defined portions, anterior and posterior. We believe that by practical surgeons the distinction between the inflammations of these two regions has been recognized; but we are not aware that any systematic writer has so clearly set it forth or pointed out their anatomic boundary.

Acute urethritis is next discussed, first as affecting the anterior part of the canal, and then the posterior; the diagnosis, prognosis, effects, and treatment of each condition being duly dwelt upon. We need only say that the views presented are in full accord with the surgery and pathology of the day.

Under the head of chronic urethritis our author lays much stress upon the use of the endoscope, describing the appearances revealed by it, and the technique of its employment. We are inclined to think that this instrument will long remain, as at present, in the hands of a few specialists, and that the profession at large will be content to accept their statements of the pathologic conditions observed by them.

The complications of blenorrhea in the male are next discussed: balanitis, infiltration and abscess, inflammation of Cowper's glands, prostatitis, epididymitis, inflammation of the seminal vesicles, and cystitis.

Chapter V is devoted to the subject of blenorrhea in the female; Chapter VI, to its complications: vulvitis, inflammation of Bartholin's glands, and inflammation of the uterus and its appendages.

Finally, a chapter is given to such complications as are common to both sexes: gonorrheal rheumatism, endocarditis, exanthemata, ophthalmia, and adenitis.

We think it would have been better to have had running headlines indicating the material contained on each page. Nor do we approve of appending to the name of each author quoted the date merely of his contribution; references in foot-notes, or a bibliographic table would enable the reader, should he so desire, to follow up the study of the views or observations mentioned. Some exception may be taken also to "Bartholinitis" and "Cowperitis," the latter being even used in the plural, "Cowperitides" (!) Notwithstanding these minor criticisms, we regard this book as a valuable addition to surgical literature, and commend it to the favor of the profession.

CORRESPONDENCE.

INFILTRATION-ANESTHESIA.

To the Editor of The Medical News,

Sir: In an abstract under the head of "Infiltration-Anesthesia," p. 442 of The Medical News, of October 20, I was surprised to find Schleich credited as "the originator of the method."

This is surely an error, for I have used it for over twenty years in preference to *deep* hypodermatic injections. In 1875, when in charge of the Post Hospital at the Portsmouth (N. H.) Navy Yard, I employed it extensively (as did also my assistant, Dr. Heffinger, and others) as a local anesthetic, as a substitute for injections of morphin in sleeplessness, and for the relief of neuralgic and other pains; hot and cold water, salt water, diluted alcohol, carbolized water, glycerin and oils, were used with good results.

The needle was carefully introduced about *half its length* parallel to the surface of the skin, and a large hypodermatic syringe *full of hot water* was very slowly injected intracutaneously, raising a large, white anesthetic wheal, the

appearance of which greatly impressed the sailors and marines.

I fancy the method was introduced by Dieulafoy, and was known to the profession long before Schleich drew attention to it in the *Therapeutische Monatshefte*.

Yours, faithfully,

C. J. Cleborne, M.D.,
Medical Director, U. S. Navy.
U. S. Naval Hospital, Norfolk, Va.

NEWS ITEMS.

Foot-ball "Accidents."—We believe that it was Mr. Jorrocks who said that hunting possessed all the glories of war and only five-and-twenty per cent. of its danger. The foot-ball percentage must be considerably higher, for though the season is yet only a few weeks old, we have already before us a list of casualties which would do credit to a little war. Since we referred to the matter last, in connection with a sudden death from injuries received by a player, we have received reports of the death of a man at Windhill, near Leeds, who during a game fell "in the ordinary way," a number of other players fell over him, and he died on the following day. A Preston player named Hall fell and broke his arm; the general symptoms became serious, and this young man of eighteen died shortly of tetanus. In an engagement between the Blackburn Rovers and Burnley after five minutes' play one man broke his leg in a collision, and during the second half another man was carried off the field with an injured leg. On the same day, near Burton-on-Trent, a player "fell with his leg under him in such a way that it was fractured." At Llanelly, in a match between that place and Neath, two men were injured, but their injuries were slight when compared with the average. So the list grows steadily from week to week, and last Monday's papers told us how on Saturday the head master of Appeldurcombe College, Ventnor, sustained a compound fracture of the right leg during a foot-ball match, and how the captain of the Maidstone team, playing at Dover, "collided with a goal-post and split his collar-bone; he was removed to the hospital." The hunting casualty-list this year contains, we believe, the name of only one lady badly wounded, but recovering. On the whole, foot-ball as at present played appears to be about as dangerous an amusement as a South American revolution.—*British Medical Journal, October 29th.*

On October 3d, at Kingswinford, Staffordshire, an inquest was held on the body of Frank Griffiths, a member of the Kingswinford Albion Foot-ball Club, who died on the 1st instant from internal injuries consequent upon a kick in the abdomen. Whilst playing for his school on the same date against Hesketh Park, J. T. Smith, aged twenty-eight, an assistant master at Bickerton House, Birkdale, Southport, received a blow in the abdomen from the knee of an opponent. The accident was not deemed serious at the time, and medical aid was not sought until after the lapse of an hour and a half. He died on the morning of the 15th from peritonitis. The following accidents also occurred on Saturday, October 13th: In a match between Sutton and Keighley Trinity, W. H. Hardacre, one of the Sutton home forwards, sustained a fracture of the clavicle. During a match between Burnley and Darwen, played at the latter town, a player was seriously injured in a scrimmage, but the real nature of his injuries has not transpired. A youth aged eighteen fractured his right patella whilst playing in a match between All Hallows and the University Extension team at Clapton.—*The Lancet, October 20th.*

From two or three American newspapers that come to us we gather the following—a few of many similar delightful proofs of the physical, moral, and educational tendencies of the game:

Hillsdale, Mich., October 23.—The foot-ball game between Olivet and Hillsdale was won by Hillsdale, score 34 to 6. The boys had it in for each other, and the consequence was several were badly bunged up. Snyder, of the Hillsdale, was so badly battered he had to have a substitute. Olivet left one of its foot-ball players at the fraternity house last night with a broken rib. One of the team went back minus half a dozen teeth, bunted out by Hillsdale's colored player.

"This makes the seventh broken clavicle at Harvard this year."

Breckinridge, of Princeton, was injured at Hightstown, N. J., in Saturday's game, and was removed unconscious from the field.

Haverford seems to be undergoing her usual course of hard luck, and at present five of her best players are prevented from playing, either on account of injuries or other circumstances. Hay, Morris, and Scattergood have stopped playing, while Alsop and Captain Webster have sustained such injuries as to prevent them from playing for some time.

The Lehigh team is badly crippled, seven men being on the injured list, and the men improve but slowly. Twisted and sprained ankles, turned joints, overtraining, etc.

Holly, Brown, Morse, and Ward have not appeared since the Cornell game, two weeks ago. Reiter and Poe were hurt, and have also not been able to play since the Lehigh game.

On Saturday, Alsop, Haverford's best tackle, hurt the same knee which was wrenched last year, and which prevented him from playing in the Swarthmore game last fall. The loss of Alsop weakens Haverford's team very much.

Captain Lincoln, of the Dickinson College eleven, has broken his collar-bone.

In Brooklyn rough play prevailed throughout the contest, and in several instances blows were exchanged between the players. The feeling between the teams was very bitter, and it looked at one time as if the crowd were going to see an old-fashioned rough-and-tumble fight. The interference of others alone prevented such a scene. Hard names passed between the men when they left the field, and the police, apprehensive of another collision, rushed among the players and cautioned them that a repetition of the pugilistic exhibitions would result in considerable trouble for the offenders.

As a result of the rough character of the play two players were so badly used up that they were compelled to leave the field.

Just as Taussig neared the ropes, Emmons, the Harvard captain, gave him a vicious push. Taussig promptly rooted up the ground for quite a distance with his rubber nose. When play was resumed he watched his chance

and dug his head into the pit of Emmons' stomach so fiercely that it almost laid the big Harvard man out. In a scrimmage at this juncture big Mackie, of Harvard, provoked hostilities with Colnan, his opponent in the line, and was more than ready to quit when the Ithacan came back with the same kind of medicine.

The Secretaries of War and of the Navy have refused, upon the recommendation of Colonel Ernst and of General Schofield, to allow the Military and Naval Academy teams to play on Thanksgiving Day. General Schofield wrote:

"The game of foot-ball as recently played requires some essential modifications. This, I believe, is the concurrent public sentiment on the subject. The required modification will be difficult to enforce for the reason that the objectionable features are those which contribute most to success in a contested game. They are those features which are most dangerous to life and limb, and may be said to most resemble military operations. They are none the less objectionable on that account. While it is undoubtedly true that experience in actual war is the best possible military training, modern civilization does not permit the making of war simply for the purpose of training an army. For like reasons the practice in peace of those operations which most resemble war must be condemned, notwithstanding the fact they are manifestly beneficial as military training.

"The reports of the superintendent show that the casualties in the play of foot-ball at West Point are much greater than they ought to be, and the same may also be said in respect to riding, although expert horsemanship, being indispensable in a large part of the military service, must be acquired, although at much risk.

"There is little need of foot-ball at West Point simply as a means of physical training, and as such it is open to the objection that it is far from universal. Probably the young men who most need such training do not get it, but only those who, being already endowed with splendid physical development, are capable by additional training of successful competition with the best of any other selected class."

The New York State Association of Railway Surgeons will hold its fourth annual meeting in the New York Academy of Medicine, November 15, 1894. The following program has been arranged. President's address: "Important and Unsettled Questions in Railway Surgery," Dr. M. Cavana, of Oneida; "When Shall We Amputate? (*a*) Arguments Favoring Early Amputations," by Dr. W. L. Estes, of South Bethlehem, Pa.; (*b*) "Arguments Favoring Delayed Amputations," by Dr. T. H. Manley, of New York; (*c*) "Technique of Amputation," by Dr. John A. Wyeth, of New York; "Asepsis and Antisepsis in Surgical Work," by Dr. F. A. Stillings, of Concord, N. H.; "Special Features in Railway Surgery," by Dr. C. B. Herrick, of Troy; "The Immediate Care of Railway Injuries," by Dr. J. A. Van Duyn, of Syracuse; "Important Factors in Unusual Results Following Traumatisms," by Dr. R. S. Harnden, of Waverly.

Johns Hopkins Medical School.—The second year of the undergraduate department in medicine opened on October 1st. There were 31 entries, making in the two years 50 students in all. Of these, 13 are graduates of the Johns Hopkins University; 8 of Yale; 5 of Harvard; the others of smaller colleges throughout the country. Of the 10 women undergraduate students 3 are from Smith College; 3 from Vassar; 1 from Wellesley; 1 from Bryn Mawr.

States are represented as follows: Maryland, 15; New York, 7; New Jersey, 4; Connecticut, 4; Massachusetts, Ohio, Wisconsin, and California, each 3; Indiana, Kentucky, Virginia, Alabama, and Minnesota, each 1, and Canada 2.

A Statue of Dr. J. Marion Sims was unveiled in Brooklyn on October 21st amid impressive ceremonies. The statue is unique in being the first statue of a physician ever erected. The pedestal bears this inscription: "J. Marion Sims, M.D., LL.D.; born in South Carolina, 1813; died in New York city, 1883. Surgeon and Philanthropist, founder of the Woman's Hospital, State of New York. His brilliant achievements carried the fame of American surgery throughout the civilized world. In recognition of his services in the cause of science and mankind he received the highest honors in the gift of his countrymen and decorations from the Governments of France, Portugal, Spain, Belgium, and Italy."

Horace Wells Anniversary Celebration.—A committee of the American Dental Association, with Dr. J. D. Thomas, of Philadelphia, as chairman, has arranged for a national celebration of the fiftieth anniversary of the discovery of the anesthetic properties of nitrous oxid by Dr. Horace Wells, to be held in Association Hall, on December 11, 1894.

A paper upon the "History of Anesthesia" will be read by Prof. Thomas Fillebrown, of Boston, and one on the "Benefits of Anesthesia to Mankind" by Prof. James E. Garretson, of Philadelphia.

The meeting will be followed by a banquet at the Union League at 6.30 P.M.

A Medical Library Association has been recently organized in Grand Rapids, Michigan, with the purpose of forming a reference-library of medicine and allied sciences. The new organization has a membership of about fifty, including not only physicians, but dentists and pharmacists as well.

One of the features of the association will be the admission of non-residents to membership, who upon payment of a small annual fee may avail themselves of the advantages of the library.

Discussion on Appendicitis.—At the meeting of the College of Physicians to be held on November 7th, Dr. John B. Deaver will read a paper entitled "Further Observations on Appendicitis: with a Report of Sixty-one Cases of Chronic Appendicitis, with One Death." Dr. Charles McBurney, of New York, will open the discussion.

Dr. A. H. Buckmaster, one of the editors of the *American Gynecological and Obstetrical Journal*, has been elected professor of the practice of medicine and of obstetrics and gynecology in the University of Virginia.

Dr. Roux, a pupil of Pasteur, who has been engaged in the preparation of serum for the specific treatment of diphtheria, has been made a Commander of the Legion of Honor.

REMARKS ON PSEUDO-MEMBRANOUS CROUP AND DIPHTHERIC CROUP, AND THE VALUE OF INTUBATION.[1]

BY FRANCIS P. BALL, M.D.,
OF LOCK HAVEN, PA.

THE two principal points which I think we should consider and discuss to-day are the identity or non-identity of diphtheric croup and pseudo-membranous croup and the value of intubation in these cases.

When we consider the wonderful advances made in bacteriology in the past few years, and the ability of the bacteriologist to designate the exact micro-organisms which are the cause of many diseases, and especially when we remember that the specific microörganism of diphtheria is a well-recognized bacterium, it would seem as though the first proposition for discussion were useless; for the presence or absence of that bacterium should settle the question as to the identity of the two diseases. But such is not the case. A review of the literature of the subject will show quite a diversity of opinion on this point, with an array of substantial reasons, both for and against the opinion.

In France, where diphtheria was known and studied long before it was recognized in England or in this country, writers on this subject, I believe, are almost a unit in their belief that all cases of laryngeal croup are diphtheric; and their writings and experiences have had an effect upon the Germans, who hold the same belief; and to some extent, though not so universally, upon the English, many of whom also believe in the identity of the two diseases. Mackenzie refers to the influence of the experience of the French in his argument supporting the unity theory, and gives them the credit just referred to.

In this country, however, pseudo-membranous laryngitis was recognized as a well-defined pathologic condition, its clinical features carefully observed and accurately recorded by competent physicians long before diphtheria invaded our land. As remarked by J. Lewis Smith, it is impossible to suppose that all these cases coming in the hands of able practitioners, as they did, should have been examples of unrecognized diphtheria primarily affecting the windpipe, and none of them showing the symptoms of faucial diphtheria. It is impossible to suppose that so many able observers should have been so completely deceived in their clinical study of the disease, and it is also impossible to suppose that so many cases as are recorded and were under observation should have been primary laryngeal diphtheria, for we know that it is not by any means the rule, nor does it occur in many cases, that the diphtheric pseudo-membrane forms primarily in the larynx. The result of the early experience and study of membranous croup, when diphtheria was an unknown disease in this country, has, I suppose, had much to do with the faith many American physcians have in the dual theory. And this early experience is to me a strong argument in favor of that theory. It is no argument to the contrary to say, as is so often done, that, because croup has increased vastly in numbers of cases since diphtheria was introduced into this country, therefore diphtheria is the sole cause of croup. It only argues that diphtheria is another factor in the production of croup, and that the larynx is only another field for the development of the diphtheric membrane. But it would seem as though the careful bacterial study of these cases should elucidate the point which has been discussed by many writers, and settle it beyond dispute. As Osler remarks, work in this field is very much needed.

The Klebs-Loeffler bacillus is the bacterium of diphtheria, and is found in all cases of diphtheric croup. When found, therefore, in any case of membranous croup, it of course proves the disease to be diphtheric. But it is not found in the fibrinous exudation of membranous croup. There are various cocci found, the staphylococcus and streptococcus, and among others the streptococcus pyogenes, but not the true bacterium of diphtheria.

If this proposition can be established, if it can be shown that in a certain class of cases the Klebs-Loeffler bacillus does exist, and in a certain other class it does not exist, there should be little difficulty in settling the question of identity or non-identity of the two diseases. The anatomic appearances of the two diseases are so nearly identical that if there is any difference it is not distinguishable, and unless they can be differntiated bacterially, as suggested, the question of unity must still remain open.

I find recently published the following results of

[1] Read before the Clinton County Medical Society, August 15, 1894.

the work of different observers bearing on this point of the bacteriology of diphtheria, which in this connection lead to interesting conclusions: Baginsky, of Berlin, examined 154 cases of diphtheria, and found the Klebs-Loeffler bacilli in 118, and none in the other 36. Prudden, of New York, examined 24 cases of diphtheria, complicating or following scarlet fever, and found no Klebs-Loeffler bacillus. Martin examined 200 cases, and found the characteristic bacillus in 121, leaving 79 without the diphtheric bacterium. Park, of New York, found it in 129 cases, and absent in 79. Thus, in a total of 534 cases of what was diagnosticated as diphtheria by different observers, the Klebs-Loeffler bacillus was present in 366 and absent in 168. With this array of cases, and their bacteriologic examination before us, let us refer to the rules formulated by Koch for the establishment of a complete chain of evidence as to the production of a disease by any special micro-organism. They are as follows, viz.:

1st. The presence of the organism in all cases of the disease, and in such distribution as will explain the lesion.

2d. The isolation of the organism in pure culture.

3d. The reproduction of the disease by inoculation with the isolated organism, and the presence of the latter in the tissues of the inoculated animal.

It is only necessary to apply the first of these rules to the foregoing cases to force us to the conclusion that we either have two diseases diphtheric in character, but quite different in their bacteriology, or that the Klebs-Loeffler bacillus is only accidentally present, and has really nothing to do with the case.

Few of us, I think, would have the temerity to assert that the latter part of the proposition is correct, and consequently we must conclude that there are two diseases diphtheric in nature and very similar in their manifestations, yet differing quite materially in their bacteriology; the one a contagious disease, the other not, and, as has been shown in a further report of the cases referred to, the one a much milder disease and more prone to recovery.

The existence of two diseases having the same physical appearance but differing in their bacteriology, the one a true diphtheria, and the other a false diphtheria, has been recognized lately by the Chief of the Bureau of Bacteriology of Brooklyn, and the difficulties of diagnosis have been acknowledged to the extent of establishing a method of bacteriologic examination of all cases of suspected diphtheria at public expense. In a recent journal I find that this Bureau of the Department of Health of Brooklyn recognizes the fact that

"Recent bacterial investigations have shown that a considerable proportion of the cases of pseudo-membranous and exudative inflammations of the throat and upper air-passages, commonly considered as diphtheria, and having the anatomic appearances found in diphtheria, are not true, but false diphtheria. On the other hand, it has been shown that a considerable proportion of the cases which are apparently false diphtheria prove, on bacterial examination, to be true diphtheria. While in true diphtheria the mortality is very high and the danger of transmission to others is very great, in false diphtheria the mortality is low and the danger of infection slight."

These statements and the recognition of a true and a false diphtheria, the one a disease in which the Klebs-Loeffler bacillus is found, and the other in which various microörganisms, but not the diphtheric bacterium, are found, may account for a statement often made to me by a member of this Society, that in Kansas, where he formerly practised, his cases of diphtheria were much milder and the recoveries more frequent, so that death was seldom expected from a case of diphtheria in that locality. Such cases did not differ in their physical aspect from the diphtheria seen elsewhere, and which is so much more fatal, but no doubt would have differed very essentially if examined bacterially.

If it is true that there is a true and a false faucial diphtheria, are we not justified in the belief that there is also a non-identity of the two diseases under discussion; or, to be more moderate, are we not correct in at least considering the question still open? The truth is that the number of cases of laryngeal croup examined for the purpose of elucidating this point is yet too small for positive conclusions, and it is a matter of surprise that there has not been a greater amount of investigation on this subject by bacteriologists. The question of the bacteriology of the disease seems to me in our present knowledge to settle down to the statement, the author of which I cannot now recall, viz: "If the Klebs-Loeffler bacillus be accepted as a *sine qua non* in the etiology of diphtheria, then croup (pseudo-membranous laryngitis) must necessarily be separated from it." Clinically, there is a difference in the symptomatology of the two diseases more easy to describe than appreciate, but the dissimilarity does certainly exist. I must confess, however, that my own experience is that of all with whose views on the subject I am familiar, that it is no easy task to differentiate between pseudo-membranous croup and primary laryngeal diphtheria. This fact is illustrated in Case VI reported herewith. In this case I was as careful as I could be in my efforts at making a diagnosis, and had the assistance of several other physicians, and yet the results, much to my sorrow and chagrin, showed that we were mistaken.

To summarize and abbreviate as much as possible, the clinical differences consist in about the following points, viz:

1. Membranous croup usually begins in the larynx, and the fauces are but slightly if at all effected.

An examination of the fauces in a vast majority of these cases reveals nothing. There may be very little increased redness and almost no swelling.

2. Croup is not infectious.

I have attended, and so have many others, case after case of pseudo-membranous laryngitis in which there was every reason to expect other children to contract the disease if it were contagious, and yet no such result has followed. This point is well illustrated in the following cases, with the exception of one in which an error of diagnosis is admitted. It is said by Dr. J. C. Wilson in Pepper's *System of Medicine*, that cases of tonsillar diphtheria also occasionally run their course without infecting others, though there may be exposure of susceptible persons. But it is admitted that diphtheria is an infectious disease, and the instances of escape of susceptible persons are exceptional; whereas, in the experience of the physicians of this city, at least, the rule in membranous croup is that the affection is non-infectious, and susceptible persons are exposed with impunity.

3. Croup has none of the serious asthenic symptoms of diphtheria.

All the serious symptoms which arise in croup are due to the obstruction of respiration, and therein alone lies the danger.

4. Croup is not followed by paralysis.

In contradiction of this statement, Mackenzie says that the reason for this is that about all cases terminate fatally, but in those cases which recover paralysis does occasionally occur. His article was written before intubation was extensively done, and consequently there were but few recoveries. Since then many cases have been saved by this operation; but I have learned of but few cases of paralysis within my own experience or that of others, and in those cases we are willing to admit that the disease was probably diphtheric, for it must be borne in mind that we do not assert that cases of pseudo-membranous laryngitis are never diphtheric and that we are painfully conscious of the difficulties of diagnosis.

5. Croup is a sthenic disease, while diphtheria is adynamic.

6. Croup is a local disease.

Whether diphtheria is first local and then general, or *vice versa*, is still a disputed point, but it is a fact that it is ultimately constitutional. No such statement substantiated by sufficient proof can be made in regard to croup.

7. The lymphatic glands are not affected in croup, but are enlarged in diphtheria.

This is explained by Mackenzie and others, by citing the well-known fact that there is no communication between the mucous membrane of the larynx and the superficial cervical glands.

8. There is no albuminuria in pseudo-membranous croup.

I am sorry the urine was not examined in all of the cases here reported, but this paper was not contemplated at the time the cases were under observation. The examination was made in only one case, and that was diphtheric, and showed a quantity of albumin.

While, then, on these grounds of bacterial and clinical difference, we argue the non-identity of the two diseases, it must still be admitted that it is very difficult and, in many cases, impossible to diagnosticate between cases of primary laryngeal diphtheria and pseudo-membranous croup. One of the cases here reported shows this difficulty, for after being carefully examined by several physicians and pronounced pseudo-membranous croup, subsequent events proved it to be diphtheric. This difficulty of diagnosis is spoken of by most authors, and in fact, is used as an argument for the identity of the two diseases.

This difficulty of diagnosis being true and an admitted fact, I fully indorse the action of the New York Board of Health in designating all cases of croup diphtheric, as being the safest method under the circumstances for the avoidance of possible risk of contagion. In fact, I would urge upon all, in view of my own experience, the propriety of isolating all cases of croup, and in future I shall certainly do so myself, though this is not an admission of the identity of the two diseases, but only a confession of the difficulty of diagnosis.

For the purpose of illustrating some of the points enumerated, namely, the non-contagiousness of croup, clinical history, pathology, difficulties of diagnosis, and also the results of treatment, I call attention to the following cases :

CASE I.—Daughter of Geo. G., aged six years. The brother had died a week or ten days previously of diphtheric croup. She had no deposit on the fauces, and I do not recall any glandular enlargement; nevertheless, considering that her brother had died of diphtheric croup a few days before, I felt justified in pronouncing her case also diphtheric croup. There was no fetor of the breath, such as usually occurs in diphtheria, nor was the constitutional disturbance in any way different from what we would expect in a case of pseudo-membranous laryngitis. The usual remedies failed, and I attempted intubation with the assistance of Dr. Watson. The operation was a complete failure. At that time I thought it was on account of loose membrane filling the tube, thus interfering with respiration, but now I believe it was want of skill in introducing the tube, and have my doubts whether it was in the windpipe at all. It was my first case of intubation, and I have learned a good many things about the operation since.

CASE II.—A son of John C., aged seven years,

was taken with symptoms of croup, and the disease rapidly developed, so that there was no difficulty in diagnosticating his disease as membranous croup. There was no offensive odor of the breath nor glandular enlargement, and the constitutional disturbance was mild, the temperature not running much above 101° or 102°. His brother played around him, kissing him and inhaling his breath, and in fact no effort was made to keep them separated, nor were any disinfectant measures used. His brother and some other children who were allowed the freedom of the sick-room without restraint did not take the disease, nor did any of them have the least sore-throat. I was somewhat anxious to know whether they did or not, and so kept myself informed in regard to all who came in contact with the patient. With the assistance of Dr. Armstrong I attempted intubation in this case. Whether the tube was in the larynx or not I am not prepared to say, for at that time my knowledge of the landmarks was not very accurate. But this I do know, that with a mighty effort he coughed up the tube and with it a membrane several inches long and a perfect cast of the windpipe. He died, however, of exhaustion the next day. In this case, as in case No. 1, the operation was too long delayed even if skilfully performed, to be of any service, deep cyanosis having occurred and mucous râles being distinctly heard over the lungs in both cases.

Case III.—A Russian Jewish boy (son of A. S.), aged five years, deaf and dumb, was taken with croup-symptoms, and Dr. Watson being called, diagnosticated the case as one of membranous croup. I saw the child the next day with the doctor and confirmed his diagnosis. We intubated him, and he recovered. No precautions were taken to keep the other children away, and the surroundings were the most unhygienic that can be imagined. Though other children had free access to him no other cases occurred in the family or neighborhood. A peculiar accident happened in this case. The little fellow being deaf and dumb could not be made to understand that he was not to disturb the string, and in some way he managed to chew the string off and finally to get the tube into the esophagus and swallow it, passing it by the rectum some days after. That it was really in the windpipe is proved by several circumstances. The breathing was much improved after its introduction, and he had the peculiar metallic ring in his voice. He vomited before he was put to bed, so that if the tube had been in the esophagus, instead of in the windpipe, he would certainly have thrown it up. While the tube was in position with the string fixed to his ear he was given liquid food, which he swallowed easily, and this he could not have done had the tube been in the gullet. I mention this accident, as it was a peculiar one and because it had afforded some amusement to my friends. I was especially chagrined at it, as it was my first case of intubation in which the patient recovered.

Case IV.—A daughter of Charles G., aged four years, was taken sick with vomiting and fever, and the parents thought also sore-throat. I was called to see her in the evening and found the child asleep on the mother's lap. When I attempted to examine her throat she struggled and resisted so that I could not see what her condition was. I intended to see her the next day, but the father came to see me and said she was up and running around and that I would not need to call. On the fourth day of her illness, however, he came to see me again and said that she had lost her voice, and, immediately suspecting the case to be one of true croup, I at once went to see her. I found her running around the room, apparently well, except that she had lost her voice. An examination showed that she was suffering with diphtheric croup, the fauces and tonsils being covered with the membrane. She was immediately put to bed and a very serious prognosis given. She was isolated from the rest of the family and given mercuric chlorid and tincture of ferric chlorid, and a spray of bichlorid was also used. On the fifth day respiration was so much interfered with that with the assistance of Dr. Watson I intubated with the most gratifying results, the little one getting so much relief that she herself said "I'm better." The tube remained in place and gave every satisfaction until the seventh day (two days) when it became filled with membrane and mucus, and after a while was expectorated along with shreds of membrane. The respiration again becoming labored the tube was re-introduced, with complete relief of the dyspnea, but the child died on the following morning, not from interference with respiration, but from the toxemia of the diphtheric poison.

Case V was a son of S. E., aged five years, seen by Dr. Watson, and a diagnosis of pseudo-membranous laryngitis was without difficulty made. I saw the case in consultation on the next day, and did not hesitate to confirm the diagnosis, and that evening performed intubation. The tube remained in place for four days, during which time there were no untoward symptoms, the little fellow feeling well, and expressing a frequent desire for something to eat, and making a complete recovery. There was no effort at isolation, and though other children had frequent communication with him no other cases developed.

Case VI.—A son of G. W. B., aged four years, had been sick two days previously to my visit, with croupy symptoms and fever, but had not complaind of sore-throat, nor was there any enlargement of the cervical glands. There was no especially offensive odor to the breath, but on inspection of the fauces there was distinctly visible a small white patch of pseudo-membrane on the posterior and inferior aspect of each tonsil. The systemic disturbance was slight, the temperature being 103° in the axilla, and digestion and appetite not more impaired than would be expected with such a febrile reaction. I am now convinced that I made a mistake in diagnosis when I pronounced the case one of membranous croup. No precautions were taken to prevent the other children from having access to the boy, and the consequence was that several cases of diphtheria of a mild type, and one of diphtheric croup, to be referred to again, followed this case in the same family. My only justification is that the case was seen by a number of other physicians, and the diag-

nosis was confirmed by all. It certainly was not secondary to faucial diphtheria, and was so mild in all the symptoms, except those of obstruction, that it was difficult to realize that it was actually a case of diphtheric croup affecting primarily the larynx. The interference with respiration was so marked and continuous that in the presence of a number of physicians I intubated him. He was given tincture of ferric chlorid and mercuric chlorid, and allowed to inhale the vapor of slaking lime. The tube remained in place for four days, the temperature gradually fell, and as there were no contradicting symptoms the tube was removed at the end of this time, and with the exception of the fact that about this time he developed measles, through which he had to pass in the usual way, he made an uninterrupted recovery.

Case VII.—A son of W. H., aged seven years, was seen by Dr. Watson on April 29th. An inspection of the fauces revealed diphtheric membrane covering the tonsils and palate, and this with the interference of respiration, loss of voice, rapid feeble pulse, and temperature of 103°, made it very easy to diagnosticate the case as one of diphtheric croup. The boy had been sick less than twenty-four hours when the physician was called, and at that time he was croupy, so that the probabilities are that the membrane was formed previously in the larynx, or at least at the same time that it formed in the fauces. The child was completely isolated from the other children of the family, and no other cases followed. He was given the usual course of treatment, but it proved of no avail, and two days after he became ill the obstruction to respiration made it necessary to intubate, which we did successfully and with complete relief to his breathing. The tube used, however, was too small, and he coughed it out about six or eight hours afterward. A larger one was introduced and remained. A few days afterward he developed measles with catarrhal pneumonia, from which he died four days after intubation. The breathing was not in the least obstructed, and he died just as he would have done from pneumonia unaccompanied by croup.

Case VIII.—A son of A. F., aged twelve years, showed croup-symptoms, and Dr. Corson, of Charlton, was called. The boy had a moderate elevation of temperature, no swelling of the cervical glands, no offensive odor of the breath, and no deposit of membrane on the fauces. Dr. C., who is a strong advocate of the diphtheric origin of all these cases, confessed that this was different in its clinical features from the cases of diphtheric croup which he had seen before. When called in consultation with him I fully agreed in the diagnosis of pseudo-membranous croup. Obstruction to respiration had become so serious that it had been feared he would not be kept alive until I should arrive, and so we proceeded with intubation. The child made a complete recovery, and in four days the tube was removed. He was not isolated, and, so far as I know, no other cases can be attributed to him as the source of infection, though there was ample opportunity if the disease had been contagious. A peculiarity of this case was the age of the patient. He was the oldest child I ever saw with pseudo-membranous croup. Cases at this age are certainly very rare.

Case IX.—A son of R. C. H., aged six years, was taken with symptoms of catarrhal croup some two weeks after an attack of measles. He had been sick several days when his father came to me for some croup-medicine, never thinking of membranous croup, but incidentally and rather accidentally remarked that the little fellow had lost his voice. My suspicions were at once aroused, and on visiting him my fears were confirmed, though I had some difficulty at first in deciding between catarrhal and pseudo-membranous croup. There was no deposit in the fauces. The temperature was 101° under the tongue. The boy was given tincture of ferric chlorid and mercuric chlorid, with inhalations of lime-water and carbolic acid. He was not isolated, and his sister played with him, and once I found her lying beside him. Other children also were admitted to the room. No other cases followed. Obstruction to respiration became so alarming that intubation became necessary on the third day after I was called, which I performed with the assistance of Dr. Watson and my student, Mr. Salmon. Rapid recovery ensued.

Case X.—This was the youngest child I think I ever saw with membranous croup, being only sixteen months old, small for its age, and of a strumous diathesis. The parents not appreciating the gravity of the disease had neglected it till the last minute. With the assistance of Drs. Watson and Lichtenthaler I intubated, but not without a good deal of difficulty. When I saw the child a few hours afterward its temperature was 105° in the groin, and while respiration was not obstructed, it breathed 74 times a minute. It died seven hours after intubation, but, much to the parents' satisfaction, was relieved of the dyspnea.

Case XI was a son of G. W. B., aged two years. This is the case referred to in reporting Case V, and occurred in the same family just two months later. In the meantime, however, there had been several cases of diphtheria of a mild type in the family, and I had urged the isolation of the affected children without avail, though as the original source of the disease was an old partly filled well into which the wash-water and refuse were thrown, and which communicated with the house by a pipe, and which I had tried in vain to have removed, they would probably have taken the disease even if they had been isolated. This child when first seen had faucial diphtheria, but no symptoms of croup. After a few days' illness, however, he began to be croupy, and his voice was markedly changed. On "flood Monday" he became so croupy and his respiration so labored that intubation was necessary. The house being surrounded by water, Dr. Watson and I got into a boat, went out, and performed the operation. On the fourth day after intubation râles were heard all over the lungs, and little air seemed to enter the vesicles. I thought that possibly the tube was filled with mucus and membrane, and removed it, but without relief, and the child died the same evening. Evidently the deposit had extended to the bronchial tubes, and I have no doubt even into the smaller ones.

On analysis of the foregoing cases, we find that five were diphtheric and six were not, and that in all except one of the former isolation was enforced so that no other cases developed from them; but in the latter, in those cases diagnosticated as membranous croup, no effort was made to keep other children away, and yet in no case except the one referred to as a mistake in diagnosis did any other children contract the disease or any sore-throat, though in every instance there was exposure of susceptible persons. On this fact, as well as the clinical history, is based the supposition that the diagnosis in these cases was correct. The one case in which a mistake was made I now believe could have been diagnosticated properly if due importance had been attached to the small speck of membrane on each tonsil. Though it was not larger than a grain of wheat, I believe such a deposit is almost diagnostic of diphtheria, for as far as I can now recall I think I never saw a deposit on the tonsils in pseudo-membranous croup.

Clinically, it may be noticed that in these six cases of membranous croup there was no deposit of membrane in the fauces, a fact which seems a strong argument in favor of the diagnosis, and especially so when we recall that in 156 cases of laryngeal diphtheria referred to by Dr. Northup, in only one was the membrane in the larynx alone, showing the great tendency to spread to adjoining parts in diphtheria as contrasted with the local tendency of membranous croup.

Of the five cases that recovered not one had paralysis of any kind.

Of those cases that recovered only one was an example of diphtheric croup, and of those that died all but one was diphtheric, the remaining one dying from a late operation in an enfeebled child of extreme youthfulness.

In closing, I wish to make a few remarks on the value of intubation in these cases.

O'Dwyer estimates that one child in ten gets well of membranous croup, whether diphtheric or pseudo-membranous, under medical treatment, but from my own experience and that of others with whom I have been intimately enough associated to know of their experience, I am convinced that when obstruction does really exist, when there is a pseudo-membrane actually formed, this percentage of recoveries is too high. And moreover I am convinced that when recovery does occur it is more by the accidental removal of the obstruction or by the *vis medicatrix naturæ* than by the potency of any drug or plan of medical treatment we can select. But even admitting that one in ten recovers, the mortality is still wofully high, and anything that will reduce it is certainly to be sought after most diligently. Intubation has reduced the mortality to 26.77 per cent., or roughly estimated, about one in four recovers after this operation, which is quite a fall in the death-rate, as is readily perceived; but I believe as the operation becomes better known, and is consequently not held in reserve to be used as a last resort, but, on the other hand, is performed early, the mortality will be still greatly lessened.

If we refer to the cases here reported and exclude the first two cases, which should not be included because they were not (for the want proper skill) intubated at all, and should not, therefore, be included in the intubations, we see that five of the nine cases intubated recovered, 55.5 per cent., or more than double the proportion of successful operations as published in the books. Of course, the number is too small to make the results of much statistical value, as the next series of cases may reduce this favorable showing considerably, but I attribute the results to the fact that in all cases an operation was urged as soon as the obstruction became very decided and before the cyanosis became too pronounced. I believe that one of the cases (Case X) would at least have stood a better chance for recovery had I seen it earlier, notwithstanding its extreme youthfulness, being only sixteen months old, and of a strumous diathesis. I saw it only nine hours before death, and it died seven hours after intubation.

Even in the cases in which intubation failed to cure, only in one case did it fail to give relief, relief most gratifying to parents and attendants, and no doubt, still more gratifying to the little sufferer. In the case in which it thus failed to relieve I am satisfied tracheotomy would also have failed, as it was quite evident the membrane had extended to the bronchial tubes, and, it seemed, also into the smaller branches.

One of the great advantages of intubation is the willingness of parents to permit it, and if physicians would be less afraid to propose it I am sure there would be more early operations, and consequently more recoveries.

RHYTHMIC HEAD-MOVEMENTS ASSOCIATED WITH NYSTAGMUS OCCURRING IN INFANTS AND YOUNG CHILDREN.

By EMILY LEWI, M.D.,

[From the service of Dr. Henry Koplik, Good Samaritan Dispensary, New York.]

Nystagmus associated with rhythmic movements of the head is a rare affection of infancy and childhood. The occurrence of nystagmus alone is not uncommon; we find a plentiful literature on this subject. Not so with the combined symptoms. It has been my good fortune to have met and studied a number of cases of these rare associated nervous disorders of the eye and head, in the service of Dr.

Henry Koplik, and it is the object of this paper to call attention to these cases in an analytical critique of their leading symptoms.

The most constant phenomenon in these cases, and one that immediately attracts attention, is the rhythmic oscillation of the head, either in the horizontal or vertical direction. Sometimes a combination of these movements has been observed. The eye-disorder is a nystagmus, occurring either at the same time with the head-movements or independently of them.

Ebert and Faber called attention to these cases many years ago. Henoch, under the title of *eclampsia nutans*, mentions a class of cases similar to these. Dr. Stephen Mackenzie and Dr. Gee have each reported two cases which must be put in this category. Dr. Gordon Norrie, several years later, in the *Ophthalmic Review*, cites cases of this type. The first American observer to publish a case, was Dr. A. Caillé, in 1890. Shortly following this there appeared Dr. W. B. Hadden's first series of cases, followed by a second series about two years later. Dr. Hadden's studies are by far the most complete and valuable contributions that have been published on this subject.

In the following series no two cases are identical in detail; their similarity is, however, sufficiently evident to justify considering them all of the same class:

Case I.—Celia S., aged seven months, was seen for the first time on April 7, 1894. The family history is negative; the child is a breast-fed baby, and has always been well; when five months old she fell from her chair, and the next day the mother noticed both head-movements and eye-movements; the latter were almost incessant; they have improved somewhat; the head-movements are about the same as at first. The examination showed a healthy child with rachitic beading of ribs and enlarged epiphyses. The head-movements are both lateral and up-and-down. The former are fairly rhythmic, occurring in series of about five or six, the first two describing a larger arc, each one growing shorter, the last being but a slight movement. Then there may be a nod or two, or a repetition of the previous rotary movements. These movements are much alike in all the cases, and any deviation will be noted. The head-shaking is increased whenever the child wishes to direct her attention to anything, or when she attempts to accommodate at a distance. Blindfolding causes complete cessation of the head-movements. The nystagmus is marked and very rapid, both horizontal and vertical, more constant in the right eye. Forcibly restraining the head does not affect the nystagmus; both head-movements and eye-movements cease when the child lies in her crib. It was noted that the room in which the child lived was unusually dark, a kerosene lamp being kept burning the entire day; moreover, the mother very rarely took the child out in the air. On April 12th the child was seen again. The nystagmus sometimes preceded the head-shakings. A lighted candle held near the eye and then at a distance, then slowly moved up-and-down, to the right, and to the left, showed that the head-movements increased when the child was looking at the candle at a distance of eight or nine feet. The same test was made with a bell and a bright red apple, and the results were the same. The pupils react to light and distance. The child was seen about every ten days. On May 4th two teeth, lower central incisors, were noticed. The nystagmus was somewhat improved. The muscles of the back of the neck were somewhat rigid. On May 25th the child fell from her chair again; for a few days the nodding and nystagmus were increased. On June 6th the nystagmus was less frequent, and the head-movements were rotary; no nodding was observed. On June 18th the head-movements were less frequent, the nystagmus still present. On June 30th the head-movements were not observed; there was occasional nystagmus, more noticeable in the right eye. On July 12th the child was well; neither movement nor nystagmus was observed; the mother said that she had noticed neither for one week.

In brief, we have in a rachitic child, giving a history of traumatism, rhythmic head-movements, nodding and rotary, also a horizontal and vertical nystagmus more marked in the right eye; the nystagmus increases when the patient accommodates for distant objects, and this may or may not be synchronous with the head-movements. Both disturbances gradually improved, then ceased, the nystagmus existing a few days after the head-movements had discontinued.

Case II.—Jenny S., aged seven months, is a breast-fed baby, bright, but a very restless child, and in perpetual motion. The mother is a very nervous, hysterical woman; two of her previous children died of convulsions. The mother has noticed a shaking of the head for the past three months. The fontanel is depressed and large; the epiphyses are large; there are no teeth. There is no traumatic history. Rotary movements of the head exist the same as in Case I, except that occasionally the child gives a quick forward jerk of the head toward the right side. The nystagmus is horizontal, occurring at the same time as the head-movements. On April 10th the candle, bell, and apple were used as in Case I. The head-movements increase when looking at a distance; nystagmus is observed independently of the head-shakings. The pupils react perfectly to light and distance. Blindfolding the child causes discontinuance of the movements, and the same is found to be the case when lying down. On June 6th the child was seen at intervals, but nothing new was noticed. On June 15th the muscles at the back of the neck are found to be slightly stiff; an object held close to the eye causes all motion to cease. The child wakened from a sound sleep, and for about two minutes nothing abnormal was noticed; when she began to observe the objects about her, movements returned.

On July 12th the child is better; the mother says that some days the head is like that of other children for three or four hours at a time. The head-movements are indisputably less frequent; nystagmus was observed twice in ten minutes. The child has no teeth as yet.

In this instance we have a somewhat rachitic child, with lateral head-movements and an occasional short, sharp twist of the head toward the right side. A horizontal nystagmus exists simultaneous with the head-movements and in the same direction. The child improved, but so far recovery is incomplete.

Case III.—Heyman K., aged ten months, healthy until five months old, when he had a fever which lasted a week, and in the course of this week he had one convulsion; since that time he has been well. One other child of the family has rachitic paraplegia. The patient is breast fed. The derangement of head and eyes has existed two months. On April 10th examination showed a large square head, the fontanel large, the jaw quite square, but an absence of teeth; the ribs are beaded, the abdomen large and very tympanitic, the glands at the angle of the jaw enlarged. Head-movements exist as in Case I, that is, both rotary and nodding; the child holds his head slightly to the left side; bandaging has the same effect as in previous cases. The nystagmus is horizontal and vertical, not very rapid, can be counted readily, and is most marked on deviation of the eyeballs to the right or to the left—what is known as external nystagmus. Extreme deviation to the right causes incessant movements of the eyeball, that of the right eye being the more rapid. There is a tendency toward rolling the eyeballs upward and to the left, and when this occurs there is no nystagmus. The experiment with the candle, bell, and apple show an increase of the nystagmus on looking forward, while on looking downward the vertical nystagmus only is more frequent. Here again head-shakings and nystagmus may be independent of each other. The pupils react perfectly. The child was seen regularly. In May the first two teeth appeared; no improvement followed. On June 18th the child was observed lying in his cradle, the head rotating from side to side the same as when in a sitting position. He was laid back in his bed repeatedly, but this did not occur again. On July 12th the child's condition was unchanged.

We have here a child with slight rachitis and giving a history of convulsions, who inclines his head slightly to the left side, and also showing the rotary and nodding movements. The eyeballs tend to roll upward to the left, while there is also a horizontal and vertical nystagmus, the former augmented by deviation of the eyeballs, especially to the right, always a more rapid nystagmus of the right eye, while the vertical nystagmus is more marked when the eyeballs are rolled downward. The movements of head and eye may or may not be simultaneous. On one occasion lateral head-movements occurred when lying down.

Case IV.—Sam D., nine months old, was visited the first time in April, 1894. The mother is very delicate. When pregnant with this child she had malarial fever during the last six months. The child was born asphyxiated, but was resuscitated in a few minutes. The patient was nursed by the mother. The child is microcephalic, the development being arrested in every respect; child is about the size of a baby one month old. The fontanel is closed; a peculiar sharp angle is formed in the middle of the forehead by the union of the frontal bones; there are no teeth; the ribs are beaded. The child cannot hold its head erect. The head falls back in a position of extreme extension, while at the same time there are rotary movements. These movements are arrested when the child is blindfolded. The eyeballs follow the light, bell, and apple, when held above the eyes, but do not follow to the side or below. Very rapid nystagmus occurs for a few seconds about once in ten minutes, is always horizontal, and unaltered by forcibly restraining the head. This child was seen three times, the condition remaining always the same. Unfortunately, it was lost sight of, owing to change of residence.

This was a microcephalic child, slightly rachitic, with the head in a state of constant extension, with rhythmic rotary head-movements, and no nodding; there was an exceedingly fine occasional horizontal nystagmus. The condition remained unimproved.

Case V.—Joseph T., aged eighteen months, was seen on May 26, 1894, for the first time. A negative family history was elicited. The child was well until three months old, when he had pneumonia, from which he recovered fully, and which was followed by a second attack when six months old; since that time he has never been strong; his first tooth appeared when one year old; there is no history of convulsions. During the last few weeks he has been attempting to walk. Examination shows the child to be very pale; he has fourteen teeth, showing rachitic ridges and discoloration; the abdomen is large; the epiphyses of the wrists and ankles prominent. Three months ago the mother noticed that the child held his head to the left when looking at distant objects; about two months ago he fell from his chair, and several days after this head-movements were observed; the eye-disturbance had not been noted by the mother. The condition was as follows: the child was sitting in a high chair, and the head held to the left side as he was looking out into the shop. There are side-to-side movements of the head, but no nodding; the rhythm was about as in the other cases. This movement is increased when attention is directed to objects at the further end of the room; blindfolding corroborates former results. The nystagmus is oblique, downward, and to the right, is exceedingly slight, in fact almost imperceptible, and, as a rule simultaneous with the head-movements. The trial with the candle, bell, and apple shows the movements, and the nystagmus increases when objects are at a distance about on a level with the eye. Forcible fixation of the head is without effect. In this instance also the living-room

is wretchedly lighted, a gas-jet is kept burning low all day, summer and winter. The child was taken up and put down in his chair several times. After a few seconds the symptoms returned, together with the peculiar position of the head; it was found that this attitude was necessary in order that the child might watch his father at work; this was also the position in which the nystagmus was most marked. The patient was seen a number of times; there was no change. On June 19th he was very restless, his skin was hot, the temperature per rectum 101°, and the symptoms the same. The child was taken ill a few days later, and died July 11th. The cause of death was not known.

This was a poorly nourished child of moderately rachitic development, holding his head to the left. A traumatic history was given, with subsequent observation of lateral and up-and-down head-movements; the rotary oscillations of the head were more noticeable when the child fixed his gaze at distant objects; in addition, a fine oblique nystagmus downward and to the right was found, and this was increased when the eyeballs moved to the right. Head-movements and eye-movements occurred independently of each other. The patient remained unimproved.

CASE VI.—Eddie H. was first seen December, 1893; the six other children of the family are rachitic. This was a bottle-fed baby and never has been strong. The mother first noticed the nystagmus in his third month, and the movements were then so rapid that the mother said it made her dizzy to watch the motions. They have continued ever since, although at present they are less marked than at first. When the child was about six months old the mother noticed the peculiar position in which he held his head. Shortly after this he had pneumonia, followed by diarrhea and complicated by convulsions. He had four or five seizures in as many days. His condition in May, 1894, when aged twenty months, shows a markedly rachitic child; the parietal bosses are prominent; he has twelve teeth; the epiphyses are very large, both of the wrists and the ankles; there is marked curving of the tibiæ; the ribs are beaded and the abdomen is large; the child is just beginning to walk. The head is moved to the left in a jerking movement when he wishes to look at any object, while at the same time there is marked vertical and occasional horizontal nystagmus; every now and then the right eyeball only seems to move. Bandaging and experimentation give the same results as in the other cases. The nystagmus was observed once or twice when the child was lying in his crib. On July 18, 1894, the condition was the same.

In this case we have a history of eclampsia in a markedly rachitic child and long-standing nystagmus. The head-movement consists of a jerking to the left, that is, a slight rotary movement. The nystagmus, on accommodating, is vertical and horizontal, exceptionally in one eye only. The nystagmus was noticed when the child was lying down. On July 18, 1894, the patient remained unimproved.

It will be noted that no ophthalmoscopic reports are made; attempts were made, but the patients failed to report at the dispensary. Such examinations were made in the cases of Mackenzie, Norrie, Caillé, and Hadden, but were of negative value so far as throwing any light on the etiology of the affection.

In every case cited there were head-movements, always rotary, in some instances also nodding; the former were by far the more frequent. Not once was there nodding exclusively. The head-shakings were augmented when the child fixed with the eyes at a distance, and were discontinued when the child was blindfolded. On one occasion only were the head-movements observed when the child was lying down. The nystagmus was always much more rapid than the head-movements, and varied in type, being horizontal, vertical, and oblique, the first form predominating, that is, the eye-movement being in the same direction as the rotary head-movement. Although, as a rule, head-movements and eye-movements were synchronous, occasionally they were independent of each other, or one slightly preceded or outlasted the other. In Case I the nystagmus was observed some days after the head-oscillations were no longer noted. In two cases movement of the globe of the right eye was the more rapid. Extreme deviation to the right caused increase in rapidity and constancy of the horizontal nystagmus in Case III, while in the same child, looking downward had a similar effect on the vertical eye-movement. In no instance did forcible restraining of the head affect the nystagmus; this is contrary to the observations of Dr. Hadden.

The presence of rachitis in every instance might be looked upon as indicating the predisposition of rachitic children to this as to almost any of the nervous disorders of infancy and childhood. Although but one patient had marked symptoms, rachitis was found to a greater or less degree in each case. This coincides with the reports of Dr. Mackenzie and Dr. Caillé, as well as with that of Dr. Hadden, who found it frequently in his second series of cases.

The family histories were negative; a personal history of convulsions was noted twice. Dr. Hadden speaks of a peculiar form of unconsciousness simulating a mild kind of epilepsy as occurring frequently; nothing of the kind was found among these cases. The children were of average intelligence.

Henoch mentions teething as a cause of this disease, but this seems coincidental rather than causal; the age at which derangement occurs covers

the period during which dentition is very active, and one would, therefore, expect the eruption of a tooth from time to time. In the case of Heyman K., two teeth appeared in June, and yet there is no improvement of the condition. On the other hand, Jennie S. is decidedly better, but has not a single tooth. Case V had fourteen teeth when the disturbance was observed for the first time.

Traumatism as a cause has been mentioned by several clinicians. Twice in the foregoing series was such an etiology traceable. In Case I a second fall during convalescence resulted in a partial relapse.

It may also be possible that the nystagmus is due to eye-strain. Dr. Hugo Magnus has recently reported a case in which the nystagmus was traced to the continued strained upward position of the eyeballs, the child having formed a habit of staring at the gas-fixtures directly over his bed. Case V, in which the child habitually kept the head in a particular and strained position, is like the case of Dr. Magnus, with the difference that in Case V the eye-strain was sideways and in the other instance upward.

It is desired, however, to call especial attention to the fact that in Cases I and V the living-rooms were most wretchedly lighted. It was found necessary to have a gas-jet burning at midday on a bright summer day if any work was being done. The mingled daylight and the gaslight gave a most imperfect and dim illumination at best. In so far as nystagmus as found in adults, most frequently in miners, is ascribed to the poor light in which they are obliged to work, it seems that here we may have an analogous condition acting as an exciting cause. In Case I, as the weather grew milder the mother took the child out in the open air; this was strongly advised. The child has steadily and rapidly improved. In Case V the mother could not find time to do this.

The probable direct etiology of this combined head-movement and eye-disturbance was pointed out by Henoch and by almost every observer since —namely, that the root-nuclei of the nerves that supply the affected muscles of the throat and neck lie in the immediate proximity of the nuclei of the ocular nerve. Any disturbance of the roots of one set might most readily affect the other. Preyor states that associated head-movements and eye-movements occur as early as the tenth week, but that not until the ninth or tenth month do they become rapidly, easily, and correctly associated. We should, therefore, expect a derangement of function most liable to occur while the function is being perfected, as was the case in the foregoing series.

The treatment resorted to by Dr. Caillé, namely, bandaging of the eyes, was based on the fact that blindfolding caused a cessation of the movements. It stands to reason that motion must cease, for in blindfolding these children they are deprived of the purposive association of head-movement and eye-movement, which light and the sense of space render possible. Improvement occurred in both of his cases in several months. Whether this was due to the procedure adopted or to the accompanying tonic treatment may be considered a moot question. Dr. Hadden, on the principle that he was dealing with an epileptoid condition, gave potassium bromid with varying results; he likewise gave tonic treatment.

We are, in these cases, dealing with a functional nerve-disturbance due to any one, or possibly to all of the causes mentioned. We have a child that shows diminished nerve-resistance, or, to put it in another way, which shows increased nerve-irritability, for which the rational treatment is a careful attending to the details of personal hygiene, especially food, sleep, and exercise. The drug-treatment, if any be given, should be directed against the rachitis; for this some stable, easily-assimilated form of phosphorus is advisable.

THE NEED OF REST IN THE TREATMENT OF HIP-DISEASE.[1]

By Robert W. Lovett, M.D.,
of Boston.

The object of this paper is to present upon some new and upon some old grounds a brief plea for the greatest obtainable rest to the joint in any treatment of hip-disease, whatever it is, and to point out how this maximum amount of rest may be obtained. It will be sufficient to state that I am a believer in the use of strong traction in the treatment of hip-disease, on the ground that it distracts the joint-surfaces; but that traction is in my opinion only a part of successful treatment. To some often-neglected factors I beg in the present paper to call attention, without discussing the general question of

[1] Read by title before the American Orthopedic Association, at Washington, May 30, 1894.

the treatment of the disease. The measures to be advocated are local and general. Among local measures the treatment of hip-disease by the long traction-splint (the Davis, Taylor, Sayre splint) is probably the most common method now in use in America. Sometimes this is in connection with the use of crutches, but more often without them, the child being allowed to walk upon the splint, which thus becomes a perineal crutch. Assuming what is generally allowed to be the case by all surgeons, that a diseased hip-joint should be protected from unnecessary jar and traumatism, it becomes of practical importance to inquire whether such traumatism occurs when a patient with hip-disease is allowed to walk upon a traction-splint, or whether the traction-splint is sufficient protection to the diseased hip under these conditions. It may be seen when one observes a child with hip-disease walking upon a long traction-splint that a slackening of the traction-straps occurs when weight is borne upon the diseased leg. The entire weight of the patient comes directly upon the perineal straps and the structure of the splint, and tends to diminish traction every time that the bottom of the splint touches the ground. It is obvious that unless the apparatus is absolutely rigid from a mechanical point of view this must occur. Intermittent traction upon the hip must thus occur, the femur being allowed to slip back against the acetabulum when the patient's weight is borne upon the splint and traction is diminished. Leaving theoretic considerations, however, aside, the following experiments were undertaken to show what practical effect, if any, is produced when weight is borne upon the long traction-splint in walking.

Into the webbing of the ordinary hip-extension two small registering spring-balances were inserted, and the long traction-splint was applied in the usual way. Traction was then applied to the hip. The amount of traction was shown accurately by the balances, which formed part of the extension-straps through which traction was made upon the hip.

Experiment I. Girl, six years old, with hip-disease; traction of 7 pounds shown by balance; standing on splint reduced it to 5½ pounds.

Experiment II. Girl, ten years old, with hip-disease of four years' duration; traction of 6 pounds; standing on splint reduced it to 5 pounds.

Experiment III. Girl, eight years old, hip-disease (slight); traction of 15 pounds; standing on splint reduced it to 8½ pounds; walking lowered it to 7 pounds; after ten minutes without walking or standing traction had been lowered to 11 pounds.

Experiment IV. Boy, six years old, hip-disease of one year; traction of 18½ pounds; standing on splint reduced it to 15¾ pounds; walking on splint reduced it to 11¾ pounds; after ten minutes traction had been lowered to 13¼ pounds.

Experiment V. Boy, eight years old, hip-disease for two years; traction of 18 pounds; standing on splint reduced it to 12 pounds; walking on splint reduced it to 9½ pounds; after ten minutes of walking and sitting the traction was reduced to 13½ pounds.

The experiments need very little comment. They simply show that at one time the head of the femur is pulled away from the acetabulum by a certain force, and the next minute by perhaps half that force. This intermittent pressure of the head of the femur against the acetabulum induced in this manner is in a smaller way the same process, so far as the hip is concerned, as walking upon the leg directly, a constant series of traumatic impacts being induced. This fact has often been alluded to, but has not I think, been demonstrated by actual experiment.

Without entering into the merits of those splints, with the aid of which it is attempted to fix the hip-joint by rising above the pelvis and grasping the thorax by a rigid arm, it may be stated with regard to the long traction-splint that its use as a walking-splint cannot be otherwise than imperfect, compared to its use as an instrument to produce steady traction. That intermittent pressure exists is demonstrated; that intermittent pressure cannot do good, and may do harm, seems obvious. Some writers believe that motion of the hip-joint within small limits is beneficial during hip-disease. None, however, could advocate on any scientific ground that a constantly varying traction-force could be of use. If this intermittent traction were a difficult matter to avoid it would not be worth while to spend so much time in its discussion; but the use of a pair of crutches and a high shoe on the well foot does away at once with the whole difficulty.

The matter of fixation has not been considered in this connection; the question has been purely one of traction.

As regards general measures, it may be said that hip-disease is, in most cases at any rate, a tuberculosis of bone. Like many forms of local tuberculosis it is attended with general symptoms. Among the earliest in most cases may be sudden loss of flesh, failure of appetite, and high temperature. The latter is definite and easily studied, and as a symptom relating to the general condition of the patient is of interest in the present connection.

Some years ago I called attention to the significance of the importance of high temperature in chronic joint-disease. At that time I had not a very extended series of observations, but now I am able to generalize from some 1050 observations of the afternoon temperatures of children with hip-disease and Pott's disease. For analysis there were taken from my notes at random records of 250 cases

of hip-disease. The temperatures were taken bebetween three and five in the afternoon at the Surgical Out-patient Clinic of the Children's Hospital. The same thermometer was used, and every care was taken to make the observations accurate and uniform, the rectal temperature being observed. The observations on temperature in hip-disease have covered a period of four years and are several hundred in number. They include routine cases taken as they came to the clinic, and no cases were omitted. The cases were under ambulatory traction-treatment. In the group of 250 observations which were analyzed the temperatures were as follows:

Temperature between	Per cent.	Number of cases.
98° –98.9°	13.6	34
99° –99.4°	26	65
99.5°–99.9°	18	45
100° –100.9°	33	84
101° –101.9°	7.2	18
102° –103°	1.6	4

Studying the temperature as applied to individual cases there was no question that in severe cases the temperatures were higher than in mild ones. As a prognostic indication the temperature was of much use in the early stages, because, as a rule, cases which later proved to be severe began with a temperature of 100° or more. On the contrary, cases with a mild initial temperature as a rule did well. The occurrence of a sudden rise of temperature in a convalescent case often indicated an approaching relapse. In general, the severer the case the higher the temperature. High temperature is an early symptom coincident with the initial muscular spasm.

But what is of especial interest in this connection is the fact that the temperature in the evening is lowered in most cases by confinement to bed. It has been demonstrated very often in my experience that a child attending the out-patient department has had for weeks a temperature in the afternoon of 100° or more, but that when deformity or other symptoms which necessitated confinement to bed have arisen the temperature has fallen to normal or to 99° within forty-eight hours after confinement to bed. All, I am sure, will agree that in routine hip-disease without active suppuration a high temperature is not often to be seen in hospital-wards. A similar series of charts in an out-patient department would show a noticeable rise of temperature in the great majority of all cases, mild and severe.

In the same way a restriction of the child's activity by enforcing periods of recumbency during the day will in most cases lower the temperature, although generally not to the normal. I have observed this repeatedly, and more often of late when I have been adopting this limitation of activity as a routine measure in all but the mildest cases. Unfortunately, the routine observations of temperature were abandoned some time ago, so that no extended series of figures bearing upon this subject can be given.

Putting aside, however, the demonstrable fact that this subsidence of temperature does occur under recumbency, as shown in the observations already quoted, the benefits of restricted activity can be called to the attention in another way by noting how often it is that patients with tuberculous bone-disease who are being treated by ambulatory methods improve temporarily in flesh, appetite, and spirits when confined wholly or partly to bed.

Although as far removed as anyone from wishing to advocate the treatment of hip-disease by recumbency, I would beg to call attention to the conclusions to be drawn from the facts presented in favor of restricted activity, on the ground that high evening temperature is present in nearly all cases of tuberculous hip-joint disease, and that this high temperature is in most cases diminished by partial recumbency. The system that I direct as a routine in mild cases is very simple. The child stays in bed until nine or ten o'clock in the morning. An hour's rest on the back is insisted upon during the morning and two hours of recumbency in the afternoon. The child goes to bed early in the evening, generally at seven. For severe cases longer periods of rest would be prescribed. No ambulatory apparatus is perfect, and it is obvious on general principles that a child with hip-disease cannot without harm indulge in the incessant activity of other children.

The measures that I advocate in connection with any treatment, whatever it may be, are the routine use of crutches and a shortening of the active period of the day, both of which should be adopted for the purpose of securing increased rest to the joint.

THE TRAUMATIC ORIGIN OF ERYSIPELAS.[1]

By H. V. WÜRDEMANN, M.D.,
of Milwaukee, Wis.,
Director Wisconsin General Hospital; Oculist and Aurist to the Children's Hospital, and to the Milwaukee County Hospital for the Chronic Insane; Instructor in Eye, Ear and Throat, Elms Hospital, and to the Milwaukee County Hospital Training Schools, etc.

Long before the inception of the microbic theory of infections diseases erysipelas was known to be contagious, as was the fact that wounds of the skin in certain localities and under some circumstances were liable to be followed by this affection. That eminent clinician, Trousseau,[11] declared years ago that infection was only possible through an external wound or abrasion. The results of modern bacteriologic

[1] Read before the Milwaukee Medical Society, February 13, 1894.

investigation corroborate this excerpt from ancient literature, but examination of classic literature of recent date does not show that the fact is even yet firmly established. We still read of "idiopathic" and "traumatic" forms. Senn[9] called attention some time ago to the fact that infection may arise through a mucous membrane. Yet writers on special pathology are strangely silent upon the subject of the disease originating within or infecting cavities lined by mucous membrane. Most of the cases that I have seen within late years have arisen in this manner.

The specific cause is considered to be the streptococcus erysipela is, Fehleisen,[3] (report published in 1883), or the S. pyogenes, Rosenbach[8] 1884, Passet[6] (1885), of which I have specimens under the microscope, taken from several sources. (S. pyogenes, kindly lent me by Dr. V. A. Moore, Department of Agriculture, Washington, D. C.; S. erysipelatis, prepared by Dr. H. B. Hitz, of Milwaukee.) Later writers (Eiselsberg,[2] Paret,[7] Lungelsheim,[5] Sternberg[10]), believe that these are simply varieties of the same species, that both may exist together and with other pus-microbes, and that there is no antagonism of species. Clinical evidence supports the view that under certain circumstances one predisposes to infection by the other (see Case V), and even that the original source of infection may be so modified by its environment as to give rise to distinct clinical pictures. Thus infection by erysipelas may, in one person, or in one portion of the body, produce typical erysipelas, and in another an acute suppurative process, while in a third the two conditions may coexist or follow one another. Such varied manifestations are commonly observed in phlegmonous erysipelas, and may be traced in such complications as suppurative otitis, etc. (See Cases I, II, III, V, IX.) It is possible that microorganisms may be modified by their surroundings, and take upon themselves the characteristics of other forms, the poisonous products of their metabolism giving rise at different times to varied specific effects and different diseases. Our present knowledge of the evolution of disease renders this theory tenable. Bumm and Widal[1] show that when the streptococcus is constrained to lead a saphrophytic existence in test-tube culture it loses its virulency, and Sternberg[10] evolves from this statement the deduction that the rarity of infection of puerperal cases is largely due to attenuation of pathogenic power, as the streptococcus is often found in the healthy mucous membrane of the vagina, fauces, nose, etc.

Hajek[4] (1886) and von Lungelsheim[5] (1891) state that the morphologic processes of the S. pyogenes and S. erysipelatis are similar, although their morbific qualities are different. The former is pathogenic for both mice and rabbits, while the latter is lethal to rabbits only.[5] The S. erysipelatis is said to occupy only the lymph-channels, its inoculation producing a superficial migrating dermatitis, while the S. pyogenes penetrates the tissues more deeply, travels beyond the lymphatic system, producing intense inflammation in the depth of the tissues. The latter is seen both in the lymphatics and around the bloodvessels, and often in their lumen.[4] As my subject limits me to narrow grounds, I simply refer in passing to the fact that lowered conditions of bodily health and certain toxemias (alcoholism, septic infection, etc.) predispose to this disease as well as to other troubles, by diminishing the resisting-power of the tissues.[10]

The various inoculation-experiments show that the germ must be deposited under the superficial layers in order to gain entrance to the lymphatic vessels[9, 10]. No infection can result from contact of the virus with sound skin or mucous membrane.[10] There must be a crevice in the armor into which the poison can creep. A wound of entrance always exists, but in those cases in which no solution of continuity has been observed it has been either so trivial or so small as to escape the attention of both patient and physician. The face and hands being more exposed to injury than other parts, explains the relative frequency of erysipelas in these localities. During the past five years my experience has been confined to cases incidental to other affections, or occurring after operations, the latter one of the most annoying of complications, and to which few surgeons are strangers. All of my cases were of the facial form, and upon due inquiry the starting-point in all instances was seen to be a local lesion, and in nearly all the original infection could be traced to some other case or to auto-inoculation.

CASE I.[12]—Contagion arising from abrasion in the anterior nares in a patient who was in the habit of picking the nose, and who has visited and nursed an erysipelatous patient in the neighborhood. Dr. Thomas Hay called me in consultation on account of acute suppuration in the left middle ear, occurring after extension of the erysipelas to the nasal membranes and naso-pharynx. Recovery took place after one relapse. Microscopic examination of the ear-discharge revealed several forms of pus-cocci, among them the S. pyogenes.

CASE II.[12]—Contagion arising in the naso-pharynx, occurring after removal of an adenoid growth, forming an abscess in the pharynx, the inflammation extending to the middle ears, through the nasal and buccal cavities to the face and scalp, and down the neck to the shoulders. Suppurative otitis media occurred. The general treatment was directed by Dr. W. H. Washburn. It was a most severe case, attended by one relapse. Recovery followed.

CASE III.[12]—Beginning in an abrasion of the

mucous membrane of the lower lip in a pipe-smoker, extending through the buccal cavity to the naso-pharynx, through the Eustachian tubes to the middle ears, causing suppurative disease. Extension took place over one side of the face and scalp. No history of contagion was obtained. The general treatment was directed by Dr. W. F. Miller. Recovery followed.

CASE IV.—This man was receiving hypodermatics of strychnin for simple atrophy of the optic nerves. After about a dozen injections in the temples (needles presumably disinfected and reserved for him alone), a swelling was noticed which had existed several days when a diagnosis of hypodermatic abscess was made. For this condition I felt responsible until I afterward found out that the man was in the habit of frequenting a house in which there had recently been erysipelas. The temperature rose rapidly, and my consultant, Dr. F. E. Walbridge, concurred with me that the trouble was septic infection, but on the morrow, after the patient was safely ensconced in the hospital among other special surgical cases, I was dismayed to discover that the trouble was undoubted erysipelas. The roseola extended over one side of the face, but the man made the usual recovery.

CASE V.—This man had been lying in the next bed to the previous case before a diagnosis of the specific nature of the former had been made, and before he had been isolated. Seven days before I had opened the mastoid for caries. Erysipelatic inflammation began under the bandages in the site of incision, and extended over the scalp. The case proved phlegmonous. The temperature was very high. Recovery ensued.

VI.—For a number of days I abstained from operating, and kept away from personal attendance upon the two foregoing cases, until, believing that I was well disinfected, I extracted a cataract for an old woman in a room on the same floor, but nearly one-hundred feet away from the one in which the other cases were sequestered. On the fourth day thereafter we found unmistakable signs of erysipelas in an abrasion of the skin at the external angle of the eye *not* operated upon. Extension of the roseola to the cheek followed. It was a light case, with recovery.

CASE VII.—A scrofulous child, with erosion of the anterior nares and upper lip from purulent rhinitis appeared one day with a swollen face, and was sent to Dr. Louis Frank, who diagnosticated erysipelas. Recovery followed.

CASE VIII.—The patient was an old man, whose nasal passages had been occluded for years by an enormous number of polypi, the operations for which were made daily for about a week. Considerable malodorous purulent discharge followed. After attempted disinfection the galvano-cautery was used, and two days later erysipelas appeared in the nares, extending over the face. Recovery ensued.

CASE IX.—This patient sat in the waiting-room of my office for a couple of hours, in the next chair to Case VIII before the diagnosis of erysipelas was made. For some obscure reason he had placed a large fly-blister on his forehead, which in consequence had become very sore. Two days later he appeared with swollen face and eyelids, and the condition developed into erysipelas. The patient was sent to Dr. William Meyer for general treatment. A number of localized abscesses appeared about the face and forehead about a week after the roseola had disappeared. Recovery followed.

The clinical history of these cases, taken in order of occurrence from my case-book, substantiates the various pathologic investigations, showing that in all instances of erysipelas there must be a wound of entrance. Several of them illustrate the fact that the contagion of erysipelas does give rise to pus-formation, and that infection from other sources may cause erysipelas.

CLINICAL MEMORANDA.

ONE CASE OF COMPOUND DEPRESSED FRACTURE OF THE SKULL AND ONE OF A BULLET-WOUND IN THE BRAIN.

BY J. S. TRIPLETT, M.D.,
OF HARRISONVILLE, MO.

ALMOST every personal experience should be of interest to us all, inasmuch as it may clear up some doubtful point and produce a clear mental picture of what is the best treatment in subsequent similar cases; moreover, familiarity with similar cases better prepares one to undertake measures in their management which one would shrink from doing were they few or seldom reported. Timidity and conservatism in surgery are accountable for many deaths; especially is this true in places remote from the large cities and hospitals. It is, however, gratifying to reflect that now these conditions obtain less than formerly, since antisepticism and improved technique are on a scientific basis. It is mainly for the purpose of emphasizing the facts alluded to that this case is reported.

On June 13th of the present year, at about 1 o'clock P.M., Fred D., eleven years of age, well developed and of healthy parentage, on going into the barn was kicked on the left side of the head by a mule. His father hearing the noise, hastened to the barn, lifted up the boy and carried him to the house, where I saw him about an hour after the inception of the injury. He was then in a semi-

conscious condition, but would answer questions on being aroused; the pupils were of equal size and reacted to light. There was no noticeable paralysis, but especial examination was not made to determine accurately as to the existence of paralysis or paresis. Inspection showed a two-and-one-half inch elliptical scalp-wound, one-and-one-half inches to the left of the median line and one inch behind the Rolandic region, with its convexity outward and forward, and a depressed fracture of the left parietal bone. The condition of the parts was explained to the parents, and operation to relieve the pressure advised, which was assented to. It was noticed that the symptoms of cerebral compression were increasing, and on two or three occasions convulsions seemed imminent.

The field was prepared for operation by washing with soap and water, then shaving around the wound for two or three inches (his hair was very short, having been cut on the previous day, and for this reason a larger area was not shaved) after which it was washed thoroughly with an antiseptic solution.

Under chloroform-anesthesia the scalp-wound was enlarged by carrying the incision toward the median line, thus making a flap which could be reflected and the fracture exposed. The bone was depressed about three-eighths of an inch below the external surface of the outer table; it was about three-fourths of an inch wide and one inch long, and beveled at the expense of the inner table. The depressed portion was comminuted and was wedged so tightly that it could not be elevated without trephining or otherwise enlarging the opening. Bone-gnawing-forceps was used in preference to the trephine, as less bone would thus be sacrificed. The depressed fragments were now loosened and removed; considerable force was required to separate the bone from the dura. The dura was of a bluish-white tint and uninjured. Pulsations were perceptible. The sharpened edges of the bone were rounded off, the parts thoroughly irrigated, a small drain of iodoform-gauze placed in the wound, and the scalp-wound closed with interrupted silk sutures, the ordinary antiseptic dressing applied and the boy put to bed in good condition.

At 7.30 P.M. the temperature was 99.5° and the boy was resting well, excepting for a little pain in the head and soreness from bruises on other parts of the body, received at the same time as the head-injury. At no time during the period of convalescence did the temperature rise above 99.5°; it was normal after the first three or four days.

The scalp-wound healed by first intention, and there was no suppuration except from a stitch-abscess; the drainage-gauze was removed on the second day, but as a small quantity of limpid fluid collected each day, a small wick of gauze was put in at each daily visitation, until June 28th, when the wound was allowed to close. Recovery was rapid and uneventful.

I believe that all depressed skull-bones should be elevated, and especially if the outer surface of the external table is on a level with or below the visceral surface of the inner table, even if no symptoms of compression or irritation are present; for subsequent trouble, such as severe headache, mental hebetude, or even epilepsy and insanity, often ensue from the irritation of the depressed bone.

The adage that "misfortunes never come singly" seems to be verified in regard to fractures of the skull for this locality—the case just reported being the fourth that has come under my observation within the last few months.

The first of these cases, seen in consultation, was remarkable, inasmuch as the majority of cases of like severity generally prove fatal in a few minutes. The patient, a healthy and well-developed man of about thirty-five years, was shot about two inches behind the left ear with a thirty-eight caliber revolver, on September 9, 1893, the ball passing a little upward and forward through the brain, and glancing when it reached the opposite side of the skull. The man was unconscious for several hours and semi-conscious for two or three days.

Immediately after the injury the wound in both the scalp and the skull was enlarged and fragments of bone and foreign objects removed. Search was made for the ball, but without avail. The nozzle of a syringe was introduced along the tract of the ball for the distance of six inches, and the parts well irrigated, after which the wound was lightly plugged with antiseptic gauze and the man put to bed with an ice-cap to his head.

The shooting occurred early in the morning, and in the evening at 9 o'clock another unsuccessful search was made for the ball, after which the tract was again irrigated and plugged with antiseptic gauze and the ice-cap applied. At the time of and before both these operations considerable brain-substance escaped; two ounces, I think, constitute a low estimate of what was lost.

The parts healed by granulation, and recovery was slow but uneventful. No sequelæ remained to locate the ball, and the only evidence that the brain had been injured was some impairment of hearing and of visual acuteness, both of which gradually improved up to the normal or nearly so.

The man is at present doing manual labor and is in perfect health, notwithstanding the fact that he carries a bullet somewhere in his skull-cavity, from which he suffers no inconvenience.

A CASE OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

BY ARNOLD W. CATLIN, M.D.,
OF BROOKLYN, N. Y.

ARTHUR H., aged nine years, first complained of being unwell Saturday, October 6th. There was general malaise; the child was feverish and debilitated; there was loss of appetite, and he was disposed to maintain a recumbent posture. He was first seen on Sunday morning, October 7th. Debility was extreme, the skin hot and dry; the temperature 102°, the pulse 120. The tongue was coated and the breath very foul. Examination of the throat showed a mass of exudation completely filling the fauces, and nasal breathing was obstructed. Diphtheria of a low type was diagnosticated. He was put upon the mercuric chlorid, gr. 1/40, and tr. ferri chlor., ♏v, every three hours, and the throat was sprayed hourly with a weak solution of mercuric chlorid. He was nourished with whiskey-punch freely, and a culture-tube was immediately forwarded to the Board of Health.

I secured five grams of the antitoxin (Aronson's *Heilserum*), and gave the whole amount in one hypodermic injection between the shoulder-blades, according to the method used in Berlin, and explained by Dr. Louis Fischer, of New York. This was at 7 P. M., Sunday, when the disease had been present certainly forty-eight hours, and probably, in view of the fact that so much surface was involved by the exudate, for seventy-two hours, although no attention was called to the throat by the patient until the morning of the day the antitoxin was used.

No reaction followed the hypodermic injection. The patient passed a restless night, and was found no better on Monday morning. The report from the Board of Health as to the culture was: "True diphtheria." The cadaveric odor from the throat was almost intolerable. The heart's action was weak, and debility was even more pronounced than on the previous day. The temperature was from 100.5° to 102°; the pulse was 120 and feeble. The child positively refused stimulants in any form by the mouth. The condition of the throat made deglutition difficult. The appearance of the exudate was about the same as at the time of the injection the night before. Continuance of treatment was directed, with the constant use of hot brandy to the surface, and hot brandied cloths to the abdomen continuously. On Monday evening no progress was noted, and the case was assuming a grave aspect. The prognosis was unfavorable, and the new remedy was considered *inert*. On Tuesday morning, thirty-six hours after the use of the antitoxin, there was an evident change for the better. The temperature had fallen, the pulse was stronger, the tongue cleaner, and the exudate was loosening at the edges, and the surrounding parts looked bright and healthy. The improvement continued throughout the day. There was a free flow of saliva and mucus from the throat, but no membrane exfoliated. It appeared thinner, and was evidently disappearing.

The child was more comfortable that night, and evidences of gain in every way were noted on Wednesday morning. The temperature was nearly normal, the pulse 86, the odor from the throat nearly gone, and the membrane was rapidly disappearing. The underlying surface could be seen, and the whole appearance was fresh and healthy. No masses or flakes of membrane were loosened or coughed up. It all appeared to be melting away. On Thursday the temperature touched normal, the pulse was 86, the throat was nearly clear, and the nasal passages were much freer. The patient declared himself well, and his general tone was certainly excellent. He was hungry, and called for solid food. His urine was examined and found free from albumin. On Friday all the visible part of the throat was free from exudate, the tongue was slightly coated, but moist at the edges, the breath was entirely free from odor, the temperature ranged from 97.6° to 99°.

The report on the cultures, taken Thursday, was that the "Klebs-Loeffler bacilli were still present." On Saturday the child was, to all appearance, well; the throat was normal, and the nasal passages clear. All evidence of the disease had disappeared; and the temperature averaged normal. He had a royal appetite. On Sunday, one week from the date of the use of the antitoxin, the child would have been declared quite well if the report on the culture had not read "bacilli still present." I kept the child in bed and quarantined for the ensuing week, and on the eleventh day sent cultures to the laboratories of both the New York and Brooklyn Boards of Health to secure comparative tests. Reports from both read, "bacilli present." Persistent nutrition was kept up, and the throat sprayed with Seiler's solution and mercuric chlorid alternately.

Cultures made on the seventeenth day showed bacilli still present, but I had been unable to detect the slightest evidence of the disease since Saturday, October 13th, six days after the use of the antitoxin. Unfavorable reports from the Board of Health continued until the twenty-first day, when the cultures were declared free of bacilli. An intercurrent attack of follicular tonsillitis, however, again showed them present until the twenty-ninth day, when they had permanently disappeared.

No albumin was found during the course of the disease save on the eighth day, and then only a trace.

This case has been of great value as showing: first, the wonderful abortive power of the new remedy in dealing with this treacherous disease; and, second, as demonstrating its ability to limit the absorption of the diphtheric poison and so prevent the sequelæ so often seen and so fatal in a certain proportion of those recovering from the acute or primary stage of the disease. I refer especially to the cardiac and renal complications.

The presence of the true diphtheric bacilli for twenty-nine days in cultures made from the throat, three weeks after all distinctive symptoms had disappeared, and the child was apparently well, is very suggestive.

It certainly emphasizes the wisdom of making cultures and the need of quarantining patients as long as an unfavorable report comes back from the Board of Health. Doubtless this is one explanation of the spread of this direful disease in our great cities, where the children herd together in our ward schools and infect each other during the period of convalescence, when, if cultures had been made, they would still be in quarantine and the mischief prevented.

AN INTRA-CRANIAL TUMOR.

BY LAWRENCE W. LITTIG, A.M., M.D., M.R.C.S.,
OF IOWA CITY, IOWA;
PROFESSOR OF THEORY AND PRACTICE OF MEDICINE, STATE UNIVERSITY OF IOWA.

THE following case seems of sufficient interest to report, not because its presents anything unusual, but rather because it approaches the type. The patient, a little girl of seven years, with no family taint, came under professional observation in September, 1890. She had suffered from the usual diseases of infancy, and, in addition, had had a "swelling and breaking out" in the right submaxillary region, of which a small scar remains. In March, 1888, while attending the district school, she began to have attacks of vomiting, and to suffer from occasional attacks of severe headache. The neighbors noticed that she had a peculiar gait, and that she seemed inclined to reel toward one side.

Her mother states that she does not vomit like other children who are "sick at the stomach." During the past two months she has vomited on an average twice daily, and the headache after these spells of vomiting is

severe, the child throwing back her head and screaming with pain. In February, 1889, I saw the patient as she was walking through a long hall. She would reel toward the left, and recover herself, to again reel toward the left. At that time, when seated in a chair, she held her head backward, turned toward the left and slightly inclined toward the right. When gazing into vacancy both eyes were turned toward the right. Motion of the eyeballs was perfect in all directions. The pupils responded to light and in accommodation. The patellar reflex was present.

On September 20, 1890, the patient had not walked for six months. She continued well nourished. Seated in bed she rested her head against a support behind; she was mentally sluggish; a naturally bright face seemed to be clouded by a mask of stupidity. Motion of the eyeballs was not impaired, the pupils reacted to light and in accommodation; choked disc was present in both eyes. The girl counted fingers at fifteen inches with the right eye, at ten feet with the left eye. The circumference of the head was 22½ inches, and there was decided paresis of the left side of the face; the tongue when protruded turned toward the left. The child did not hear a watch on contact with the left ear, but heard the same at six feet with the right ear.

Both upper extremities were paretic, the left the more so, and ataxia existed in both. When placed on her feet the patient reeled or staggered, and would have fallen if not supported. Sensation to pain over the entire body was impaired, and conduction was slow. The patellar reflex was present. The sphincters of the bowel and of the bladder were both capable. As the patient lived ten miles in the country she was not seen again until April 29, 1891. The circumference of the head was 23¼ in.; the right pupil was dilated, and did not react to light; the left reacted slightly. The eyeballs were protruding; the forehead prominent. The girl protruded the tongue slowly. She passed urine involuntarily twice every twenty-four hours, and had no evacuation of the bowel without the use of a syringe.

At the autopsy, one week later, the circumference of the head was 23½ inches. The coronal suture was open; the skull was parchment-like in thickness, and the calvarium was removed in part with the saw and in part with scissors. In many places the convolutions of the brain were flattened, and the ventricles much dilated. The cerebellum was much increased in size, and contained a tumor located slightly to the left of the median line. The transverse and antero-posterior diameters each equaled 1¾ inches and the vertical diameter 1½ inches.

The tumor developed from the pia mater of the posterior fossa, and in its development it simply pushed the cerebellar substance before it, so that the cerebellum could be as easily lifted from the tumor as the operculum from the island of Reil. The inferior worm, the middle peduncle, the pons, and the medulla were most disturbed in function by the growth. The location and size of the tumor readily explain all the symptoms. Microscopic examination revealed a small round-celled sarcoma.

Prof. Ludwig Mauthner, who was but recently elected to the chair of ophthalmology in the University of Vienna, died suddenly on October 20.

MEDICAL PROGRESS.

Successful Operation for Suppurating Congenital Cyst of the Neck in an Infant.—Crivelli (*Australian Medical Journal*, 1894, vol. xvi, No. 8, p. 367,) has reported the case of a boy, four months old, who presented a large, soft, and fluctuating tumor occupying the posterior triangle of the neck. The tumor began to increase in size a few days after birth and rapidly assumed such proportions that to avert threatened suffocation, eight ounces of transparent and slightly yellow fluid were withdrawn by aspiration. The tumor refilled rapidly, and was aspirated a second time with strict antiseptic precautions. A third aspiration, however, was followed by suppuration of the cyst. When the child came under observation he appeared to be in a dying condition. The face was emaciated, the eyes sunken, the skin pale and wax-like, the body and limbs wasted, the pulse rapid and scarcely perceptible, the skin covered with cold perspiration, and the breathing rapid. The child also had rigors, was unable to take nourishment or to sleep, and presented a typical picture of septic infection. The tumor was quite subcutaneous and occupied the left posterior triangle of the neck, being bounded in front by the sterno-mastoid, which it overlapped and pushed to one side, and below by the clavicle and the first rib. It was almost as large as the child's head. It was not transparent, nor did it present pulsation, and no murmur could be detected. The overlying skin was red and painful and very thin at the apex, while the base of the tumor was surrounded by a margin of thick, edematous tissue. Extirpation of the tumor was decided upon as urgent, to be attempted as a last resource, in spite of the grave apprehension that was felt on account of the prolonged administration of an anesthetic to a child so young and so enfeebled. Ether was used to induce anesthesia, and the usual aseptic precautions were taken. A vertical incision, about three inches in length, was made downward in the skin over the apex of the tumor, and some six ounces of very thick, greenish pus escaped, which had no odor, but contained shreds of necrosed fibrous tissue. The cyst was unilocular, but exhibited traces of incomplete subdivisions. On introduction of the finger into the cavity a chain of enlarged glands was felt behind the sterno-mastoid, the most central of which was about the size of a walnut. The cavity was thoroughly emptied and washed out. A strip of skin was removed on each side of and parallel to the original incision, so as to facilitate the extirpation of the cyst. The cyst was universally adherent and its removal required most careful dissection to avoid injury to nerves and vessels. It extended upward almost to the side of the pharynx and to the greater cornu of the hyoid bone and a prolongation extended under the sterno-mastoid and was adherent to the glands and the sheath of the carotid vessels. This prolongation was so bound by adhesions and penetrated so deeply that its complete removal was not possible. The operation having occupied a considerable time, and as some uneasiness was felt on account of the weakness of the patient, the walls of the remainder of the cyst were now rapidly scraped with a sharp spoon and a drainage-tube passed to the bottom of the cyst. The wound was then quickly sutured and a strong solution of lysol injected through the tube, then dusted with

aristol and dressed with gauze and antiseptic wadding. The child was extremely weak after the operation, and rallied only after considerable stimulation. On the following day, however, the improvement was most marked. The dressing was changed for the first time on the second day, when the wound looked well and presented no pus. Two days later a small quantity of thick pus and some shreds of necrosed tissue escaped from the drainage-tube, around which the skin was somewhat reddened. Three days after this the drainage-tube and sutures were removed. Union had taken place except at the lowest part of the wound, from which a considerable quantity of pus was escaping. Eleven days after the operation some redness and swelling, with heat and tenderness, were observed an inch in front of the line of sutures at the level of the prolongation of the cyst and in the neighborhood of the carotid glands, which it had been impossible to completely remove. The skin here was hot and tender. A second incision gave exit to a small quantity of pus and a large piece of necrosed tissue of spongy consistence. A small drainage-tube was introduced into this new opening and the cavity was washed out at each dressing with a 5 per cent. solution of lysol. After this the amount of pus progressively diminished. The general condition of the infant greatly improved. He took the breast well, grew fatter, and slept well. Sweating ceased and the temperature fell to normal. The opening at the base of the line of stitches completely closed. Both of the drainage-tubes were gradually removed. Less than six weeks after the operation the child was completely cured, and in the course of the next few months he grew to be a large, strong, healthy baby, almost double his previous weight.

The Relationship Between Bovine and Human Tuberculosis.—SHERMAN and LAMKIN (*Medical Record*, No. 1247. p. 412) report the case of a boy, four years old, whose maternal grandfather had died of pulmonary tuberculosis, and whose nurse had about a year previously attended a daughter who also had died of pulmonary tuberculosis. The child had slight adenoid vegetations in the vault of the pharynx, and had suffered from two attacks of pneumonia, from both of which he had recovered entirely. When the boy came under observation he presented a spastic gait, frequently stumbling. Classic symptoms of meningitis, believed to be of tuberculous origin, progressively developed, and led to a fatal termination. Inoculation with tuberculin of three cows, from which was derived the mixed milk used by the patient, induced febrile reaction in two, and post-mortem examination in these demonstrated the existence of tuberculosis.

THERAPEUTIC NOTES.

The Effect of Creosote upon the Virulence of the Tubercle-Bacillus.—At the recent meeting of the British Medical Association, FYFFE (*British Medical Journal*, 1894, No. 1760, p. 644) read a paper detailing the results of an investigation undertaken with a view to determine whether the administration of creosote in the treatment of pulmonary tuberculosis is attended by a restraining influence upon the growth of the tubercle-bacillus, or by an improvement in the digestion, together with a better assimilation of food. The conclusions arrived at are summed up as follows: In cases in which creosote was given simply by inhalation, in addition to such drugs as cod-liver oil and the hypophosphites, no effect upon the virulence of the disease was noted. In cases in which the drug was administered by the mouth in doses ranging from 2 to 12 minims, three times a day, the diminution of the virulence was slight when the smaller doses were given, but when the larger amounts were reached there was an extremely marked diminution in virulence. In the case of guinea-pigs that received injections of tuberculous sputum into the legs, and were subsequently placed in a chamber in which creosote was heated until the air was saturated with the vapor, it appeared that the animal lived longer than untreated ones. Creosote injected under the skin of tuberculous guinea-pigs had a markedly restraining effect upon the morbid process, provided the disease were not too far advanced.

The Treatment of Cystitis in Children.—ESCHERICH (*Sem. méd.*, Aout, 1894; *Revue Internat. de Méd. et de Clin. Prat.*, No. 18, p. 322), in the treatment of cystitis in children with alkaline urine, practises lavage of the bladder twice daily with a warm 1 or 2 per cent. solution of boric acid, or a 5 per cent. solution of thymol. Besides he employs the following formula:

℞.—Potassium chlorate . . . gr. vi-ix.
Simple syrup . . . . . f ʒss.
Water . . . . . f ʒj.—M.

S.—A dessertspoonful every two hours.

In addition he makes an infusion of the leaves of uva ursi (half an ounce), in boiling water (five ounces), and adds simple syrup (two drams and a half). Of this also a dessertspoonful is to be taken every two hours.

In cases in which the urine is acid good results will be obtained by lavage of the bladder with weak solutions of creolin (from ten to fifteen drops in boiled water, eight ounces), and the internal administration of salol in small doses.

For the Relief of Pruritus Vulvæ.—A strong solution of methylene-blue is recommended by MADDEN (*Provincial Medical Journal*, No. 153) as an analgesic lotion in the treatment of pruritus of the vulval area. An essential point in the local treatment of this condition is to secure asepsis of the parts by frequent ablutions with hot water (120° F.) and the use of some antiseptic detergent, followed on each occasion by the application of mercuric chlorid (1:1000) or other antiseptic wash. Thus prepared, the parts are ready for the application of the antipruritic lotion, which, in conjunction with the internal use of the same agent, in two-grain pills, two or three times a day, is said to bring about marked relief. The persistent local coloration produced by the application of methylene-blue is an objection to its employment.

For Pityriasis Capitis.—

℞.—Sulphuris præcipitati . . . . ʒjss.
Adipis lanæ hydrosi . . . ad ℥ij.
Misce et fiat unguentum.

S.—To be applied to the affected parts every second day. *The Practitioner.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, NOVEMBER 10, 1894.

A SUGGESTION TO STATE UNIVERSITIES.

IN our State universities there is a growing tendency to come into closer touch with the people. This is shown by the summer schools, by the relations that exist between teachers' associations and the faculty, by the extension-work both in voluntary centers and country agricultural societies, and by the organization under the wing of the university of museums and laboratories, formerly independent. No attempt has been made, so far as we know, to place under university management the charitable and reformatory functions of the State. It is not to be doubted, however, by any one with sufficient knowledge of existing conditions, that it would be productive of good to place under the care of the State university the institutions for the blind, for the deaf, for the feeble-minded, and the normal schools. It would be a matter of congratulation to see these institutions conducted on that broad and educational basis which we see manifested in our more progressive State universities, instead of on the narrow, provincial, and often mercenary basis which now prevails in many of them.

There are some who believe that our penitentiaries and hospitals for the insane, our jails and poorhouses, ought to be open to the students of our State universities and furnish them laboratories for the study of crime, poverty, and mental infirmity. These advocates affirm that when medical students have been freely admitted to hospital-wards for the purposes of clinical instruction, the beds have been cleaner, the food better, the death-rate lower, and the average stay of patients in the hospital shorter on that account. They affirm, moreover, that the corruption, favoritism, and neglect previously prevailing, have been regularly diminished by the unbribable supervision of students, and that a superior administration and a superior medical and surgical treatment have been at once obtained. As an example near at home, the history of the Charity Hospital in New Orleans is often cited. It is believed that the presence of students at law, of sociology,and of medicine, in the charitable and reformatory institutions of the State would have a corresponding beneficial influence, and in proof is cited the great work of the Massachusetts State Board of Health, which comes very largely through its close connection with the Boston Institute of Technology, and the supervision which it exerts over the water-supply and sewerage of cities and towns in that State. Attention is called to the function of the University of the State of New York, which now practically includes every pupil in all the public and private schools of the Empire State, and many more students in other States and in almost every part of the world. Some citizens would, however, be slow to place at once as integral parts of the university such diverse bodies as the institutions for defectives and criminals, the State boards of health, of charities, of education, of factory-inspection, and the commision of labor, of live-stock and of fish.

There are many medical men who are asking themselves why such universities as those of Illinois, Wisconsin, Nebraska, and Kansas do not do something for medicine. When we look into the courses of study in these institutions we see that they require for the bachelor's degree something like forty or fifty units of work. Of these at least ten or twelve are identical with or accessory to the course that every graduate in medicine should take. Some of them are identical in name though superior in educational quality to courses required in the better class of medical schools. In looking over an ideal curriculum of a four-year course in medicine amounting to forty-eight units, we find that at least

thirty of these units could be given by the present faculty of the University of Illinois, or of the University of Nebraska. These institutions are situated in cities too small to furnish adequate clinical facilities for a medical school. They have no appropriations for medicine, and with a divided medical profession appropriations are hard to get. These institutions could, nevertheless, offer without extra expense a larger part of the medical course with the facilities they have at hand, and allow election to their students in this direction during the last two years of the course leading to the bachelor's degree. They could give this degree on the completion of the required amount of work, that is, forty or fifty units, and there would still remain something over two years of work before the degree of doctor of medicine would be given. The university could lay out a course of study comprising about forty-eight units of work, upon the completion of which it would confer upon students the degree of doctor of medicine. Some or all of the first half of this course would be parallel to or identical with work which might be elected in the last two years of the course for the bachelor's degree. When the student had exhausted the facilities of the State university, and had received his bachelor's degree, he would be allowed to attend any reputable medical school for the remainder of the course, returning to the university once a year with evidence of work done, to pass examinations before the faculty of the university, and receive his credits. When all the required work had been accomplished by the student, and when he had received credit by examination, he would receive the degree of doctor of medicine from the university.

Thus the student would be encouraged to complete his literary work in the university and receive his literary degree, and then, in the course of two or three years at most, would be able to do non-resident work in the best medical schools of the country, and receive his degree of doctor of medicine from the State university. He would thus be classed with educated men. When we remember that the medical departments of the University of Michigan and of Harvard University, and the College of Physicians and Surgeons of New York, still require no more for admission than is required to enter the freshman class in the respective universities to which these schools belong, we can recognize the desirability of establishing schools in which the medical degree will have greater value. Such a supervision of medical schools as this plan would entail would have a salutary effect upon the medical colleges which these universities would recommend, and would especially increase the quality of the education in them.

REGISTRATION OF TUBERCULOUS PATIENTS.

THE Board of Health of the city of New York has recommended that "physicians and other persons to whom the knowledge of the existence of a case of tuberculosis may come be requested to report to this department all such cases within seven days of the time when such sick person comes within observation; that the medical sanitary inspectors, as a part of their duty, investigate cases of the disease reported, and take specimens of the sputa for diagnostic purposes, as is done in cases of diphtheria. These specimens should be transmitted to the division of bacteriology for examination, and upon verification of the diagnosis the inspector should visit the physician reporting each case and request him to fully instruct his patient and the persons with whom he is brought in contact concerning the nature of the disease and the danger of its transmission."

Registration, however, is not, as yet, compulsory in New York, and while many support the recommendations, as made by DR. CYRUS EDSON, the Commissioner of the Board of Health, many of the older and more prominent physicians of that city look upon such an innovation with distrust. DR. EDSON reports an encouraging advance, nevertheless, in gaining the goodwill and confidence of the medical profession toward the measures which he and many others believe to be for the public good. The maintenance of a bacteriologic laboratory by the city has been of great assistance to physicians on the one hand in verifying to a certainty, in doubtful cases, or on the other hand in eliminating the diagnosis of suspected tuberculous disease. Not only are the reports of cases carefully guarded by the Board of Health in a confidential manner, but the relations of the inspectors of the Board to individual physicians who report cases are governed by strict professional courtesy, and no bad results are said to come from the report of a case of tuberculosis.

The services of the New York bacteriologic laboratory can be had by any physician who, on reporting a case of pulmonary tuberculosis, forwards with his

report a small amount of sputum from the suspected case. Physicians are informed, through the agency of the medical press and circulars of information from the Board of Health, of the depots at which they can obtain, free of expense, "culture-tubes," in which the suspected matter is placed, and which have to be returned to the depots properly labelled. The collectors make the rounds of the depots daily, collecting the tubes charged during the preceding twenty-four hours, and which have been returned to the depots for collection. The charged tubes are taken to the bacteriologic laboratory, and are examined for the tubercle-bacillus, and a report is forwarded to the physician in charge of the case, informing him of the facts.

As soon as a case is diagnosticated as tuberculous an inspector visits the house and leaves circulars of information, which are concise and which direct the patient and those in contact with him how to avoid the danger of transmitting or acquiring the disease. On the death of a case the premises are disinfected, and are not permitted to be used by any new family, should the family remove, until the rooms have been thoroughly renovated by scrubbing, painting, or kalsomining. This is obligatory on the owner or lessee of the premises, and is enforced through the order of the Board of Health.

It is well known that tuberculous patients are not panicky; they are almost always hopeful and willing to co-operate by trying to carry out reasonable means for the protection of others; but to prevent antagonism too much should not be attempted at first, or the entire system will be likely to miscarry.

The motto of every Board of Health should be: *Innocenter*, *Patienter*, *Constanter*. People, the physician, no less than the laity, must be educated. More societies for the prevention of tuberculosis should be organized, and the great truths as to the nature and prevention of the disease should be judiciously and widely disseminated. We want a medical propaganda with earnest, active members, but yet as wise as serpents and as harmless as doves. No foolish antagonism and sweeping laws should be permitted. Let the system be advisory at first, and later on, if medical sentiment and public sentiment approve, put it upon the statute-book. Organize and maintain special hospitals and cottage-sanitaria for tuberculosis. Find out the localities where medical measures will receive the greatest aid from natural resources of air and sunlight. Make it easy, if we can, to take these afflicted beings out of cities to brighter skies and evergreen forests, where Nature and art, hand-in-hand, may work together for their good, and, it may be, for their final cure.

EDITORIAL COMMENTS.

The External Use of Guaiacol as an Antipyretic.—Excessive zeal and indiscriminate employment too often result in obscuring or aborting the usefulness of newly advocated therapeutic measures. This has been the history of antipyrin and other coal-tar products of recent origin; and it will be conceded that tuberculin has at least great diagnostic if not some therapeutic utility. Although mercury intelligently employed acts with almost specific effect in the treatment of syphilis, its misdirected use may result in fatal intoxication. Again, it will not be denied that when indicated, bleeding subserves a purpose not to be fulfilled by any other therapeutic measure, but its indiscriminate application cannot be too severely condemned as baneful. While quinin has cured innumerable cases of malaria, there can be little doubt that some cases of hematuria, and perhaps some deaths, are attributable to cinchonism. Drugs must thus be looked upon as two-edged swords, equally capable of evil as well as good. Thus the recent reports of the results obtained from the topical employment of guaiacol in the reduction of the temperature of pulmonary tuberculosis have oscillated between extremes, the one showing desirable the other undesirable effects. An intelligent conclusion in such a doubtful matter is only to be arrived at by the long-continued and patient observations of careful investigators, of keen discernment and conservative judgment. Probably the first record in the United States of the endermatic employment of guaiacol in the reduction of the high temperature of pulmonary tuberculous was made by J. Solis-Cohen (see The News, Sept. 30, 1893, p. 380). Other reports of an allied nature were made in The News by Da Costa (Jan. 29, 1894, p. 85), and by Thayer (March 31, 1894, p. 343). Cohen (*Fort Wayne Medical Journal*, vol. ii, No. 11, p. 348) has continued his observations, and is now able to report a series of thirty cases of tuberculosis in which the theraputic measure here considered was employed with satisfactory results. The applications were only made when the temperature rose above 102°.

The skin is first washed with soap and water at the seat of application and then dried thoroughly. From 10 to 25 minims or more of guaiacol are poured into a vessel and brushed upon the skin with a camel's-hair pencil, which is to be rubbed upon the parts again and again until the whole dose has been absorbed. This procedure will occupy ten or fifteen minutes, and sometimes more. The part treated can be rubbed dry with the hand. It is covered with a layer of cotton and paraffin paper or oiled silk. In many cases the temperature will drop a degree or two before the rubbing has been completed, and a drop of 2° is quite frequent within thirty minutes of commencing the application. Free perspiration is a good indication of the satisfactory effect of the remedy, and should be encouraged by the use of a hot drink, preferably milk, and the application of a hot-water bag. Should the decline of temperature be too great a little artificial heat will prove grateful.

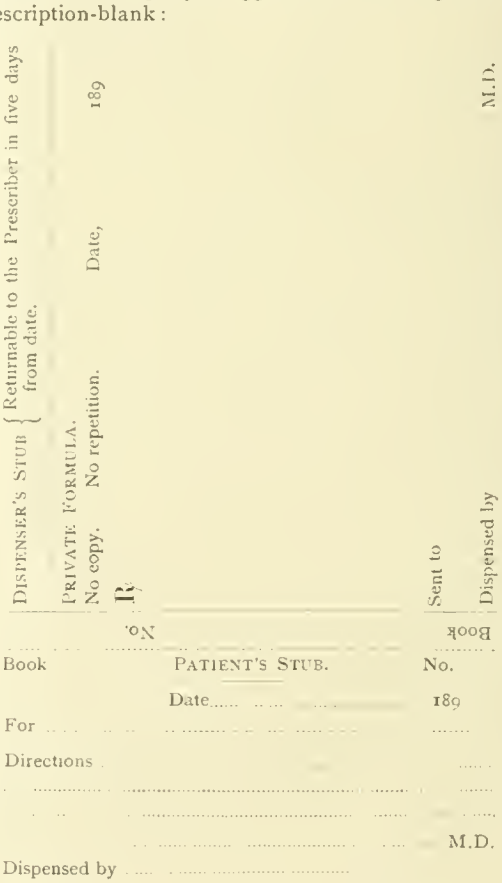
Indirect Injury to Health from Foot-ball.—A physician whose deserved fame is known of all medical men, and whose credibility is beyond suspicion, informs us that a number of foot-ball players on one of our college-teams were brought to him suffering from very decided gastric disturbances. The young men were always healthy until these symptoms developed, and they only developed after the players went under training. It seems that they were kept upon a most rigid diet, which was evidently regulated in violation of all principles of ordinary hygiene, by a trainer who did not even consult a physician or a physiologist, in spite of the fact that in the faculty of the college to which this crowd belongs he could have had the best of advice. The chief constituents of the diet appear to have been very thoroughly cooked beefsteak, eggs, and as a fluid, cold tea; water was rigidly excluded, in spite of the fact that these boys necessarily perspired very freely. As a natural result, after about six weeks the entire crowd was completely upset in its digestion, and although this appeared to be a matter of complete indifference to the trainer, the fact that these boys could no longer play with any degree of spirit or with any strength and persistence awakened him at last to the idea that something was wrong. The most interesting fact in this history was that each of these men maintained that the change in weight during a game of foot-ball was very marked. One man, who weighed 200 pounds, lost eight pounds of weight in about two hours, during the last game; a second man, who weighed 165 pounds, lost five pounds during the last game; a third, who weighed 160 pounds, and was the best of the three in point of digestion, lost three pounds during the last game. These men are accurately weighed before and after playing; they have no object or desire in misrepresenting, and their statement has been amply confirmed by outside sources.

"Now, it seems to me that any sport which involves expenditure of vital energy sufficient to compensate in two or three days for a loss of from three to eight pounds weight in two hours is injurious. It must call for an activity in the chemistry of the body which puts that body upon an awful strain. I do not wonder that these three young men are suffering, not only in their digestive system, but also in their nervous system; and it seems to me that such a method of training and of exercise is destined to permanently impair their health."

Such a statement by an intelligent and impartial observer and an advocate of the college spirit is certainly beyond comment, and is deserving of respectful consideration of even the ardent supporters of foot-ball.

The Influence of Massage upon the Body-Metabolism.—Intelligent massage has a potency not yet fully and generally appreciated or understood. The observations of Dr. J. K. Mitchell, recently recorded (see THE MEDICAL NEWS, December 23, 1893, p. 715; and the *American Journal of the Medical Sciences*, May, 1894, p. 502), show beautifully the marked changes that may be brought about in the globular richness of the blood by well-directed manipulation. One would *à priori* be led to believe that such a form of exercise would be attended with metabolic changes, the evidences of which are to be looked for in the excreta. This deduction is confirmed by the results of an investigation by BENDIX (*Zeitschr. für klin. Med.*, Bd. xxv, Heft 3 u. 4; *Centralbl. f. innere Medicin*, 1894, No. 40, p. 944), who has found that general massage of healthy individuals constantly induces an increase in the daily amount of urine and of the excretion of nitrogenous matter in the urine. The increase occurs on the first or second day of the manipulations, rising slightly on the following days, finally reaching a level that is preserved throughout the period of observation. Upon cessation of the manipulations the curve does not fall suddenly, but in the course of from two to five days. When the manipulations are intermitted for a considerable time, one or two days usually elapse after its renewal before its effects are again observable. It is believed that as a result of the massage more water is sent to the kidneys through the blood, and that urinary secretion is still further stimulated by substances expressed from the muscles. The increased elimination of nitrogenous matters is ascribed to the acceleration of the circulation. It was also found that the manipulations were attended with a diminished presence of fat in the intestinal evacuations, together with an increased elimination of nitrogenous matters.

A Non-repeating Prescription-blank.—With a view to prevent the unauthorized and indiscriminate renewal of prescriptions, G. R. Shimmel in the *Bulletin of Pharmacy*, vol. viii, No. 10, p. 457, suggests the following form of prescription-blank:



Prescription and stub are sent to the pharmacist, who affixes the stub to the bottle or box and after five days returns the prescription to the writer. The druggist is

of course at liberty to make copies of such prescriptions as he may select for self-protection or other legitimate purposes, but all applications for renewal or copy on the part of patients are to be referred to the physician. The proposition seems reasonable and practicable, and its general adoption would do much to encourage and strengthen the cordial and confidential relations that should exist between doctor and druggist.

Atrocious Villainy.—The appalling corruption and degradation of the New York City government has seemed to reach its lowest depth during each day of the entire investigation of the Lexow Committee. But it is now impossible to imagine anything worse than was revealed last week, when it was shown that there has been a systematized official plundering and protection of criminal abortionists. Such a thing has never entered into the thought of the most pessimistic vilifier of human nature. That men whose duty it has been to protect society from the most depraved of human beings and callings should deliberately organize themselves to protect the villains, and by protecting extort from them unknown amounts of money (one man paying $2825 within six weeks)—all this surpasses belief, and makes us shudder to think of the modern degradation of human beings. The wise physician finds something better to do than to "meddle with politics;" but when "politics" means the debauching of his profession and the brutal traffic in human health and human beings, then it is time for him to make his influence felt. It was stated that in New York there are two-hundred of these professional abortionists. We trust not so many, but it is only too true that in every large city criminal abortion is carried on to much larger extent than any one individual can know; and when we hear nothing about it, when all goes on smoothly and silently, when no cases are brought to view and to trial, then and there, probably, is the fiendish trade most rampant.

A Biologic Laboratory for the Philadelphia Board of Health.—At a recent meeting of the Philadelphia Board of Health the Sanitary Committee presented a report recommending the establishment of a Biologic Laboratory and the engagement of a competent bacteriologist and such assistants as may be required for the purpose of conducting investigations of contagious diseases, and facilitating diagnosis, of investigating water-supplies and food-supplies, and of indicating and, as far as possible, providing the appropriate remedial measures. The board already possesses a complete outfit for general bacteriologic investigation, and the Building Commission has placed a sufficient amount of room at the disposal of the board. City Councils are now asked to make an appropriation of $15,000 for the purposes of organizing a Division of Bacteriology and Disinfection, engaging the necessary experts, purchasing additional apparatus, and for incidental expenses. The project should receive universal endorsement, and as little time as possible should be lost in putting it into execution. The work of the Division of Pathology and Bacteriology of the New York Board of Health affords convincing evidence of the sanitary good that can be effected by rigorous and intelligent application of the principles deducible from existing knowledge of the causes and prevention of disease. Philadelphia should not be a tardy second in emulating the good example set by the great metropolis.

The Temperance Reform League of Massachusetts and the Keeley Cure.—Dr. B. D. Evans, the Medical Director of the New Jersey State Hospital for the Insane, has been admitted to membership in the Temperence Reform League of Massachusetts. This ends a battle between Dr. Evans and the Keeley cure, as far as Massachutetts can decide it, with victory in favor of the former. Dr. Evans, it will be remembered, gathered statistics from insane asylums over the United States and among the one-thousand insane patients in the hospital of which he has charge, compiling valuable and detailed "tables of cases of relapse, suicide, mania, and dementia subsequent to the graduation at the Keeley Institute." His article, which was published in The Medical News of May 6, 1893, was reprinted in Boston papers, and his report was laid before the Temperance Reform League. It was bitterly denounced by the "Keeley Cure," which applied to the Temperance Reform League for an examination, for this organization by its charter from the State is a quasi-court, whose functions are those of a judge who examines conflicting medical evidence in a suit for malpractice and announces the result. The end of the trial has been reached, and Dr. Evans is honorably welcomed into the society, and thanked for his services in exposing pseudo-reform, while the Keeley offices in Boston have been abandoned.

The Optician's Impudence.—We wish to call the attention of those ophthalmalogists who have contended that the treatment of refractive errors is a matter of non-mydriatic mechanics and optics to the use that the optician is making of their absurd contention. Supported by the authority of such physicians the commercial optician is demanding and convincing the public of this dangerous error. He is reproducing their words in flaming advertisements, gathering and reporting his cases just as a physician does, and talks glibly of reflex diseases of the eyes cured by his great skill, and of ophthalmometers, phorometers, etc., and of the absurdity of the use of belladonna. He cures all cases of squint, of muscular as well as refractive errors, by his wonderful glasses. In the same circular he promises "strict co-operation" with the general physician, and appeals to him to send patients to the great optician, and thus utterly abolish the ophthalmalogic physician. It is a fine scheme, but it has already failed more than once, and especially must it fail when the optician-long-ears quotes the neurologist *ad nauseam* that "*the oculist fails if he is only an oculist,*" leaving the stupidest suggested query unanswered, "But if he be only an optician must he not more certainly fail?"

Bacteriology of Baked Bread.—In a recent issue of *The Lancet*, Messrs. Waldo and Walsh give the results of an investigation to determine to what extent baking destroys the vitality of the microbes of dough. They succeeded in cultivating thirteen different species from a portion taken out of the center of recently baked loaves. These facts may seem at first to be of little value, but it is shown that bread may be an active distributer of con-

tagion. Dr. Waldo, who is medical officer of one of the London districts, gives a startling account of the filthy and insanitary condition of some of the bakeries. Many are located in cellars. These insanitary conditions affect both the producers and consumers. It is stated that journeymen bakers as a class are shortlived. It has been generally supposed that even if dough should become infected, it will be rendered sterile by the baking, but this is now shown to be erroneous. The fact is that bread-manufacture should be conducted entirely on a large scale by the aid of machinery, so that the materials shall not be touched by human hands throughout the process. This is now perfectly feasible. The subject of the conveyance of infection by food other than by milk merits further study.

Honor to Whom Due.—It was a generous impulse that prompted Prof. Roux, of Paris, when complimented and praised for his labors in connection with the preparation of the antitoxin of diphtheria, and its successful clinical employment, to modestly disclaim the credit for the discovery of this promising and powerful therapeutic agent, and to yield priority to his German confrères, and more particularly to Prof. Behring, of Berlin, whose method Roux frankly admitted he had followed. How much more admirable this than the unseemly contests for "priority" with which the world has from time to time been edified in connection with so-called discoveries in medicine. Great as is the credit and the honor that must be conceded to Koch's pupils for their great work in the domain of biologic therapeutics, a full share belongs also to their French colleagues, the pupils of Pasteur, and a special obligation is owing to Prof. Roux for his frankness and truthfulness, especially on an occasion on which the reverse was more than tempting.

Edible Mushrooms.—The last annual report of the Division of Microscopy, U. S. Department of Agriculture, gives some finely executed plates of edible mushrooms. Five species are figured. The food-value of mushrooms has been rather overrated; although containing much nitrogen, they are not easily digestible. In view of the poisonous action of many species, it is an advantage to have correct and vivid representations of the safe forms.

REVIEWS.

Laboratory Manual of Elementary Chemical Physiology and Urine Analysis. By J. H. Long, M.D., Sc.D., Professor of Chemistry in the School of Medicine and Pharmacy of Northwestern University. Small 8vo, pp. 360, and Index. Chicago: E. H. Colegrove & Co.

This is a departure in some respects from the type of laboratory manuals. It associates physiology and chemistry more intimately than is usual in such works. It covers the work done in the second year's course in the medical school with which the author is connected. We note in the preface, with much satisfaction, that Dr. Long favors the plan of making chemistry a requirement of entrance to medical study, and thus relieving the college proper of the duty of teaching. We fear he is right in saying that this consummation is far in the future, but it is surely one devoutly to be wished. It will be a happy day for medical colleges when they can devote themselves to giving instruction in actual medical and surgical work, and not be burdened with lectures, laboratory instruction, and quizzes on accessory sciences.

The work begins with a consideration of the methods employed in physiologic chemistry, interspersed with experiments illustrating these methods. The definition of normal solution given on p. 9 is likely to be confusing to students. The formal definition given in the first part of the paragraph should not have been inserted, since it is mentioned only to be practically set aside a few lines below. We feel also obliged to say that unless Dr. Long's pupils are more apt at mathematics than is usual in colleges of pharmacy and medicine, they will find some difficulty with the explanations in specific gravity.

A valuable feature of the book is the explanations of polarization methods. Rotary actions are so frequently mentioned in the teaching of physiology and organic chemistry that it is necessary to discuss the subject somewhat, and unless it is carefully explained students are likely to confound rotation with refraction. Fifteen pages are devoted to the theory of polarization and descriptions of polarimeters, the details being illustrated with cuts, all of which are superior to those in other parts of the book. It is interesting to reflect as to what is to become of our standard methods of explaining polarization if the opposition to the undulatory theory of light, now so vigorously led by Ostwald, should be successful.

We regard the manual as excellently adapted for medical colleges.

The Science of Vital Force. Its Plan, Division of Function, and Operative Methods in Health and Disease. An Involuntary Agency of Nature that can be Harnessed and Utilized. By W. R. Dunham, M.D., author of the *Higher Medical Culture*. 12mo, pp. 198 Boston: Damrell & Upham, 1894.

In reading this tilt against the theories and established facts of modern biologic science, one is reminded of the assurance and result with which Sir Uwaine is described as having undertaken to unhorse Sir Launcelot. "And there with al syre Uwaine gate his spere in his hand and rode toward syre Launcelot, and syre Launcelot knew him wel, and so he mette him on the playne and gafe him such a buffette that he was astonyed, that long he wyst not where he was."

In the present encounter the would-be scientific knight evidently "wyst not where he was" before he began, and when the gentle critic turns down the last page he is again reminded of an amusing incident charmingly recorded in Christopher North's *Noctes Ambrosianæ* (xxv). On the occasion referred to, the Ettrick Shepherd got "rattled" during a discussion upon commerce and credit with Christopher North, Mr. Tickler and the English opium-eater, and in the following wise:

Mr. De Quincey had secretly fed a box of opium-pills, by way of experiment, to a young Newfoundland dog that North had just introduced to their notice. The dog got crazed with the opium and cut up a number of

pranks in the which a swarm of bees got loose and stung the opium-eater, Mr. Tickler and the Shepherd; the latter two quite badly, for their swollen faces required leeches and lotions. After the basins and towels and such like had been removed the following colloquy ensued:

Shepherd: "Hoo's my face noo?"

North: "Quite captivating, James. That dim discoloration sets off the brilliancy of your eyes to great advantage, and I am not sure if the bridge of your nose as it now stands is not an improvement."

Shepherd: "Weel, weel, le's say nae mair aboot it."

"That's richt, Mr. Tickler, to hang your silk handkerchief ower your face, like a nun taking the veil; where were we at?"

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. Designed for the use of Students and Practitioners of Medicine. By AUSTIN FLINT, M.D., LL.D., Late Professor of the Principles and Practice of Medicine, and of Clinical Medicine in Bellevue Hospital Medical College, N. Y. Seventh edition, thoroughly revised by FREDERICK P. HENRY, M.D., Professor of the Principles and Practice of Medicine in the Woman's Medical College of Pennsylvania, Philadelphia. Pp. 1143. Philadelphia: Lea Brothers & Co., 1894.

DR. HENRY is to be congratulated on the success with which he has accomplished the revision of Flint's classic *Practice*. The task of revising the work of another after the lapse of a period of eight years is not a light one, but in this instance it has been performed with a skill and a delicacy that command admiration and disarm criticism. Of the original work there is naught to say; this has attained a high place in American medical literature; while the additions and alterations are characterized by a care and thoroughness for which the reviser has earned a deserved reputation. The most important change in the present edition is the omission of the section on general pathology, as finding a more appropriate place in special works devoted to the subject. Many new articles (upward of twenty) have been incorporated in the text, and throughout the work may be found such annotations of the reviser as the progress of time has necessitated. The section devoted to the consideration of the functional disorders of the stomach, together with modern methods of study of the gastric functions for diagnostic purposes, has been brought up to date and constitutes a terse and clear delineation of the present aspect of this intricate and not yet finally elaborated subject. The editor states that he entered upon the task of revision with a feeling of reverence for the memory of the distinguished author of the original, and that "if he has erred, it has been in the direction of conservatism." We can only add that he has performed his task well and thereby served to insure for Flint's *Practice* a continuance of the popularity it has so long deservedly enjoyed.

ON DOUBLE CONSCIOUSNESS. By ALFRED BINET. The Religion of Science Library. The Open Court Publishing Company. Chicago: 1894.

THE author of this little book belongs to the so-called most advanced school of French psychologists. The book is very interesting, but one cannot help feeling that if the writer had more skepticism the reader would need less. It would appear, for instance, to the ordinary thinker, that an apparently anesthetic hand which wrote when a pencil was put in it was not really anesthetic; rather than that, the person holding the pencil had a second consciousness of which he was not conscious. The explanation of many curious phenomena by reflex action and automatism receives scant attention. Truly there is much paradox in advanced psychology, and much faith in the childlike innocence and truthfulness of hysterics.

A MANUAL OF HUMAN PHYSIOLOGY; PREPARED WITH SPECIAL REFERENCE TO STUDENTS OF MEDICINE. By JOSEPH H. RAYMOND, Professor of Physiology and Hygiene at the Long Island College Hospital, and Director of Physiology in the Hoagland Laboratory; with 102 illustrations in the text and 4 full-page colored plates. 8vo, pp. 382. Philadelphia: W. B. Saunders.

THE conciseness and lucidity with which the subject is handled by Prof. Raymond in his excellent little manual challenge admiration, and, if calling forth criticism at all, it is not so much with the book as with the fact that our medical schools allot so brief a time to the study of physiology, "that the students can assimilate only the main facts and principles of this branch of medicine, which lies at the very foundation of a sound knowledge of the healing art," and which therefore necessitates the use of books which give no insight into the historic development of physiologic science, or any knowledge of the methods which have served to establish the aforesaid "main facts and principles." Physiology is preëminently an experimental science, and the student cannot afford to content himself with the mere memorization of facts and principles, but must make himself familiar by laboratory-experiment and the study of thorough-going treatises dealing with the development of this fundamental department of medical science. This little volume is, however, one of the best of its kind, quite up to date, and will be found valuable to all who are so unfortunate as to be limited in time.

THE JEWISH METHOD OF SLAUGHTER COMPARED WITH OTHER METHODS, FROM THE HUMANITARIAN, HYGIENIC, AND ECONOMIC POINTS OF VIEW. By J. A. DEMBO, M.D. Translated from the German, with the author's amendments. Published by the Trustees of the late J. A. Franklin. 8vo, pp. 14. London: Kegan Paul, Trench, Trübner & Co., Lt.

THIS work grew out of an agitation against the Jewish method of slaughter, the opposition being in the main from some of the European societies for the prevention of cruelty to animals. It is probable that the anti-Semitic element in many places took up the cry, not from any sympathy with the slaughtered animals, but for the purpose of annoying Jewish fellow-citizens. Dr. Dembo goes into the question thoroughly, discussing all the methods of slaughter from anatomic and physiologic standpoints. He has also investigated the influence of the various methods on the palatability and keeping qualities of the meat. The text has a strong flavor of

controversy. It is evident that much feeling has been engendered by the dispute.

The work defends unreservedly the Jewish method as the most humane and certain, and the one producing the most wholesome meat. In a few lines given to slaughter by electricity the inference is suggested that this method for execution of criminals has failed in the United States. The translation is well done.

The Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. Abbott, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. New second edition. 12mo, 472 pages. Illustrated. Philadelphia: Lea Brothers & Co., 1894.

This excellent manual needs no introduction to students of bacteriology, who will welcome a new edition in which the text has been doubled and elucidated by means of many additional illustrations. The colored illustrations, of which there are seventeen, are a new feature, and like the differentiated or counterstained preparations they represent, several of them afford very pretty and instructive pictures of bacteria in tissues.

While the arrangement and purpose of the earlier edition have been maintained, the descriptive portion of the work has been extended, and a new and valuable chapter has been introduced, entitled "Infection and Immunity," in which the author defines clearly and concisely the types of infection, and gives a chronologic *résumé* of experimental research bearing upon the nature of immunity, concluding with a summary of our knowledge of these conditions at the present time.

A list of apparatus and materials necessary to equip a bacteriologic laboratory appear in an appendix, and will be helpful to the beginner.

NEWS ITEMS.

The Mississippi Valley Medical Association will hold its twentieth annual meeting in Hot Springs, Ark., November 20, 21, 22, and 23, 1894. The following program is announced:

Cases of Traumatic Cataract in Children Treated by Extraction, by James M. Ball, St. Louis; Toxics, by W. F. Barclay, Pittsburg; The Philosophy of Stimulants, by A. D. Barr, Calamine, Ark.; Squint, with Special Reference to an Operation, by Charles H. Beard, Chicago; Conservative Surgery, and What it Means at the Present Time, by A. C. Bernays, St. Louis; The Deeper Inflammations of the Skin, by A. W. Brayton, Indianapolis; Intestinal Indigestion, by A. P. Buchman, Fort Wayne, Ind.; The Medical Expert Witness, by Robert M. Campbell, Esq., Ashland, O.; Some Observations on "Sore-throat" Due to Concretions in the Tonsils, by L. C. Cline, Indianapolis; The Differential Diagnosis of Coma, by W. J. Conklin, Dayton, O.; Constipation, by George J. Cook, Indianapolis; Syphilis, and Its Relation to Other Affections, Especially those of the Skin, by William T. Corlett, Cleveland; Surgical Treatment of Uterine Fibroids; Disposal of the Pedicle, by A. H. Cordier, Kansas City, Mo.; Stab-Wound of Pericardium; Resection of Rib; Suture of Pericardium; Recovery, by H. C. Dalton, St. Louis; Surgical Treatment of Trachoma, by Davis A. Dean, Pittsburg; Possibilities of Medicine, by J. O. DeCourcy, St. Libory, Ill.; Some New Instruments and Means of Physical Diagnosis, by Charles A. Denison, Denver, Col.; subject unannounced, Arch Dixon, Henderson, Ky.; Quinin in Chorea, by Frank R. Fry, St. Louis; A Few Remarks on the Early History of Rectal Diseases, by S. G. Grant, Kansas City, Mo.; Report of a Case of Trephining for Cerebral Clot, with Loss of Vision, Recovery, by John B. Hamilton, Chicago; Diseases of the Accessory Nasal Cavities; Their Influence Upon the Organs of Sight; Modern Surgical Treatment, with Report of Cases, by C. R. Holmes, Cincinnati; Spot Specialism, by C. H. Hughes, St. Louis; The Management and Treatment of Endometritis, and the Prevention of Tubal and Ovarian Diseases, by W. H. Humiston, Cleveland; Functional Stenosis; Its Relation to Malformations, Dislocations, and Flexions; and Conditions Characterized by Amenorrhea, Dysmenorrhea, and Hyperemias; with a Scientific Rationale in Therapeutics, by George F. Hulbert, St. Louis; subject unannounced, W. S. Kerr, Mansfield, O.; subject unannounced, W. E. Kiely, Cincinnati; The Neatest Method of Circumcising, by Bransford Lewis, St. Louis; Colles' Fracture, by J. E. Link, Terre Haute, Ind.; Double Nasal Atresia, due to Smallpox, by H. W. Loeb, St. Louis; Tubercular Meningitis, by I. N. Love, St. Louis; Physicians' Prescriptions, by Starling Love, Columbus, O.; Traumatic Lesions of Cranium and Brain; Report of Clinical Cases, by Geo. N. Lowe, Randall, Kan.; Observations on Residual Urine and Remarks on Perineal Section, by G. Frank Lydston, Chicago; Modern Surgical Technique, by Henry O. Marcy, Boston; subject unannounced, Heine Marks, St. Louis; Tumors of the Neck, by Donald Mclean, Detroit: Advantages and Disadvantages of Kraske's Operations, by Joseph M. Mathews, Louisville; Resection of the Knee for Separation of the Lower Epiphysis of the Femur; Case of Two Years' Standing in a Patient Thirteen Years of Age, by A. H. Meisenbach, St. Louis; Accidents and Injuries from Electric Currents of High Potential, by Harold N. Moyer, Chicago; The Mental Symptoms of Cerebral Syphilis: A Clinical Study, by Frank P. Norbury, Jacksonville, Ill.; Enlarged Tonsils and Their Treatment, by John North, Toledo, O.; My Experience With Cold as a Therapeutic Agent, by A. M. Owen, Evansville, Ind.; The Surgical Treatment of Injuries of the Head, by Charles B. Parker, Cleveland; Headache, by Curran Pope, Louisville; Address on Surgery, by Joseph Ransohof, Cincinnati; Syphilis, by A. Ravogli, Cincinnati; Reform in the Management of the Insane and the Neurotic Viewed from a Gynecological Standpoint, by Charles A. L. Reed, Cincinnati; Retinitis Syphilitica, by Dudley S. Reynolds, Louisville; The Spine and the Elevator, by B. Merrill Ricketts, Cincinnati; Infantile Paralysis, by John Ridlon, Chicago; President's Address, X. C. Scott, Cleveland; Epilepsy, by C. E. Smith, Waco, Tex.; Climate and Tuberculosis, by S. E. Solly, Colorado Springs, Col.; Toxicity in the Production of Nervous Diseases, by Albert E. Sterne, Indianapolis; Constipation from a Surgical Standpoint, by Leon Straus, St. Louis; Laparotomy for Pelvic Diseases no Longer Necessary, by R. Stansbury Sutton, Pittsburg; Medication of the Air-Passages by a New Atomizing Vapor-

izer; With Experiments on Animals, by Homer M. Thomas, Chicago; The Importance of Urinalysis in Diagnosis, by A. B. Walker, Canton, O.; Reflex Irritation as a Cause of Nervous Diseases, by Edwin Walker, Evansville, Ind.; subject unannounced, H. O. Walker, Detroit; Hydrocele, by W. C. Weber, Cleveland; Address on Medicine, by J. T. Whittaker, Cincinnati; Tumor Albus of the Knee-Joint, by William E. Wirt, Cleveland; Influence of Inflammation of the Seminal Vesicles in Maintaining Gleet, by W. N. Wishard, Indianapolis; Modern Antiseptic and Aseptic Midwifery in Private Practice, by E. Gustave Zinke, Cincinnati.

The Southern Surgical and Gynecological Association will hold its Seventh Annual Meeting at Charleston, S. C., on November 13, 14, and 15, 1894. The following program has been arranged: Address of Welcome and Response; Memorial Address on Dr. Warren Stone, by A. B. Miles, M. D., New Orleans, La.; Operation for Complete Perineal Laceration, by Jos. Price, M.D., Philadelphia, Pa.; Gonorrhea in Women, by J. B. S. Holmes, M.D., Atlanta, Ga.; Some Cases of Intestinal Obstruction, with Deductions Therefrom, by A. M. Cartledge, M.D., Louisville, Ky.; Hernia of the Diaphragm, with Report of a Case, by Floyd W. McRae, M.D., Atlanta, Ga.; The Treatment of Sinuses Following Celiotomy, by W. H. Wathen, M.D., Louisville, Ky.; The Diagnosis and Treatment of Congenital Cystic Hygroma, by J. A. Goggans, M.D., Alexander City, Ala.; Some Complicated Cases of Abdominal Surgery, by J. G. Earnest, M.D., Atlanta, Ga.; Early Operation in Appendicitis, with a Case, by J. McF. Gaston, M.D., Atlanta, Ga.; Appendicitis, by W. B. Rogers, M.D., Memphis, Tenn.; Attention to Women Before and After Labor, by W. G. Bogart, M.D., Chattanooga, Tenn.; Plastic Operations for Carcinoma of the Breast, by J. T. Wilson, M. D., Sherman, Texas; Gunshot Wound of Spleen, Hemostasis by Deep Suture, Recovery, by L. McLane Tiffany, M.D., Baltimore, Md.; Technique of Vesical Drainage, by G. Frank Lydston, M.D., Chicago, Ill.; Successful Treatment of Case of Nevus by Electricity, with Remarks, by William Perrin Nicolson, M.D., Atlanta, Ga.; The Use of Electricity in Late Syphilis, by Lewis Wheat, M.D., Richmond, Va.; Observations on the Action of Chloroform on the Functions of the Human Brain and Spinal Cord, as Witnessed in Extensive Injuries of the Cranium and Brain, by Bedford Brown, M.D., Alexandria, Va.; Treatment of Abscess of the Liver, by J. D. S. Davis, M.D., Birmingham, Ala.; Puerperal Peritonitis, by V. O. Hardon, M.D., Atlanta, Ga.; Treatment of Peritonitis, by Richard Douglas, M.D., Nashville, Tenn.; Movable Kidney, by Geo. Ben Johnston, M.D., Richmond, Va.; History of Vaginal Extirpation of the Uterus, by Geo. J. Engelmann, M.D., St. Louis, Mo.; The Present Status of Gall-Bladder Surgery, by A. Vander Veer, M.D., Albany, N. Y.; Gynecological Surgery Away From the Large Cities and Educational Centers, by W. L. Robinson, M.D., Danville, Va.; Reminiscences of Dr. J. Marion Sims in Paris, by Edmond Souchon, M.D., New Orleans, La.; President's Address, by C. Kollock, M. D., Cheraw, S. C.; Transfusion in the Treatment of Acute Hemorrhage, by T. J. Crofford, M.D., Memphis, Tenn.; A Case of Vaginal Hysterectomy for Carcinoma of the Uterus, Three Days After Parturition, by Geo. H. Noble, M.D., Atlanta, Ga.; The Simultaneous Appearance of Cancer in the Breast and Uterus, by James Evans, M.D., Florence, S. C.; Something About the Final Condition of the Mouths in Gastro-enterostomies, with Specimens, by H. Tuholske, M.D., St. Louis, Mo.; Puzzling Point in Labor, by Geo. R. Dean, M.D., Spartanburg, S. C.; Suprapubic Cystotomy Compared with Perineal Operations, by C. H. Mastin, M.D., Mobile, Ala.; Tracheotomy for Foreign Bodies in the Air-Passages, by W. F. Westmoreland, M.D., Atlanta, Ga.; Ligation in Continuity, with Report of Case 1. Ligation of the External and Internal Carotid Arteries and Internal Jugular Vein. Case 2. Ligation of the External Carotid Artery, by Jno. A. Wyeth, M.D., New York; The Placenta: When and How Delivered, by J. B. Murfree, M.D., Murfreesboro, Tenn.; Report of Cases of Varicocele Treated by the Open Method and Shortening of the Scrotum, by W. E. Parker, M.D., New Orleans, La.; Treatment of Cystitis in the Female, by Hunter McGuire, M.D., Richmond, Va.; Hydro-pyonephrosis—Successful Removal of a 40-pound Tumor of the Kidney, by Jos. Taber Johnson, M.D., Washington, D. C.; The Value of Plastic Work in Intra-peritoneal Operations, by J. W. Long, M.D., Richmond, Va.; Fibroid Tumor of the Uterus, with Suppurating Ovary Discharging per Rectum, by Rufus B. Hall, M.D., Cincinnati, Ohio; Technique of Operations on the Pregnant Uterus, by W. D. Haggard, M.D., Nashville, Tenn.; The Relation of Uterine and Ovarian Disease to Insanity, by L. S. McMurtry, M.D., Louisville, Ky.; Surgery of the Ureters, by Howard A. Kelly, M.D., Baltimore, Md.; Ideal Operation for Varicocele, by G. Frank Lydston, M.D., Chicago, Ill.; The Value of Coccygeal and Sacral Resection in the Treatment of Congenital Occlusion of the Rectum, by Rudolph Matas, M.D., New Orleans, La.; The Surgical Treatment of Spina Bifida, with an Illustrative Case, by H. O. Marcy, M.D., Boston, Mass.; Ligation of the Uterine Arteries in the Treatment of Chronic Metritis, by W. E. B. Davis, M.D., Birmingham, Ala.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1895, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College, Dr. C. W. Dulles, on or before May 1, 1895.

Each essay must be sent without signature, but must be plainly marked with a motto, and be accompanied by a sealed envelope having on its outside the motto of the paper, and within it the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

A Generous Gift to the University of Pennsylvania.—Mr. and Mrs. H. H. Houston have given $100,000 to the fund for the erection of a students' hall at the University. In recognition of this gift the trustees have decided to name the hall after Howard Houston, son of the donors, who was a student in the University at the time of his death.

The Eastern Iowa District Medical Society will hold its twenty-third session at Keokuk, Iowa, November 15, 1894. All members of the medical profession are cordially invited to be present.

BOOKS AND PAMPHLETS RECEIVED.

Anomalies of Refraction and of the Muscles of the Eye. By Flavel B. Tiffany, M.D. Author's Edition. Kansas City, Mo.: Hudson-Kimberly Publishing Co., 1894.

The Eye Treatment of Epileptics. By Ambrose L. Ranney, A.M., M.D. Reprinted from the New York Medical Journal, 1894.

Ueber mucinartige Bestandteile der Neurofibrome und des Centralnervensystems. Von P. G. Unna. Sonder-Abdruck aus Monatshefte für praktische Dermatologie. 1894, Band xviii. Verlag von Leopold Voss, Hamburg u. Leipzig.

Hysterical Seizures Relieved by Hypnotic Suggestion. By Judson Daland, M.D. Reprinted from the University Medical Magazine, 1893.

The Diagnosis of Mitral Valvulitis, with a Report of Three Cases. By Judson Daland, M.D. Reprinted from the International Clinics, vol. iv, third series.

Saint Bartholomew's Hospital Reports. Edited by W. S. Church, M.D., and W. J. Walsham, F.R.C.S. Vol. XXIX. London: Smith, Elder & Co., 1893.

Three Years' Experience with the Electrical Treatment of Fibroid Tumors of the Uterus, with a Report of Forty-four Cases. By By W. L. Burrage, A.M., M.D. Reprinted from the American Journal of Obstetrics, 1894.

Breathing Exercises a Curative Measure for Consumption, with a New Theory Advanced as to the Etiology of that Disease. By Eugene L. Crutchfield, M.D. Reprinted from the Maryland Medical Journal, 1894.

A REVIEW OF SOME OF THE DISPUTED POINTS IN CONNECTION WITH DIPHTHERIA AND CONDITIONS WITH WHICH IT HAS BEEN CONFOUNDED.[1]

BY A. C. ABBOTT, M.D.,
OF PHILADELPHIA;
FIRST ASSISTANT LABORATORY OF HYGIENE, UNIVERSITY OF PENNSYLVANIA.

A RETROSPECTIVE view of the confusion of ideas that existed upon diphtheria prior to the discovery of its etiology illustrates how essential to a correct understanding of the manifold phases of a disease is a knowledge of its cause. From the time of Bretonneau to the date of the observations of Klebs and of Loeffler much valuable information was accumulated, but in the state of knowledge in existence at the time it could hardly be estimated at its true value.

It may be of profit to pass in review some of the more important features of the disease, and endeavor to learn in how far opinions expressed by the early observers have been supported or refuted by the results of later methods of investigation.

The first observations that attracted attention to the disease, diphtheria, as we know it, were made in 1826, by Bretonneau, of Tours, who endeavored to extricate from the chaotic mass of ideas existing at the time some definite conception of a malady that had hitherto been loosely classed with a group of gangrenous and necrotic conditions with which it had but little in common, either clinically, anatomically or etiologically. He suggested the use of the term "diphtheritis" for the disease, which was characterized by the presence of a skin-like pellicle upon the mucous membrane of the throat, for the reason that he considered this the feature by which it was distinguishable from all others with which it might be confounded. It may be mentioned at this point that in 1771, Samuel Bard, of New York, in a monograph entitled *An Inquiry into the Nature, Cause and Cure of the Angina Suffocativa, etc.*, gave a description of the clinical and anatomic manifestations of diphtheria that was quite comparable, in its essential details, with that subsequently given by Bretonneau.

Though Bretonneau's teachings constituted a step in the right direction, and did much to relieve the confused notions upon the malady, it was not long before objections were raised to the grounds taken by him. The teachings of Home, from 1765, to the effect that there existed a disease, designated as croup, and characterized by the formation of pseudo-membranes in the larynx, were revived, and there was thenceforth a division of opinion, some adhering to the teaching of Bretonneau, viz., that all the pseudo-membranous processes in the upper air-passages were identical, while others, with Home, believed in the existence of two distinct affections. With the hope of clearing away doubts and shedding some light upon the disputed point, the question was taken up by the pathologists, and through the labors of Virchow, Weigert, Cohnheim and their pupils, the two processes were subjected to histologic study. The outcome of this work was a classification based entirely upon anatomic grounds and a nomenclature that was used only in its anatomic sense. From this standpoint it was taught that there existed: 1st, a true croupous process, characterized by the deposition of a fibrinous pseudo-membrane upon the surface of the mucous membrane; 2d, that there existed a true diphtheria, similarly characterized by the local appearance of a fibrinous condition, which was not, however, confined to the surface of the mucous membrane, but extended into it; and 3d, that there existed a mixed anatomic condition known as diphtheric croup, in which there appeared both the superficial pseudo-membranous deposit and the involvement of the deeper underlying structures; this latter being the local condition commonly seen in true diphtheria. The entire process in all cases was seen to be a coagulation-necrosis, the direct effect of the causative irritant, a process characterized by a combination of cell-death and inflammation, the coagulation and fibrin-formation resulting from the contact between the inflammatory serous exudate and the fibrin-ferment supplied by the dead cells.

While this is the anatomic nature of the local process in diphtheria, and constitutes the condition known as diphtheric, it is, nevertheless, one that occurs as a result of the action of many irritating agents; and, while always present as the local manifestation of diphtheria, it is often seen in other parts of the body than the throat, and in conditions that are etiologically distinct from diphtheria.

It is easy to see, therefore, that the use of the

[1] Read at the meeting of the Pathological Society of Philadelphia, held Nov. 8, 1894.

terms diphtheric and croupous in their anatomic sense, regardless of the causes underlying them, may, and doubtless often does, give rise to confusion. Though of the utmost importance in elucidating the nature of the tissue-changes seen locally in laryngeal and pharyngeal pseudo membranous inflammations, these observations afforded but little aid to the clinician in recognizing the nature of the various exudates *intra vitam*. He was still obliged to rely, as hitherto, upon the symptoms and the naked-eye appearances of the exudations; and it was then, as now, the experience of every clinician that these features of the disease are far too variable to admit of a positive diagnosis in all cases.

The means afforded for the correct diagnosis of the nature of these conditions constitute the first and most important outcome of the discovery of the cause of diphtheria. With the demonstrations by Loeffler, that there existed in the diphtheric deposits in the throats of all persons sick of diphtheria a distinct species of microörganism that was not present in other anatomically similar exudates, that the organism could readily be recognized, isolated and cultivated, and that it possessed the power, when introduced into susceptible animals, of reproducing conditions anatomically identical with those occurring in man afflicted with the disease, grounds for confusion could no longer exist, and from that time the question has been not so much with regard to the anatomic character of the local pathologic changes as to the presence or absence of the specific causative factor. If this agent is present, diphtheria exists; if it is absent, then the local conditions and constitutional manifestations must be attributed to some other cause, and the disease is not diphtheria.

Thus it soon became manifest that the dispute over the relation between diphtheria and so-called membranous croup was to be incontestably settled. By the bacteriologic and histologic study of the latter condition it has been found to be due to the activities of the same microörganism that is concerned in the production of diphtheria, and to present fundamentally the same histologic conditions that are found in the diphtheric exudate. I am aware that there are still individuals who adhere to the opinion that true, specific, fibrinous laryngitis occasionally occurs spontaneously; but, unfortunately for this view, it is usually supported by clinical evidence alone, and has rarely, if ever, been formulated from the results of bacteriologic study of the cases.

Still another local process characterized by fibrinous exudation has been shown by bacteriologic analysis to be etiologically identical with diphtheria. I refer to the affection of the mucous membrane of the nostrils known as membranous rhinitis, a condition that receives but little attention because of the mildness of its clinical course, but which, nevertheless, depends for its existence upon the activities of the same organism that is concerned in producing diphtheria. Because of their apparently innocent nature these cases are not considered as menacing to the health of individuals with whom they come in contact, and are not, therefore, isolated or otherwise regarded as dangerous, and yet examples are not wanting to show that they are communicable from one person to another, and there is some evidence to prove that true diphtheria has been contracted from them.

Another important question upon which there has been a conspicuous divergence of opinion, and which was also answerable only through the light shed by modern methods of research, is as to the local or constitutional origin of diphtheria. The careful study of an enormous number of cases occurring in man, and produced experimentally in animals, has demonstrated that the disease is purely local in its origin, and that the pseudo-membranous processes in the throat, the secondary manifestations in the internal organs, and the clinical symptoms, are one and all the result of a soluble poison, produced by a microörganism that has its seat of primary invasion in the mucous membrane of the upper air-passages. It is important to note that the disease is not a septicemia, in the sense of being associated with a distribution throughout the body of the microörganisms causing it, but is strictly a toxemia primarily, though a septic condition may be engrafted upon the toxic one later in its course.

Even the tissues in the throat in which the diphtheria-bacilli are growing give evidence of the effect of the poison independently of the immediate presence of the bacteria by which it was produced. In sections through the pseudo-membranes one sees that the most superficial layers contain bacteria in large numbers, among which the bacillus diphtheriæ can easily be recognized by its peculiar morphology; beneath this one sees a feebly-stained layer rich in cells but containing little or no fibrin, and in this layer the Klebs-Loeffler bacillus is often the only organism present; and especially is this the case just above the still deeper densely-stained fibrin-layer. The layer next to the mucous membrane is rich in fibrin, but contains no bacilli, and as a rule, no bacilli are found in the underiying necrotic mucous membrane.

The Klebs-Loeffler bacilli, we see, not only do not invade the infected mucous membrane, but do not usually even penetrate through the entire thickness of the diphtheric pseudo-membrane. The picture presented suggests a conflict at long range, so to speak, the invaders being the bacteria whose weapons are the easily soluble poisons manufactured by them upon the surface of the affected part, and through the absorption of which the tissues undergo

the peculiar metamorphosis seen in this disease. If our bacteriologic investigations are conducted further into the remote internal organs, there too, we find an absence of the specific microörganisms. This is true not only for the internal viscera generally, but likewise for those organs affected with the peculiar form of localized necrosis described by Oertel as so common in this malady.

It is not, however, unlikely that during the course of the disease a few scattered organisms may accidentally gain access to either the lymphatic or vascular circulation, and thus become deposited in remote organs, as they may also be carried thither through the phagocytic activities of wandering leukocytes. The possibility of finding diphtheria-bacilli in the internal organs at autopsies upon individuals dead of the disease has recently been demonstrated by Frosch, Wright, and others; but nothing that we have learned from the study of the conditions occurring in the deeper tissues leads to the belief that they are in any way dependent upon the immediate presence of the specific bacilli.

The poisons produced by the bacilli at the seat of primary invasion, to the absorption of which, as has been said, the secondary manifestations and constitutional symptoms are due, are likewise produced by the bacilli when growing under artificial conditions of cultivation.

When isolated, free from the organisms by which it was manufactured, it is seen to be capable of causing in susceptible animals identically the same group of tissues-changes that are produced when the bacilli themselves are introduced. The interesting and important features in connection with it are its nature, being analogous chemically to the venom of serpents, and the potency of its poisonous properties, which exceeds in degree that of almost any other substance with which we are acquainted. Roux and Yersin present some idea of the intensity of its action; they have estimated that 0.4 milligram of the dried poison is sufficient to kill eight guinea-pigs weighing each 400 grams, or two rabbits weighing each two kilograms, a degree of toxicity almost beyond the grasp of our imagination.

In 1888 Oertel directed attention to a group of pathologic conditions that he found in the internal organs of individuals dead of diphtheria; and more recently this subject has attracted additional attention through similar observations made by Welch and Flexner upon animals that had died of the experimental form of the disease. These changes consist of foci of a peculiar form of necrosis, varying in extent and scattered irregularly through the internal organs. They are characterized by nuclear fragmentation of the cells of the parts affected. The fragments into which the nuclei are seen to disintegrate are conspicuous for the readiness and intensity with which they become stained and for the manifold shapes which they are seen to assume, at times appearing as little else than dust-like particles strewn through the necrotic and hyaline area, or again as clusters of granules indicative of the location of the nucleus from which they originated; again, all manner of irregular and bizarre shapes that may be likened to whetstones, crescents, balloons, clubs, dumb-bells, etc., will be seen. Frequently a nucleus will appear as if drawn out so that it may present a tail-like elongation, and again it may be pinched and distorted. In certain spots there may be almost an absence of stained cells and fragments, but it is usually possible to detect faint outlines of cells and more or less of a refractive, granular substance that gives the staining reaction of fibrin. In the investigations of Oertel and of Welch and Flexner these necrotic areas in greater or less extent have been detected in all the internal viscera, being particularly prominent in the lymphatic apparatus, in the liver, and in the spleen. To a limited extent the same process was also detected in the muscles of the heart. While not strictly confined to the disease, diphtheria, this nuclear fragmentation is nevertheless always an accompaniment, and affords, by the rapidity with which it is produced, another illustration of the energy of action possessed by the poison producing it. It has been seen to occur in the internal organs of animals with all its characteristics in so short a time as thirty-eight hours after inoculation with small quantities of cultures of the bacillus diphtheriæ.

Through similar methods of investigation a satisfactory understanding of the pseudo-membranous anginas of scarlatina and measles has also been reached. These processes are not, as has been supposed, of a diphtheric nature, etiologically speaking, though it is often impossible to distinguish them from diphtheria by the means ordinarily possessed by the clinician. When not complicated with diphtheria the local manifestations in these diseases are etiologically quite distinct. They are due, as a rule, to a streptococcus similar to and probably identical with that concerned in the production of erysipelas and phlegmonous forms of inflammation. A clearer understanding of the pathology of these conditions has recently been reached through the studies of Booker, who states that from the material examined it is safe to say that the local changes seen in the throats of patients with scarlet fever and measles are anatomically distinct from those seen in diphtheria, and that the anatomic alterations observed in the deeper structures of the body resulting from the scarlatinal virus, unlike those secondary to diphtheria, are accompanied by the immediate presence of streptococci, and are largely suppurative in nature, appearing to be the direct outcome of the organisms associated with them.

From this imperfect review of the more important of the mooted questions in connection with diphtheria and allied pseudo-membranous inflammations of the upper air-passages, it is manifest that such doubts could only have existed as a result of incomplete acquaintance with the causes underlying the several processes; and with the exact means of differentiation that have been afforded by newer methods of investigation our conception of the nature of these processes, particularly of diphtheria, occupies a place on a par with that of tuberculosis, anthrax, and other infectious maladies from which so much of value has been learned. The discovery of the bacillus diphtheriæ and the practical application of the knowledge gained by this discovery has shed a flood of light upon these processes that could not possibly have been obtained through any other channel of study.

As bacteriologic study of diphtheria and conditions with which it might be confused met with wider application certain irregularities were encountered. It was discovered that the causative factor, the genuine bacillus diphtheriæ, was simulated in morphologic and biologic peculiarities by what was believed to be another organism which was distinguishable from it only by the absence of pathogenic properties. This latter organism was known as the pseudo-diphtheric bacillus, and was considered as distinct from the genuine diphtheric bacillus simply because of its inability to kill susceptible animals when inoculated into them subcutaneously. As this organism had been seen in conditions not believed to be diphtheria, as it had been seen in mild cases of a doubtful nature, and as it had been seen in genuine diphtheria in association with the true diphtheria-bacillus, it became necessary to determine its relation to the virulent bacillus diphtheriæ before the value of the latter organism as an absolute means of diagnosis could be firmly established. The simplest way out of the difficulty was to consider them as in no way related, but as entirely distinct species, and this, in fact, is what was done.

It was, however, soon observed that the genuine, virulent diphtheria-bacillus was liable to fluctuate in the degree of its pathogenic properties, at times possessing these to such an extent that when inoculated into guinea-pigs death resulted in from thirty-six to forty-eight hours, while again the period of inoculation was much longer, often reaching five and six days, and in not a few cases organisms were obtained from undoubted cases of diphtheria that failed to give more than a temporary local reaction when inoculated into these animals. In many cases of diphtheria the two organisms have been seen to be simultaneously present, and in the observations of Roux and Yersin it was detected that as the disease advanced toward recovery the number of the less virulent and non-virulent forms became more numerous in proportion. Singular as it may seem, the only, or principal point of distinction between these two organisms, if distinct they are, was held to be the ability of the one and the inability of the other to cause the death of the inoculated animals, and no attention whatever was paid to the nature of the local reaction that was caused by the organism that failed to kill. I have taken occasion to examine the condition of the tissues at the seat of inoculation in animals into which non-virulent forms of this organism had been introduced, and have found that, though the death of the animals did not follow the inoculations, locally, tissue-changes indistinguishable, save in degree, from those produced by the fully virulent forms were to be found; there was the same edema, though less in extent, the same hyaline condition of the muscle-fibers, the same fibrin-exudation and the same characteristic fragmentation of nuclei that one finds locally in the animals inoculated with the true, fully-virulent bacillus of diphtheria. This, I think, offers another argument in favor of the opinion already expressed elsewhere by Roux and Yersin, myself and others, that the diphtheric bacillus and the so-called pseudo-diphtheric bacillus are one and the same organism, the latter representing the former, whose virulent properties have become diminished.

It must not be inferred, from what has been said in regard to the gradual appearance of the attenuated forms of this organism with the establishment of convalescence, that when recovery is complete, the organisms are no longer virulent. Such a conception would not accord with the results of observations upon convalescents from diphtheria. The study of a large number of cases has demonstrated that with recovery many of the diphtheric bacilli in the throat not only do not lose their virulence and vitality, but retain both these properties for days and weeks, and it is often possible to isolate from the throats of convalescents from diphtheria virulent diphtheria-bacilli for as long as two and three weeks after all traces of the disease have disappeared, a point of inestimable importance in establishing rational prophylactic measures against the spread of the malady.

It is interesting that it is not always possible to establish a dependence between the clinical course of the disease and the degree of virulence possessed by the organisms causing it. From many of the most alarming cases organisms are often isolated that are much less virulent, as determined by their period of incubation in animals, than those seen in other cases, the clinical manifestations of which are much milder. There are undoubtedly modifying conditions at play, upon whose nature we can do

little more than speculate—conditions, possibly, of individual susceptibility or tolerance to the action of the poison, or some local factor favors or retards the absorption of the poison from the point at which it is produced; certain it is that in its clinical, anatomic, and certain of its bacteriologic phases, diphtheria varies within very wide limits, but possesses at the same time certain features that serve to distinguish it from other diseases with which it is likely to be confounded.

With the further application of bacteriologic methods to the study of diphtheria, attention was turned to the question of immunity against the disease, and finally to the discovery of a cure.

The outcome of experiments conducted principally by Behring, Kitasato, Wernicke, Wassermann, Brieger, Ehrlich, Roux, Martin, and others, is to apply to diphtheria the principles of the important observations made by Behring and Kitasato upon tetanus, to the effect that the blood-serum of animals that have been immunified against tetanus possesses not only the power of conferring immunity against this disease to animals into which it may be injected, but that it also possesses the property of arresting the malady after it is already in progress. This observation represents the foundation-work of blood-serum therapeutics, around which so much interest has lately centered.

Through the combined labors of those cited, and more especially through the investigations of Behring, it has been found possible to do in diphtheria just what he and Kitasato did in tetanus, viz., it is possible to render susceptible animals immune to diphtheria by the introduction into their tissues of the modified poisons produced by virulent diphtheria-bacilli, and to obtain from the blood of these animals serum that will not only afford immunity to other susceptible animals, but which, as in the case of tetanus, has the power of arresting the disease after it has already been in progress for a time. When this method of treatment is applied to animals that have purposely been infected with pure cultures of the bacillus diphtheriæ, and not too long after infection, the results are so uniformly favorable as to place the operation far beyond the experimental stage. If, however, the disease is permitted to proceed for a time the results are not to be counted upon with such certainty; in short, the success of the operation is dependent upon the stage to which the disease has progressed. In mixed infections, that is, those in which some other organisms, especially the streptococcus, commonly associated with the bacillus diphtheriæ in human diphtheria are present, the experiments of Roux and Martin indicate that the results of the treatment are still less certainly favorable.

You are all too well acquainted with the astonishingly favorable statistics that have been presented recently for hospitals in which this method of treatment has been employed, to require mention of the reduction in the death-rate from diphtheria since the use of this method, and I believe it safe to predict that as our knowledge upon the subject increases, and as we become more familiar with some of the obscure points the results of the treatment will be still more favorable.

As to the *modus operandi* of the immunifying process and the therapeutic action of the serum of the immunified animals, we are still in the dark; but the hypothesis of Buchner, to the effect that the introduction into susceptible animals of the modified poisons produced by virulent bacteria serves as a stimulus to the integral cells of the tissues, and awakens a reactionary change that results in the appearance in the circulating blood of a something that is highly antagonistic to the fully toxic poisons that may subsequently gain access to these animals, seems most reasonable, and at present meets the requirements of the case more satisfactorily than any of the other explanations that have been advanced.

A PLEA FOR A METHODICALLY-WRITTEN TEXT-BOOK ON ANATOMY.[1]

By EDMOND SOUCHON, M.D.,
PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY, NEW ORLEANS, LA.

It is my belief that students of anatomy would better learn and remember the innumerable and more or less complicated facts of anatomy if they had at their disposal a text-book written with constant uniformity and rigorous method. The guide or course followed in describing the organs should be inexorably systematic and always the same for each and every one of the organs, and should apply as well to the largest organs as to the smallest, even to a cell. It might be dry and monotonous reading for the cursory reader or for office-reading, but it would be of the greatest assistance to those who have to learn and to remember.

It is true that all text-books on anatomy have about the same main divisions or headings in describing an organ, but it is specially in the details and smaller things under those headings that the students need systematic and uniform assistance. All superfluous words, remarks and dissertations were better omitted, so as to leave the facts as simple and prominent as possible; but the guide does not interfere with extensive descriptions.

Students of ordinary intelligence can readily supply in their own minds connecting words, and even sentences. Thus such ponderous books as we now

[1] Read at the meeting of the Association of American Anatomists, at Washington, D. C., May 29, 1894.

see carried around by students would be reduced one-third or one-half.

I have elaborated such a guide, and I here present it for consideration to the members of the association. Of course, the guide or course describing an organ should be followed more or less closely according to the importance of the organ or of the facts connected with it. If some facts connected with one particular part of an organ are of no importance, they should be skipped, and stress should be laid upon those facts only which present a practical bearing or a scientific interest.

It would be essential to follow the guide systematically, as one fact is so intimately connected with the following one that the place where to say it cannot very well be altered without disturbing the harmony of the whole. There is a place for everything, and everything should be in its p ace. We should say at the beginning what belongs there, and not say it in the middle of the description. Again, we must say in the middle of it what belongs there, and not say it at the end.

It may seem difficult and complicated at first, but after one has committed the guide thoroughly to memory, so as to have it at the tongue's end without hesitating to think, it will be seen how smoothly it works, and how much it will assist. It is impossible to forget or skip anything, as every few words almost in the guide call for an answer at its proper place, which answer is easily remembered by one who has studied the organ two or three times with this severe system and training.

In describing an organ we should give: 1st. Definition of the organ, its synonymy and etymology; 2d. Divide the organ into separate parts, if necessary; 3d. State the number; 4th. The dimensions; 5th. The situation; 6th. The direction; 7th. The means of fixity; 8th. The mobility; 9th. The shape; 10th. The surfaces, borders, angles, or extremities, as base and apex; 11th. The structure.

To avoid repetition the definition should be based upon the function of the organ.

If the organ is a complex one, such as are sphenoid and temporal bones, it is important to divide it into several parts, describing each part as a separate organ.

In connection with the number, it should be stated whether the organ under description is single or double, and whether there are not sometimes supernumerary organs, such as the spleen, of which in some instances there may be one, two, or three supernumerary organs; also, whether in cases of double organs they are known to unite sometimes to form but one, such as is the case occasionally with the two kidneys, which unite by their extremities to form the so-called "horse-shoe kidney."

We must say, also, if the organ is ever known to be absent altogether.

The dimensions of the organ should be described, either by comparing the organ to some familiarly known object or to some other organ of the human body (this is the relative dimension), or by actual measurement in inches or fractions (these are the absolute dimensions of the organ). When the organ is a hollow tube or a channel one should give the dimensions of its caliber or bore.

The situation should be first stated in a general way, or in regard to the region it occupies; then its relative position should be mentioned, that is, the position it occupies in regard to the surrounding organs; thus, for the spleen, we say it is situated in the left hypochrondrium, below the diaphragm, above the kidney, behind the stomach, etc.

The direction of an organ should be stated first as compared with the axis of the body, and then as compared with its own axis; thus, the fibula is vertically directed as compared with the axis of the body, and is twisted as regards its own axis.

The means of fixity of organs are either connections by adhesions through more or less loose or tough connective tissue, or ligaments formed of folds of the membranes enclosing them, or by vessels, or they are supported by organs situated beneath; thus, the liver has ligaments formed by the peritoneum; its upper border is closely adherent to the diaphragm by rather tough connective tissue; it is partially held in position by the hepatic veins passing from its substance to the ascending cava, and it is supported as on a soft cushion by the stomach and intestines.

The mobility of an organ affects the whole organ or a part of it only; thus, the head and part of the body of the pancreas are firmly bound down, whereas the tail is more or less movable. The organ may be movable by itself, as are the intestines, or its motion is communicated by another organ, such as the motion communicated from the diaphragm to the liver. Finally, it should be stated whether at times the mobility does not become excessive without interfering with the functions; thus, the kidney will sometimes escape more or less from its bed of areolar and adipose tissue, and, without impairing its usefulness, float about in the abdomen.

The shape of the organ should be next considered. It is very important to define it accurately, either by comparing it to a geometric figure, or by comparing it to the shape of a familiarly-known thing, because, according to its shape, an organ presents more or less surfaces, borders, angles, or extremities, or a base and an apex.

In describing each surface we should mention the other names by which it is known, also its ex-

tent, whether it is large or small; also its direction, whether it is directed forward or backward, above or below, or in an intermediate direction; also the form or shape of that surface, whether it is plane or concave or convex, either in the vertical or the horizontal direction, and if it is or is not the same all over the surface; also its peculiarities, which are represented either by projections (folds, processes, tubercles, protuberances, ridges, or crests) or by depressions (orifices, blind foramina, grooves, canals). When enumerating numerous peculiarities we should invariably begin on the median line and then on the sides, proceeding always from before backward, and from above downward, and from within outward.

In describing a groove we should say if it leads or not to a canal, its depth and the organs contained therein, artery, vein, nerve, or a membranous process, or a special organ. In mentioning an orifice we should describe its size, shape, boundaries, structure, and contents. Finally, we should give the relations of the surface, which may be with skin (*i. e.*, what part of the surface of the body its course corresponds to); or with bones, joints, muscles, viscera, vessels, nerves. The same course is to be followed in describing a border; first, give its other names; then its extent, then its shape; say if it is blunt or sharp, or bevelled at the expense of one surface or the other.

All thick borders should be divided into two edges or lips, and an intermediate interstice, giving the peculiarities and relations of each, then its relative direction, whether vertical, horizontal, oblique, forward or backward, above or below, inward or outward; afterward, its absolute direction, rectilinear or sinuous, concave or convex; next mention its peculiarities and its relations, following the same course as for a surface. The same course applies to the description of the angles of the organ, or to its extremities, or to the base and apex, if it should have any.

It is now the time to describe the structure of the organ. This should always be preceded by mention of its color and its consistency, as these properties are connected with the structure. In speaking of its consistency we must say whether the organ is soft or hard, friable or not, elastic, dilatable, or retractile. As regards the structure we should first describe the envelops; a great many organs and most viscera are provided with a serous coat, reduced to its endothelial layer. Next comes a fibrous or fibro-elastic and muscular coat, bearing or not a special name or several names, varying in thickness and resistance, more or less elastic, presenting an external surface more or less elastic, and more or less closely connected with the surrounding tissues and organs; an internal surface more or less intimately connected with the proper tissue or substance of the organ, and sending into this proper tissue filaments or processes that divide the interior of the organ into a large number of alveoles, in which are deposited the proper or characteristic anatomic elements of the organ. Almost always the fibrous coat is reflected at the point called the hilum into the interior of the organ, and then divides into smaller and smaller processes, which join those given off from the inner surface, and assist in forming the alveoles. The whole of these processes and the alveoles which they form constitute what is called the stroma or fibrous skeleton of the organ, which supports the more delicate elements of the proper substance. This stroma is more or less apparent, according to the organ; it is, like the fibrous coat, formed of more or less dense connective tissue, to which is often added elastic fibers and smooth muscular fibers in greater or lesser quantity. The proper substance of many organs is divided into an external or cortical substance and into an internal or medullary.

The proper or characteristic elements of an organ are either cells or fibers, tubes, or prisms, arranged in a peculiar manner according to the organ, to which are added capillary arteries, veins, and lymphatics, and nervous filaments. The capillaries in many organs present a most interesting and often characteristic arrangement. If the organ described is a gland with an excretory duct, that duct should be described as a separate organ. If the organ is a hollow one, like the stomach or the heart, we should describe the interior with its lining membrane. We should mention with care the consistency of the membrane, its thickness, its elasticity, degree of adhesion of its deep surface, and in regard to its free surface, its color, its peculiarities, the nature of its epithelium, and, if any, the kind of glands which it contains. Some organs present a peculiarly interesting chemic composition which should be mentioned. Usually the point of interest lies in the relative amounts of the higher organic and the lesser organic elements.

To be thorough the mode of development of the organ should now be given, and the changes that it undergoes from its embryonic formation to the very oldest age.

Finally, in a last paragraph, we should mention the peculiarities and varieties of the organ, due to sex, habits, trades, constitutions, individualities, nationalities, and races.

The same course is applicable to bones, ligaments, vessels, and nerves, although it may seem odd at first, since it is quite a departure from the old plan. It would be a waste of time before such an audience to give any example by actually describing a muscle or a nerve after this plan.

All the foregoing points and details are summarized in the following table:

Guide to Describe an Organ (*applicable to all organs*).

1. Definition.
   Synonymy, etymology, history.
2. Division of a complicated organ into separate portions and description of each portion as a separate organ.
3. Number.
   Single or double.
   Supernumerary organs.
   Absence of the organ.
4. Dimensions.
   1. Relative size, or size compared to other organs or to familiar objects.
   2. Absolute size.
      Diameter, transverse, vertical, antero-posterior; caliber.
5. Situation.
   1. General situation or region it occupies.
   2. Relative situation, as compared to the surrounding organs.
6. Direction.
   1. Compared with axis of body.
   2. Compared with its own axis.
7. Means of fixity.
   Adhesions.
   Ligaments.
   Vascular connections.
   Supported by other organs.
8. Mobility.
   Of the whole organ.
   Of a part of it.
   Intrinsic mobility.
   Extrinsic mobility, or communicated by other organs.
   Extent of mobility.
   Exceptional mobility.
9. Shape.
   Compared to a geometric figure.
   Compared to the shape of a familiarly-known object.
10. Surfaces.
    Synonymy.
    Direction: Forward or backward.
    Above or below.
    Intermediate direction.
    Shape: Plane, concave, or convex.
    Vertical or transverse direction.
    Peculiarities.
    Projections: folds, processes, ridges, or crests, tubercles, protuberances.
    Depressions: orifices (size, shape, boundaries, structure, contents), blind foramina; grooves and canals (depth, extent, contents, vessels, nerves, or organs).
    When enumerating peculiarities begin on the median line, and then on the sides; proceed from before backward, from within outward, or from above downward.
    Relations: With skin (*i. e.*, to what part of the surface it corresponds) or
    With bones, joints.
    Muscles.
    Viscera.
    Vessels and nerves.
11. Borders.
    Synonymy.
    Dimensions.
    Direction.
    1. Relative direction: vertical, horizontal, oblique, forward, or backward, above or below, inward or outward.
    2. Absolute direction: straight, sinuous, concave, convex.
    Shape: Blunt or sharp, or bevelled at the expense of one surface or the other.
    Peculiarities, as for surfaces.
    Relations, as for surfaces.
    All thick borders ought to be subdivided into two edges or lips, and an interstice. Give for each, peculiarities, insertions, and relations.
12. Angles or extremities: same as borders.
    Base and apex: same also.
13. Structure.
    Color.
    Consistency: density, friability, elasticity, contractility.
    Envelops or coats: thickness, resistance, elasticity.
    External surface, relations, adhesions.
    Internal surface, relations, adhesions, processes from internal surface. Reflections into the interior of the organ.
    Stroma: If delicate or apparent, is composed of connective tissue, or elastic, smooth, muscular fibers.
    Proper or characteristic elements.
    Cells, fibers, tubes, prisms.
    Capillary arteries, veins, lymphatics, nerves.
    Excretory duct of glands (as a separate organ).
    Lining membrane of a hollow organ.
    Thickness, consistency, elasticity, adherent surface (degree of adhesion).
    Free surface: Color, peculiarities, epithelium, glands.
14. Chemic composition.
    Organic and inorganic elements.
15. Development of the ages.
16. Peculiarities or varieties, or anomalies due to sex, habits, trades, constitution, individualities, nationalities, races.

Meningitis due to the Bacillus of Typhoid Fever.—Daddi (*Sperimentale*, Juillet, 1894; *Revue Internat. de Méd. et de Chir. Prat.*, No. 18, p. 335) has reported the case of a boy, nine years old, who in the course of an attack of typhoid fever was seized with symptoms of meningitis, to which he succumbed. In the creamy exudate covering the upper surface of the brain and cerebellum, as well as in two small abscesses situated symmetrically at the level of the spines of the scapulæ on either side, the bacillus of typhoid fever was found in pure culture.

CLINICAL MEMORANDA.

OPERATIVE TREATMENT FOR THE CURE OF VASCULAR NEVI.[1]

BY A. F. JONAS, M.D.,
OF OMAHA, NEBRASKA;
PROFESSOR OF CLINICAL SURGERY IN THE OMAHA MEDICAL COLLEGE; SURGEON TO THE METHODIST EPISCOPAL, PRESBYTERIAN, AND DOUGLAS COUNTY HOSPITALS; PRESIDENT OF THE MISSOURI VALLEY MEDICAL SOCIETY, ETC., ETC.

I DESIRE to make a preliminary report of a case of vascular nevus of the face, in which we have instituted operative measures for the cure of a condition that, while not painful, is annoying alike to the possessor and to the immediate friends. To be afflicted with a vascular growth, in the form of a telangiectasis, nævus flammeus, or angioma simplex, involving nearly one side of the face, means almost social ostracism. It is a source of constant mortification. The individual often becomes reticent, and avoids social intercourse because he is avoided by others. He prefers almost any other deformity to this; his mental suffering is intense, and he will submit to almost any form of treatment, however painful or prolonged, that he may be rid of what he almost considers a moral stigma. If the treatment fails his despondency increases; he feels himself a branded outcast. It seems strange that a deformity which in no way interferes with functional activity should usually so unfit the individual for the ordinary enjoyment of life. No amount of reason or moral suasion will give him peace of mind; nothing short of such physical means as will remove the hideous blemish.

One who has seen many of these cases and has been called upon to treat them will testify how difficult it is to achieve results satisfactory alike to his patient and to himself. The time-worn methods of caustics in their varied forms, while they frequently destroy the cutaneous vascularity, thereby removing the annoying color, leave a mass of cicatricial tissue, which, by its contraction, causes such distortion of the features that the exchange of a red or bluish blotch for the resulting deformity can hardly be called an improvement.

A careful microscopic examination discloses the fact that angioma simplex, which is by far the most common form, consists of an intricate, preëxistent, and newly-formed network of tortuous, frequently anastomosing, bloodvessels, somewhat larger than ordinary capillary vessels, containing at short intervals varicose dilatations, spindle and cylindric sacculi, with walls somewhat attenuated (Ziegler). We observe small vascular lobules located about the sweat-glands and hair-follicles (Billroth), constituting vascular districts, which coalesce, forming larger or smaller vascular areas. In the connective tissue, which has increased, and the intervascular spaces, are many lymphoid cells, single and in groups (Kaposi). We find this vascular growth usually occupying the rete mucosum and the corium, nearly always reaching and frequently occupying the subcutaneous cellular tissues, reaching as deeply as the hair-follicles and sweat-glands. This vascular network is composed of a surprisingly large number of bloodvessels, so that in artificially-injected sections (Ziegler) they are so numerous that the intervascular connective tissue seems exceedingly insignificant.

It will be seen that any caustic measures, to be effective, must destroy the entire thickness of the integument, including a portion of the subcutaneous connective tissue, and cause a burn of the third degree. While this mode of treatment may be of service in small nevi, it becomes exceedingly objectionable in those large forms that extend over the greater part of one side of the face, on account of the resulting cicatricial contraction.

Such remedies as nitric acid, glacial acetic acid, solution of caustic potash, which have so long been popular, have been, as they should be, relegated into the forgotten past. Their action, while destructive to the tissues to which they were applied, usually effectually obliterates the cutaneous vascular supply, and cannot be limited to the affected tissues. The destructive action frequently extends to the facial muscles, and sometimes to the nerves, so that we have the effect of a facial paralysis. The vascular obliteration by means of subcutaneous injections of tincture of ferric chlorid or tincture of cantharides is dangerous on account of the risk of embolism, which in several instances has caused death (Van Harlingen, Holgate). Vaccination, so highly recommended, may be of service in nevi of limited size, but can be of little service in extensive affections. Of extensive linear scarification, while it has improved a number of my cases, I cannot say that the results have been satisfactory. The use of the Paquelin cautery, in the practice of others and in my own, has left linear cicatrices, which always remind one of the seamed face of the German duel-loving student, which in Germany may be considered a mark of bravery, but in this country might suggest the battle-scarred ruffian. With ligatures I have failed, and could hardly have expected to succeed when it is remembered that in rare instances only large arterial trunks communicate directly with the vascular growth. With injections of alcohol, as proposed by Holgate, I have had no experience, but they would seem to me to be open to the same objections as those of ferric chlorid. A solution of 8 per cent. corrosive sublimate in collodion as a caustic has proved successful in small nevi, but in the large varieties has been almost a failure in my hands. Electrolysis has given me more satisfaction than any of the methods mentioned. The electrolytic action is entirely under the control of the operator. The destructive action of the needle can be checked in an instant. As large an area can be treated as is desirable or seems indicated. But in spite of the greatest care a streaked appearance of the nevus cannot be prevented. We cannot judge of the depth or the amount of the tissue involved by the vascular structure.

It occurred to me that if we could devise a method by which the entire structures involved by the vascular growth could be accurately and completely removed, and the cutaneous defect thus produced be so repaired as to prevent extensive cicatricial contraction, and to establish a normal color of the part, we should have found an ideal method. In the following case I have made an attempt to accomplish this end. While my experience has been limited, yet the results promise so much that I feel encouraged to continue work in this

[1] Read before the Missouri Valley Medical Society, at Council Bluffs, Iowa, September 20, 1894.

line, with the conviction that with increased experience we shall be able to record improved technique and better results.

M. B., twenty-four years of age, has always been well except for the diseases incident to childhood. She stated that from birth she had been afflicted with a "port-wine mark," possessing the same proportionate size throughout life. I found, on inspection, an area beginning in the left temporal region, extending along the margin of the lower eyelid toward and to the median line of the face, reaching as high as the brow, extending over the left side of the nose downward over one-half its surface, and involving the entire thickness of the upper lip. From the left angle of the mouth the line of demarcation extended with a downward curve upward to the temporal region. The color of this area was a reddish-purple, but all color disappeared on pressure. The margins of this discoloration appeared irregular and sharply defined, but on careful inspection faded rapidly into the normal cutaneous color—constituting what is ordinarily known as a nævus vasculosus, or an angioma simplex. The left side of the face was decidedly enlarged, particularly the left half of the upper lip. The alveolar mucous structure of the left half of the superior maxilla contained a vascular new-formation, soft, compressible, of a dark-purple color—a cavernous angioma.

On September 11, 1893, a solution of 8 per cent. corrosive sublimate in collodion was applied over the outer third of the nevus. In one week a slough exactly corresponding to the surface covered by the sublimate collodion film separated, leaving a granulating excavation, which rapidly filled and underwent epidermization in two weeks. Then the second third of the nevus underwent a similar process, and finally the remaining portion. A wedge was excised from the inner side of the lip, and the alveolar angioma was treated with galvanism by means of needle-punctures. The patient was discharged from the hospital with the hope that in time there would be capillary obliteration sufficient to change the nevus to the desired color. She returned in three months. The only improvement noted was a change from a purple hue to a dark pink. The patient had been very despondent, had secluded herself and despaired of ever being freed of her misfortune. The thought suggested itself, why not remove the entire abnormal growth with the knife, and immediately cover the defect with transplanted normal integument.

Accordingly, on March 12, 1894, under chloroform-anesthesia and strictly aseptic conditions, one-third of the affected integument was dissected away, cutting well into the subcutaneous tissues, so as to insure the entire removal of the growth. The left arm having been rendered aseptic, several Thiersch flaps were removed, of sufficient length and breadth to cover the facial defect, except at the outermost angle, where, experimentally, a small portion of the affected skin was placed in order to note what changes, if any, would take place in it. The denuded surface having been entirely covered with Thiersch flaps, a thick coating of iodoform was applied, then a piece of perforated aseptic silk protective, then iodoform-gauze, a cotton pad, and a binder. This dressing was removed in forty-eight hours, and the wound was irrigated with sterilized water. All the flaps showed evidences of adhesion. A dressing was applied as before, and changed daily. In one week all flaps had become firmly adherent.

It was interesting to observe, from day to day, the changes that took place in the angiomatous graft which was placed at the outer angle of the wound. In forty-eight hours it had become adherent; its color was of a darker shade, and it seemed thicker. It grew darker and thicker from day to day, until the tenth day, when it had assumed a dark-purple hue. It was compressible, but immediately became swollen again when pressure was removed. The graft was then removed with a knife, and it was found to have become firmly adherent. Vascular communication had become established. The graft was found to have become a cavernous angioma.

On this day a second section of integument was removed and covered with Thiersch flaps, and dressed as before. The upper end of one flap, under the margin of the eye, became detached during the first dressing, and this sloughed, and the wound healed by granulation.

Two weeks later the last third of the nevus was dissected away. Considerable difficulty was experienced in removing the integument about the inner canthus and between this point and the brow. The skin was not very thick at this point, so that there was danger of injuring the canaliculi. Thiersch flaps were used as before, and became rapidly adherent. It was now found that at the point where one of the flaps which had been placed with one end against the denuded lower lid, and had been detached accidentally during the first dressing, and later sloughed, the wound healing by granulation, contraction had taken place and everted the inner third of the lower lid, requiring a second denudation and flap.

I must confess that it may be too early to judge of the result at the present time; still the appearance of the site of the old nevus is such as to be in every way encouraging. The appearance is identical with that observed in other cases in which flap-transplantation was employed after the removal of other forms of neoplasm and in granulating surfaces after burns, the skin becoming in the course of time of a normal appearance. In the case under consideration there remains no trace of nevoid structure, the whole surface is gradually becoming of a lighter shade, and the only discoloration remaining is of a pinkish hue, as I have invariably found in transplanted skin of recent date.

The method pursued in this case seems rational and promising, because, first, we remove the entire nevoid structure, and, secondly, because the defect is covered with integument of a normal character. It is like the removal of sod, poor with wire grass, from a lawn and replacing it with a new blue-grass sod, which is more pleasing in appearance. The immediate transplantation of skin-flaps prevents the contractions and the consequent deformity seen so constantly after such methods as cauterizations of every description. The wound-repair is prompt, rapid, and painless.

The removal of the nevoid structure should be as rapid as consistent with good work, as the hemorrhage is likely to be profuse. A slow and tedious dissection might entail such a loss of blood as to be harmful; cut away rapidly, swabbing just enough to enable you to see that you are beneath the vascular zone. Have artery-clamps lying near, in order that no time may be lost in catching spurting points. When denudation is com-

plete, and all bleeding points tied, apply a thick wad of iodoform-gauze, and direct an assistant to make firm pressure while you uncover the previously disinfected arm, which, meanwhile, has been wrapped in a sublimate towel. Then with your razor, ground flat on one side and concave on the other, you carefully remove a flap of skin, your left hand having grasped the arm in such a manner as to make the skin tense. This skin-flap may be from four to six inches long, and from one to one and one-half inches wide, and of a thickness reaching into the papillæ. As you cut, the flap will shrink together on the concave side of the razor. When long enough, detach it from the skin. Remove the gauze pad, spread the flap on the denuded surface, and tease it into place with a probe and grooved director. Avoid thumb-forceps, as you may bruise the flap and destroy its vitality. It will be found that the flap has contracted nearly one-half; therefore it is necessary to cut flaps nearly twice as large as desired. A sufficient number of flaps are used to entirely cover every part of the vivified surface. Use extreme care about the lower lid; be very liberal with the flap, exercise every precaution so that the edge of the flap be not turned under, as in this case it would fail to adhere. If the flap should fail to adhere at this point, or is accidentally torn off with the dressing, immediately apply a new graft, in order that healing by granulation, with consequent contraction and eversion of the lower lid may be prevented—a deformity quite as undesirable as the nevus itself.

Every antiseptic precaution must be observed to obtain the best result. The surface to be operated upon must be rendered aseptic, and the operator's hands, sponges, instruments, especially the razor, must be rendered aseptic. The arm, or rather the portion of the body from which the flaps are removed, must be given the same careful attention. The field of operation must be carefully surrounded with sublimated towels, and an aseptic cap applied to the head. If we are surgically clean, the transplanted flaps are almost certain to adhere. If any detail is overlooked, we are almost certain to fail.

A CASE OF CONGENITAL DEFORMITY OF THE UPPER AND LOWER EXTREMITIES AND OF THE SPINAL COLUMN.

By I. NEWTON SNIVELY, A.M., M.D.,
INSTRUCTOR IN PHYSIOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

On September 22, 1891, I was called to attend Mrs. C., who was reported to be suffering from an attack of "cramps." I found my patient to be a young woman, eighteen years of age, of small stature, thin in flesh, pale and anemic, and of a highly nervous temperament. I was told by members of her family that she had been marrried only four months and had not had her menses during that time.

After observing the patient a few moments, it was evident that she was in the first stage of labor. Upon digital examination I found the os partially dilated and the occiput presenting. The abdomen was not as large as is usual in pregnant women at full term. Labor progressed normally for about one hour and a half, when the uterine contractions began to grow weak and finally almost ceased. One hour later, when I returned to my patient, I found the labor-pains quite severe and following one upon the other in close succession; from this time on labor advanced normally to delivery, four hours and twenty minutes after I was first summoned to the case.

A boy-baby with numerous deformities was born. These consisted in absence of the lower end of the spinal column, the coccyx, and the protruding backward of the lower end of the sacrum. Double club-foot was present, double club-hand, displacement of both ankles, imperfect knee-joints, and left hip-joint. There was also imperfect development of the wrist-joints and elbow-joints, flat-feet, flat-hands, imperfect external ears, a double great toe on each foot to the distal joint, with double nail. The fingers were normal and their joints perfect; the great toe on each foot was unusually long, fully twice its normal length; the other toes were perfect. The child was a strong, fleshy, vigorous, and healthy infant.

Perhaps the most striking deformity was the absence of the coccyx and the pointing backward of the sacrum. This deformity is well shown in Fig. 1. It was not a

Fig. 1.

spina bifida; the prominence seen above the anus was of bone, and resistant to the touch, and not of that smooth elastic nature found in tumors caused by incomplete closure of the bony canal in the spinal column. It contained no fluid, and could not be reduced in size by pressure. The right foot was in the most extreme form of talipes equino-varus; the sole of the foot pointed upward and rested on the abdomen. The foot was flat, the plantar fascia and internal lateral ligaments were shortened, and the tibialis anticus and posticus muscles were contracted. There was marked displacement of the tarsal bones; the astragalus was tilted downward, the scaphoid was displaced inward and downward by the action of the tibialis posticus, and the tubercle on this bone was very prominent; there was in addition marked rotation at the astragalo-scaphoid and calcaneo-cuboid junctions. The displacement of these bones gave the foot a short, flat appearance, somewhat resembling the human hand. The os calcis was rudimentary, and in consequence the heel was less prominent than normal. The articulation at the ankle-joint was imperfect, owing to the displacement of the astragalus. The foot was strongly adducted. The right knee-joint was displaced inward at a right angle, the tibia and fibula were shorter than normal and curved inward, and the patella was rudimentary on the right side. The femur was normal and in the socket at the acetabulum. The right hip-joint was perfect in development, and admitted of free

motion in all directions. The left foot was in extreme talipes equinus. The gastrocnemius and soleus muscles were shortened, the tendo Achillis was tense, so that flexion of the foot was impossible ; the foot was slightly adducted. The sole of the foot rested on the scrotum and buttocks, from the strong flexion of the limb at the knee and thigh. The left knee was strongly flexed; efforts at extension were met by bony and ligamentous resistance. The left hip-joint was also in extreme flexion, and could be extended only to an angle of 45°. The left femur was normal in length and development. The flexion at the hip-joint was due to a contracted condition of the flexor muscles of the thigh.

The deformities were alike on both sides in the upper extremities, and resembled very much those found in the lower limbs. The humerus was normal in length and perfect in development on both sides. The shoulders were perfect and admitted of free motion. The deformities of the upper extremities are well shown in Fig. 2. The

FIG. 2.

forearm was tightly flexed upon the arm and could not be extended beyond an angle of 35°, from contraction of the biceps muscle. The radius and ulna were shorter than normal, and curved inward; the ends of these bones were rudimentary. Efforts to extend the forearm at the elbow caused a creaking noise, especially when forced beyond an angle of 35°. The wrist-joints were rudimentary, the hands were adducted. The palms of the hands rested on the arms in the deltoid region ; there was slight motion at the wrist-joints. The fingers were normal in length, and the phalangeal joints perfect. The external ear was marked by the absence of part of the lobule. The head and trunk were perfect in form and development, except for the absence of the coccyx.

The infant cried lustily after birth, was well nourished, and gave every promise of living if properly cared for and nourished.

The father, when he saw the hideousness of the deformity, and being desirous also to conceal the birth of a child so soon after his marriage, placed it, contrary to my wishes and advice, in a foundling-home in Philadelphia. The physician of that institution reported its death as due to debility when it was twenty days old.

Medical literature is replete with instances in which vivid mental impressions are supposed to have produced a direct effect upon the development of the fetus. Mrs. C. gives a history of having received at least two severe mental shocks during her period of gestation—one seventy-one days after conception, and another three months before parturition. On February 25, 1891, while employed in a paper-box factory, she saw the clothing of a friend caught by a revolving shaft, which drew her to the floor, and as she fell her limbs and arms were twisted about the shaft. Some of her clothing was torn off, and there was considerable blood lost by the tearing out of part of her hair. Mrs. C. was close by when the accident occurred, and was very much frightened, and did not fully recover from the shock for several months.

She was, as I have already said, naturally of a weak, nervous temperament, which condition was, no doubt, augmented by her having conceived out of wedlock and having to support herself by working in a close, dusty room in a box-factory. Her surroundings were not calculated to produce that cheerfulness and equanimity of mind desirable for pregnant women; on the contrary, her weak body and agitated mind were well calculated to produce the result in her offspring that has been here shown, if sufficient emotional excitement were brought to bear upon her. She gives February 25th as the day of the fright. It was the birthday of a lady friend, who visited her in the factory that day and saw the accident with her. Supposing the child to be a full-term baby, if we count back 280 days, it would bring the day of conception on December 16, 1890. This was seventy-one days before February 25th, the time of the fright.

Mrs. C. gives the history of having had a second fright in June, 1891, about six months after the beginning of pregnancy. At this time her own clothing was caught by a revolving belt, and part of it torn from her body. This accident does not seem to have made as vivid an impression upon her mind as the first, as she does not recall it in all its minutiæ, as she does the one of February 25th.

I wish to mention in this connection that the woman for three or four months prior to parturition had been in the habit of lacing herself very tightly, so as to conceal from friends and relatives the near approach of her maternity. She had so far misled her relatives that they administered anodynes for her "cramps" prior to sending for me. Authorities on this subject do not believe that tight lacing has anything to do with the production of deformities.

On November 19, 1892, fourteen months after her first confinement, I delivered the woman of a perfectly formed male child. This second child has since developed a strumous diathesis, and at present has enlarged suppurating glands in the neck.

The husband has lately died of tuberculosis of the lungs, with which disease he had suffered for five years or more. His family history is tuberculous. The mother's relatives are all healthy, and none is deformed.

2501 OXFORD STREET.

GUNSHOT-WOUND OF THE SPLEEN AND KIDNEY; ABDOMINAL SECTION; HEMOSTASIS BY DEEP SUTURE; RECOVERY.[1]

BY LOUIS McLANE TIFFANY, M.D.,
OF BALTIMORE, MD.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF MARYLAND.

GUNSHOT-WOUND of the spleen, recognized, treated, and cured, is believed to be of sufficient rarity to justify placing the following case on record.

The patient was a male negro, twenty years of age.

[1] Read before the Southern Surgical and Gynecological Association, Charleston, S. C., Nov. 13, 1894.

Two hours previous to entering the University Hospital, March 21, 1894, he had been shot with a small-caliber rifle from a distance of twenty feet, the weapon being directly behind him and he being erect. His urine was slightly albuminous; the pulse, temperature, and respiration normal. There was a bullet-wound three inches to the left of the spine just below the last rib, from which blood oozed. Dr. Spruill, Resident Physician, after proper cleansing, enlarged the wound, found that the kidney had been injured and that the bullet had passed onward, presumptively into the peritoneal cavity; he filled the wound lightly with gauze and notified me. I saw the patient three hours later, about five hours after the shooting. The only change that had taken place since entry into the hospital was an increase of five per minute in the number of respirations; the pulse and temperature were not changed, and there was no appearance of shock and no pain. External examination of the abdomen by touch and palpation revealed nothing, not even painfulness. Dr. C. W. Mitchell, one of my colleagues, thought that the respiratory movement was rather less marked over the left than the right side of the abdomen. I could not detect the difference however.

The patient was anesthetized, laid on the belly, and the wound, after being enlarged, was examined. The upper portion of the left kidney was perforated, and dark blood flowed from the peritoneal cavity beyond. This large wound was filled with gauze, the patient turned on the back, and the abdomen freely opened along the left semi-lunar line. A moderate amount of blood was free in the peritoneal cavity; no wound of the intestine could be discovered, but the spleen was found perforated, blood flowing freely from the wound of entrance, as well as from the wound of exit; the latter wound, in the concavity of the organ, was slightly the larger of the two.

The perforation through the spleen was about three inches from the free lower border. Unwilling to subject the patient to splenectomy, I attempted to arrest the bleeding in the following manner: A long needle threaded with silk was passed entirely through the spleen central to and parallel with the bullet-track; the long ligature was then tied over the free border of the organ so as to press the surfaces of the wound together tightly enough to arrest bleeding, yet not to tear through the splenic tissue; the ends of the ligature were cut short, the peritoneal cavity cleansed by copious irrigation with hot water and the abdominal wound closed. The kidney was tamponed with gauze through the dorsal wound. Convalescence was uneventful; the anterior wound healed by primary union; urine flowed from the dorsal wound for two days only, union by granulation taking place. The patient left the hospital well, April 2d.

The literature treating of spleen-wounds is meager. Probably about all that is known will be found in the *Medical and Surgical History of the War*, Part II, Surgical Vol., p. 149 et seq., and it is not necessary to recapitulate here the information there set down.

Symptoms and treatment deserve mention. The wound being small, hemorrhage was not profuse, and no abdominal organ save the spleen was wounded. I could not recognize any evidence of spleen-wound without inspection; pressure, handling, percussion, revealed nothing, the belly remaining soft and flaccid. Twice I have opened the abdomen for gunshot-injury, finding wounded intestines; both cases had the belly-walls much more rigid than had the subject of this report. The lumbar incision showed me dark blood flowing from within the peritoneal cavity, and for this reason the abdominal section was performed, and not because of information elicited by handling.

Treatment of a wounded spleen by celiotomy places that organ in the category with other peritoneally covered organs, and calls for no comment; but the mode adopted for the arrest of hemorrhage is noteworthy. The classic treatment for a perforating wound of the spleen is splenectomy, because it has been held that bleeding is not otherwise to be stopped; this we now know is not so, but that it is possible by ligature to induce hemostasis. In case the wound is larger than in the instance here reported, it would be necessary to interfere without delay and pass several sutures in the manner stated, so as to make pressure over a larger area. When rupture of the spleen has occurred this method of hemostasis seems especially indicated, for thereby support to the injured viscus would be afforded.

A CASE OF APPENDICITIS.

BY J. W. HICKMAN M.D.,
OF TACOMA, WASHINGTON.

A. W. L., aged thirty-three years, was in the early afternoon of September 19th suddenly seized with excruciating pain in the belly in the right inguinal and right lumbar regions. The only symptoms prior to this were a chill of several minutes' duration about twelve hours previously, and in the morning a feeling of "stiffness," as he expressed it, referred to the abdomen, but to no particular part of it. The forenoon was occupied in dictating letters of business and in looking after a sick member of his household. I first saw him about 5 P.M., and was told that in addition to the pain he had vomited a few times. His pain was more intense in the region noted, but radiated here and there over the whole abdomen. There was no very well-marked tenderness. The temperature was 102°, the pulse 120, the hands and feet cool. The bowels had been moved the day previously, the last time they ever did move. I gave the man 12 grains of Dover's powder and 2 grains of calomel in four powders, and directed that one be taken every half-hour, and further directed that two hours after the last powder a heaping teaspoonful of magnesium sulphate be given every hour and a half, to be stopped when the bowels should be thoroughly evacuated. I was called to see the patient at 5 A.M. of the next day; the pain was so excruciating that I gave him ⅓ grain of morphin hypodermatically, which relieved him completely. The pain was referred at this time to the entire abdomen, and was accompanied by a widespread tenderness, more intense, however, over the ileo-cecal region. The temperature was 99.2°, the pulse 140, tense, and shotty to the finger. The face wore an ominous, relaxed expression, as the man slept after the morphin. His breathing was thoracic. There was now no difficulty in making a diagnosis of general peritonitis. Notwithstanding that he had taken about 2 ounces of magnesium sulphate, most of which he had retained, his bowels had not operated, nor had there been any rolling or rumbling of the intestines. About 10 A.M. I was

again hastily summoned on account of pain. Realizing the gravity of the case, I asked for a consultation. The same conditions obtained except that the temperature had risen to 101.5°. The same treatment was continued. Three hours later there was scarcely a perceptible pulse at the wrist; the breathing was about 30 and shallow; the hands and feet were cold; in short, the patient was in collapse. He died at 11.20 P.M., about thirty-four hours after the initial pain. A post-mortem examination was held the next morning, and from a pint to a quart of fetid pus was found in the abdominal cavity, with no adhesions except very feeble ones at a couple of points. The appendix was gangrenous and had a ragged-looking opening in one side.

The unusual feature of this case is, of course, that there was practically no complaint until the rupture of the appendix gave rise to a general peritonitis. There was obtained an indistinct history of an attack, similar to this at its beginning, eight years ago.

Since writing the foregoing note I have operated on a case forty hours after the first pain, finding the appendix gangrenous and ready to give way at several points, and the cecum in the same condition at the appendicular junction over an area about the size of a silver quarter.

MEDICAL PROGRESS.

Puerperal Infection with the Bacterium Coli Commune.—EISENHART (*Archiv für Gynäkologie*, Bd. xlvii, Heft 2, p. 189) has reported the case of a woman, thirty-two years old, who, following her fifth, uncomplicated, labor, presented fever, pain in the right side, and an offensive vaginal discharge. The functions of the bladder and bowels were undisturbed, but an obstinate swelling of the right foot appeared. The uterus was displaced backward and somewhat to the right. Upon its right margin a painful exudate was detectable, while the cervix was surrounded by a suppurating ulcer. The temperature was 104°, the pulse 122. A diagnosis of acute purulent parametritis was made. Following the use of the ice-bag, the administration of opium and the employment of vaginal injections of lysol, the symptoms soon disappeared. In a short time, however, pain appeared at the flexure of the right thigh, where there was found a dense infiltration, extending three or four fingers' breadth above Poupart's ligament, and beneath which could be felt a thrombus occluding the femoral vein. Local applications and manipulations failed to afford relief. In a short time an abscess formed above Poupart's ligament, which on palpation yielded a sense of the presence of air. A similar sensation was imparted over a small area below Poupart's ligament. Additional tumefaction was observed, involving the upper third of the right thigh. This was sensitive, soft and elastic. The patient referred certain peculiar sensations and sounds to the bladder at the termination of micturition. The urine removed by catheter was of orange-yellow color, and emitted a peculiar but not disagreeable aromatic odor. It had a specific gravity of 1015, was of a feebly acid reaction and deposited considerable sediment. It contained large quantities of albumin, but no blood. Microscopically large numbers of colorless corpuscles were found, but no tube-casts. Bacteriologic investigation disclosed the presence of the bacterium coli commune. The swelling of the thigh increased, and edema of the dorsum of the right foot and the greater and lesser labia became added to the symptoms. An incision into the swelling gave exit to a large quantity of thick, creamy pus, containing many large and small air-bubbles. This pus had a peculiar, though not putrid or fecal odor. Bacteriologic examination disclosed also the presence of the bacterium coli commune. The abscess-cavity at first secreted considerable quantities of pus, which later diminished under the use of methyl-violet in the form of bougies. For a short time the condition of the patient improved, the swelling and edema disappeared, pus was freely discharged in moderate amount, but subsequently the woman became worse. Hyaline casts were for the first time found in the urine. Symptoms of nephritis with uremia developed and finally progressed to a fatal issue.

On post-mortem examination a moderate excess of fluid was found in the pericardial, pleural and peritoneal cavities. The intestinal serosa was smooth and glossy, and free from adhesions excepting on the part of the rectum with the adjacent uterus. The spleen was enlarged and soft. The kidneys were in a state of parenchymatous degeneration, together with amyloid change. The external wound communicated with a sub-peritoneal sinus passing from the middle of the horizontal branch of the right pubic bone backward and upward toward the vertebral column, and terminating at the level of the promontory of the sacrum in a cavity about as large as a pigeon's egg, filled with thick pus, and not distinctly circumscribed from the surrounding structures, which appeared undermined and friable. Behind and to the right side of the uterus were numerous cicatrices. An incision into the upper third of the right thigh disclosed the presence of pus distributed between the muscles and other structures.

A Convenient Clinical Manometer.—A portable manometer for the estimation of blood pressure in the radial artery, devised by CHAPMAN (*Birmingham Medical Review*, September, 1894, p. 146), consists of an ordinary U-shaped mercurial manometer having the upper end of the shorter limb, which is ten inches in height, bent at a right angle, and fitted into a perforated india-rubber stopper, over which is drawn and securely ligated an ordinary air-tight india-rubber finger-stall. The longer limb of the U is double the length of the shorter, and open at its end. The shorter limb is graduated into fourteen centimeters. Zero begins at the upper level of the mercury, about an inch below the angle; the space above communicates with the interior of the finger-stall, and contains air. Both limbs of the tube are fractured, the longer limb in mid-length, the shorter in its horizontal portion, the ends being united by means of thick India-rubber tubing. This arrangement enables the tubes to be bent upon themselves, in which position they are retained by means of a rubber band, and this prevents the escape of the mercury at the open end of the longer limb, and allows the instrument to be put into a case of convenient size.

The application of this manometer is devoid of difficulty. The patient's wrist is adjusted beneath the finger-stall, in a slightly-extended position, and if pressure is then made on the finger-stall by the fingers of the

operator the mercury will fall in the shorter and rise in the longer limb, and the difference between these levels will represent the intra-arterial radial blood-pressure. The hope is expressed that the instrument will come into general use, its claims to favorable recognition being based upon the simplicity of its application, its small cost, which "is no more than that of a clinical thermometer," and upon the valuable information so quickly and easily obtained by its use.

The Occurrence of the Bacillus Diphtheriæ Outside of the Body.—Wright and Emerson (*Centralbl. für Bakteriologie und Parasitenkunde*, Bd. xvi, No. 10, 11, p. 412) have made a study of the dust upon the floor of the diphtheria-pavilion of the Boston City Hospital and upon the clothing and person of the attendants, to determine if diphtheria-bacilli could be found. The diphtheria-pavilion is isolated and divided into large and small apartments. It contains seventy beds. The general sanitary condition is good. The results were as follows:

Of four cultures from floor-sweepings from the brush and the cloths used in dusting, but one (from the brush) was positive as regards diphtheria-bacilli. Other bacteria were also present. Of four examinations of the dust and other matters adherent to the shoes of the attendants, three showed the presence of a small number of diphtheria-bacilli, together with other bacteria. Cultures were made from the hair of the attendants in four cases, with positive results in one. Examination of the margins of the dresses of the attendants, of the bed-clothing, of the shirts of the patients, and of the finger-nails of the attendants, were all negative as regards diphtheria-bacilli, as was also an examination of the air of the pavilion. In two of the five examinations in which bacilli were found the degree of virulence was slight.

The Bacteriology of Diphtheria.—From a study of eighty-two cases of diphtheria Wright (*Boston Med. and Surg. Journ.*, vol. cxxxi, No. 14, p. 329), concludes that there is practically no difference in virulence to be observed between the bacilli derived from severe and mild cases of diphtheria. Cases in which true diphtheria-bacilli have been present for a longer or shorter period of time furnish fewer virulent cultures than cases of recent beginning.

The diphtheria-bacillus does not, as a rule, lose its virulence by long-continued residence in the pharynx and air-passages. It exists in all degrees of virulence down to innocuousness, as far as is shown by the results of its inoculation into guinea-pigs, and the intensity of the reaction in the animal bears no constant relation to the symptoms presented by the case from which it was derived. There is no relation to be observed between the age or sex of the patient and the virulence of the bacillus.

Hepatic Colic without Gall-stones.—Lépine (*Intern. klin. Rundschau*, 1894, p. 387; *St. Petersburger med. Woch.*, No. 36, p. 331) contends that hepatic colic may result from simple spasmodic contraction of the gall-bladder or biliary ducts. This opinion is based on both clinical, pathologico-anatomic, and experimental evidence. From the clinical point of view reference is made to the hepatic colic observed in hysterical individuals as a result of emotion, without discoverable cause in the intestinal evacuations. In some individuals the ingestion of certain articles of food is followed by hepatic colic. A case is cited in which after death no concretions were found in the choledoch duct, although a few small grains were present, together with active contraction of the walls of the duct. In dogs spasmodic contraction of the lower portion of the choledoch duct may be induced artificially. It is maintained that contraction of the biliary canals may be induced reflexly.

The Sterilization of Catgut.—Tschernig (*Hospitals Tidende*, 1893, No. 48; *Centralbl. f. Chir.*, No. 38, p. 897) has employed dry heat in the sterilization of catgut for sutures and ligatures, with satisfactory results. Catgut thus prepared retains its strength, and is easily preserved. The gut is cut in suitable lengths for use in operation, and enclosed in double sealed envelops. These are placed in a sterilizing oven and the temperature gradually raised, an hour being occupied in increasing the heat to 176° F., and two hours more in increasing it to 302° F. For three hours the gut remains exposed to this temperature, and then the oven is permitted gradually to cool. Bacteriologic investigation has shown gut thus treated to be absolutely sterile.

The Functions of the Supra renal Gland.—As the result of a further study (see The News, July 21, 1894, p. 71) Auld (*British Medical Journal*, No. 1762, p. 745) concludes that the functions of the supra-renal gland are the destruction of certain effete products of metabolism which are of the nature of ptomains, and the elaboration of a secretion which is absolutely essential to the blood (hemopoietic). The destruction of the gland is followed by an auto-intoxication and a profound alteration in the chemistry of the blood, which entails, amongst other things, degenerative or nutritional changes in the nervous and digestive systems, and derangement of the color-regulating metabolism.

Pneumonic Orchitis.—Prioleau (*Le Mercredi Médical*, 1894, No. 36, p. 439) has reported the case of a man of advanced years in whom a suppurating orchitis developed in the interval between two attacks of pneumonia. The first attack lasted for twelve days, and was of an insidious type. Three days after its termination the patient was seized with pain in the left testicle, with chill and fever. An abscess formed, examination of the pus from which disclosed the presence of diplococci. The patient recovered, but a month later was seized with a second attack of pneumonia, which terminated fatally.

The Disinfection of Catgut.—At a meeting of the Surgical Society of Berlin, Schimmelbusch (*Deut. med. Woch.*, 1894, No. 38, Supplement p. 97) described the method of treating catgut for surgical purposes employed in the clinic of Prof. v. Bergmann. This consists in first removing the contained fat and then placing the gut in a 1 per cent. solution of mercuric chlorid in 80 per cent. alcohol, and frequently stirring. Repeated bacteriologic examination has shown such catgut to be free from microörganisms.

THERAPEUTIC NOTES.

The Antitoxin-Treatment of Tetanus.—DOUGLAS (*British Medical Journal*, No. 1765, p. 934) has reported the case of a gardener, sixty-three years old, who was bitten upon the thumb by a dog. The man did nothing to the wound, but continued to work in his garden. Five days later he began to feel some stiffness about the jaws, with difficulty of swallowing. When seen, three days after this, the teeth were clenched, and the jaws could be opened only about one-quarter of an inch. The original wound was quite healed. Eserin salicylate, gr. $\frac{1}{100}$, was injected subcutaneously, and chloral hydrate, gr. xx, was ordered every three hours. On the following day the man was easier, and the trismus was not so evident, but the next day there was considerable pain in the back and abdomen. Then followed stiffness in the legs and back, and convulsions, while the temperature began to rise. On the thirteenth day half a tube of Tizzoni's antitoxin dissolved in 22 c.cm. of sterilized distilled water was injected by seven punctures into the abdomen and thighs, with strictest aseptic precautions. The condition of the patient, however, failed to improve, and gradually progressed to a fatal issue. Not much was to have been expected from the specific treatment instituted at so late a stage of the disease.

Pilocarpin in the Treatment of Acute Articular Rheumatism.—DRAPPIER (*Journal des Sciences Médicales de Lille*, No. 37, p. 243) reports the case of a man, forty-five years old, who suffered yearly from two or three attacks of acute articular rheumatism. At first the salicylates were employed with success, but subsequently these failed. Other remedies were also employed without avail. In one such attack pilocarpin was employed, subcutaneous injections of $\frac{1}{6}$ grain of the nitrate being made daily. These induced profuse sweating and rendered the patient perfectly comfortable. The treatment was thus pursued for five days more and proved entirely successful; nor did the symptoms return.

In the Treatment of Premature Alopecia LASSAR (*Gaz. Méd. de Liège*, August 9, 1894) recommends washing the hairy scalp with soap and water for about ten minutes daily, using tar-soap and lukewarm water, and finally cold water; the hair should be dried, and frictions with the following solution made: Water, 250 grams; mercuric chlorid, 50 centigrams; glycerin and cologne-water, each 50 grams. This may be followed by shampooing with absolute alcohol to which has been added from ½ to 1 per cent. of naphtol, and anointing the scalp with the following mixture: Salicylic acid, 2 grams; tincture of benzoin, 3 grams; Neat's-foot oil, 100 grams.

The Treatment of Syphilis by Hypodermatic Injections of Mercurials.—At a recent meeting of the French Society of Dermatology and Syphilography AUGAGNIER (*Annales de Dermatologie et de Syphiligraphie*, tome v, Nos. 8–9, p. 927) contended that the employment of mercurial injections in the treatment of syphilis ought to be reserved for exceptional cases, on account of the attendant inconvenience and danger. If in cases of cerebral syphilis, when the indications are extremely urgent, one may at once begin injections. If the urgency is not clear inunctions should be given the preference, and only in case of their failure should resort be had to the injections.

For Bronchitic Asthma.—

℞.—Extracti stramonii . . . gr. ⅛.
Potassii iodidi . . . . gr. v.
Ammonii carbonatis . . . gr. iv.
Tincturæ lobeliæ æther. . . ♏v.
Aquæ chloroformi . q. s. ad ℥ss.
Misce et fiat mistura.
S.—A tablespoonful from every four to six hours.
Provincial Medical Journal.

In the Treatment of Chronic Articular Rheumatism, LETULLE (*La Presse Médicale*, September 29, 1894, p. 313) recommends rest in bed, the repeated application of the actual cautery to the affected articulations, passive movements of the joints, sulphurous baths, alternating with warm douches of simple or sulphuretted water, in conjunction with the internal administration of potassium iodid in doses of from 7½ to 30 grains in the twenty-four hours.

For Infantile Colic.—

℞.—Tinct. belladonnæ . . . gtt. x–xi.
Infus. canellæ . . . . f ℥ij.—M.
S.—℥j every hour until the pain is relieved.
For the constipation, upon which the colic usually depends, a teaspoonful of cod-liver oil may be administered thrice daily. URRIOTA—*La Semaine Méd.*, No. 53.

For Leukoplakia LEISTIKOW (*Monat. f. Prak. Dermat.* Bd. xix, No. 7) recommends the following formula:

℞.—Terræ siliceæ . . . 22½ grains.
Resorcini . . . . 45 "
Adipis . . . . 7½ " M.
S.—Make a paste and apply topically several times daily by means of a cotton swab.

For Metrorrhagia.—

℞.—Ext. opii. . . . . gr. jss.
Tinct. hydrastis. Canad. . . f℥ss.
Tinct. zingiberis. . . . . f℥ijss.
Syrup. aurantii cort. . . . f℥j.
Aquæ destil. . . . . f℥iij.—M.
S.—A tablespoonful every three hours.
LUTAUD—*Frauenarzt; Centbl. f. d. ges. Ther.*

Salol in Herpes Zoster.—BILLSTEIN (*Phila. Polyclinic*, vol. iii, No. 33, p. 324) reports cases of herpes zoster in which successful results were obtained from the topical application of salol in powder. Twenty grains of the drug in an ounce of ether were given, with instructions to make the application twice daily by means of a camel's-hair brush.

For Lichen Urticatus.—

℞.—Spiritus rectificati } . . . āā f℥j.
Saponis mollis }
Olei cadini . . . . . f℥v.
Aquæ . . . . . ad f℥x.
Misce et fiat lotio. S.—To be applied night and morning.
The Practitioner.

Philadelphia.

SATURDAY, NOVEMBER 17, 1894.

THE MEDICAL NEWS' SPECIAL REPORT ON THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

At a very considerable expense of labor, time, and money, and under strictly scientific conditions, The Medical News instituted, in Philadelphia, the treatment of certain cases of diphtheria with the antitoxin. At the time not an instance of such treatment was known to have taken place in Philadelphia, and there was no injecting material to be had here. Despite many difficulties, we have succeeded in being able to lay before our readers in the current issue the partial reports of five cases thus treated. The investigation is to be continued. For most willing and valuable assistance and coöperation, we are under great obligations to Dr. Louis Fischer, of New York, who having some serum at his disposal, has made a number of visits to Philadelphia for the purpose of making the injections; to Dr. William Welch, of Philadelphia, in charge of the Municipal Hospital, as also to Dr. Bemis, his able resident and assistant; to Dr. D. Braden Kyle, the bacteriologist, of Philadelphia; to Drs. Frese and Kneass, of the German Hospital; to Dr. Coplin, and to others. To the publishers of The Medical News for their generosity, encouragement, and hearty interest, is due our especial gratitude. We trust that the results, direct and indirect, of our endeavors may be found of value to the profession.

THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

It is a great misfortune, a profound obstacle to medical progress, to have been over-confident and enthusiastic in the adoption of a new treatment or method of procedure. Whatever truth there was in the "Tuberculin Craze;" whatever of final and unexpected good may have resulted or may still result from Koch's premature announcement, it cannot be questioned that a great mistake was committed, either popularly or professionally, or both, and that this error has resulted in a reactionary skepticism and a failure to test ever so conservatively the value of serum-therapy, and especially that branch of it relating to diphtheria. We have been so fearful of over-zealousness and of possible blundering that we have delayed overlong the duty of testing, even carefully and scrutinizingly as we should test any such thing, the discovery of a therapeutic method of great probable value. All at once, now, we are awakening to a realization of the profound importance of this treatment, and as with all late converts, we are perhaps in some danger of excessive trust and propagandism. We, therefore, wish to urge again the old necessity of caution and prudence in the interests of true medical progress. Let us be in no ridiculous haste. Let us be sure our serum is genuine, that the cases treated are those of proved diphtheria, and let us be on our keenest guard in reporting our cases, that we do not mistake *post-hoc* recoveries for *propter-hoc* therapeutics.

But, in the interests of the same scientific spirit and progress, do let us no longer delay putting this method to the test. It comes to us with a good record, and from excellent sponsors. That we have delayed for a year or two even to think of it, much less to practically experiment with it, still much less to prepare our own immunized serum, is not to the credit of American medicine.

The following figures are given by *La Médecine Moderne*, 1894, No. 85, p. 1319, to show the results obtained by the treatment of diphtheria with the antitoxin: Behring and Kossel, 30 cases, with a mortality of 20 per cent.; Ehrlich, Kossel, and Wassermann, 67 cases, with tracheotomy, with a mortality of 44.9 per cent.; 153 cases, without

tracheotomy, with a mortality of 23.6 per cent.; Katz, 128 cases, with a mortality of 13.2 per cent.; Weilger, 63 cases, with a mortality of 28 per cent.; Aronson, 192 cases, with a mortality of 13 per cent.; Roux, 448 cases, with a mortality of 24.33 per cent.—making a total of 1081 cases, with an average mortality of 24 per cent.

Roux (*British Medical Journal*, No. 1765, p. 931) relates that in one of the hospitals of Paris the total mortality in the diphtheria-wards for four years was 51.71 per cent., while among 448 children treated from February 1 to July 24, 1894, with the antitoxin, there were 109 deaths, a mortality of 24.5 per cent. On the other hand, during the same time, 520 cases of diphtheria were treated at the Trousseau Hospital, but without the antitoxin, with 316 deaths, a mortality of 60 per cent. In cases of simple diphtheria not requiring tracheotomy the mortality for four years has been 33.94 per cent. During the months of trial at l'Hôpital des Enfants it fell to 12 per cent., while during the same time at the Trousseau Hospital the mortality was 32 per cent. In the cases of "croup d'opérés" requiring tracheotomy the mortality for four years has been 73.19 per cent.; with the antitoxin-treatment it fell to 49 per cent, while during the same time at the Trousseau Hospital the mortality was 86 per cent.

There have been recorded in the *British Medical Journal* 39 cases of diphtheria treated with the antitoxin at the hands of a considerable number of practitioners, with 3 deaths, a mortality of 7.6 per cent.

It is announced that the British Institute of Preventive Medicine is prepared to furnish the antitoxin at the bare cost of production, which it is believed will be about 12 or 18 cents for the ordinary dose.

Katz (*Berliner klin. Wochenschr.*, July 16, 1894; *Lancet*, No. 3713, p. 1004) relates that the mortality from diphtheria in the Kaiser and Kaiserin Friedrich Kinderkrankenhaus in Berlin was, in 1890, 50.4 per cent.; in 1891, 32.5 per cent.; in 1892, 35.4 per cent.; in 1893, 41.7 per cent.; and from the beginning of 1894 until March 14th, when the antitoxin-treatment was begun, 41.8 per cent. From March 14th till June 20th, 1894, 128 cases, in all of which the bacillus of Loeffler was detected, were treated with the antitoxin, with a mortality of 16.5 per cent., as compared with a mortality of 37 per cent. for the same period of the previous year. Of 47 mild cases, all recovered; of 35 more severe cases, 1 died; of 42 still more severe cases, 11 died; while all of 4 septic cases died. In no case was the antitoxin found to act injuriously. In mild cases the dose was gradually increased from 5 to 7.5 c.cm.; in severe cases from 3 to 5 c.cm. to 20 c.cm. A weaker solution was employed as a prophylactic in 72 cases exposed to infection, and only 8 of which were attacked.

Ehrlich (*Medical Press and Circular*, No. 2894, p. 429) has reported 40 cases of diphtheria, of which 20 were "tracheotomy-cases," treated with the antitoxin, with 4 deaths. Of 41 other cases not thus treated 18 died. In another group of 48 cases treated with the antitoxin there were 6 deaths.

Maurice (*Lancet*, No. 3713, p. 973) has reported two cases of diphtheria treated with the antitoxin, one successfully, the other unsuccessfully. The fatal case occurred in a delicate, weakly child four years and three months old, who, when seen on the fourth day of its illness, was pallid and collapsed. Twenty minims of the antitoxin were at this time injected; on the following day twenty minims more; on the next day again twenty minims, and a day later seventeen minims. The child could not, however, be brought out of its condition of collapse, and finally succumbed. The other case occurred in a well-nourished girl, two years and six months old, who was seen on the second day of her illness. On the third day two c.cm. of the antitoxin were injected, and on the fourth day one c.cm. Convalescence soon set in and progressed to ultimate recovery. In the first case it is believed that life was prolonged as a result of the injections, and in the second there was no doubt that great benefit was derived from the use of the antitoxin.

Rice (*British Medical Journal*, No. 1764, p. 891) has reported two cases of diphtheria successfully treated with the antitoxin. Both were in women, aged thirty-four and thirty years respectively. In one eight minims of Aronson's serum were injected on the morning of the second day, and again in the evening; six minims on the third day, and eight minims on the fourth and fifth days. In the second case eighteen minims were injected on the second day, nine minims in the morning and again in the evening of the third day.

Maclachlan (*British Medical Journal*, No. 1765, p. 933) has reported a severe case of diphtheria in a boy, thirteen years old, in which a fatal termination was apprehended, and who, on the fourth day of his illness, was given an injection of forty minims of

Aronson's antitoxin into the back. After the injection the child fell into a gentle slumber lasting for five hours. Improvement gradually took place, the temperature alternately rising and falling for a few days, and convalescence shortly set in and led to final recovery.

Gleason (*Medical Record*, No. 1253, p. 598) has reported the case of a boy, eight years old, in which on the second day of an attack of scarlatina a fibrinous exudate made its appearance on both tonsils and pharynx. The tonsils were greatly enlarged and swallowing was difficult. The exudate gradually changed its appearance, and upon the seventh day the case was diagnosticated as one of true diphtheria engrafted upon the scarlatinal angina. The glands of the neck were enlarged and an excoriating nasal discharge was present. Twenty minims of Aronson's *Heilserum* were injected, and in six hours forty minims more. Within twenty-four hours the temperature fell from 104.6° to 99°, with a corresponding amelioration of the symptoms. Convalescence was thereafter speedy.

Macgregor (*Lancet*, No. 2714, p. 1027) has reported the case of a boy, ten years old, in which on the tenth day of an attack of diphtheria the aspect and general condition of the patient indicated rapid collapse and early death. An injection of 15 minims of the antitoxin at this juncture was soon followed by sleep and distinct improvement. From this time on the progress of the case was favorable and advanced to final recovery.

Bokai (*Lancet*, No. 3714, p. 1065) reports 35 cases of diphtheria treated from September 21st to October 22d, with the antitoxin, at the Budapest Stephanie Hospital for Children, including 9 cases of pharyngeal diphtheria, 7 of associated pharyngeal and nasal diphtheria, 4 of associated pharyngeal and slight laryngeal diphtheria, and 15 cases of grave laryngeal diphtheria. The oldest patient was twelve years of age, but the majority were under four. Among the whole number there occurred 5 deaths, a mortality of 14.33 per cent. The significance of this result is apparent when compared with the mortality during the month of October of the years 1891 (56.8 per cent.), 1892 (42.9 per cent.), and 1893 (61.7 per cent.). The immunizing influence of the serum was less positive.

Frith (*British Medical Journal*, No. 1766, p. 1007) reports a case of diphtheria in a child, eleven years old, in which an injection of 19.5 c.c. of the antitoxin into the right flank on the second day of the attack was followed by a favorable termination. Characteristic bacilli were found in the false membrane from the throat.

Fowler (*British Medical Journal*, No. 1766, p. 1007) also reports a case of diphtheria successfully treated with the antitoxin. It occurred in a girl, thirteen years old, who received an injection of 2 c.c. of Aronson's serum on the second day of her illness.

Wakeling (*British Medical Journal*, No. 1766, p. 1008) has reported a fatal case of diphtheria treated with the antitoxin, occurring in a girl six-and-a-half years old. On the eighth day, when the child was weak and the breathing difficult, an injection of 6 c.c. of Aronson's serum was made. Slight improvement followed, and on the second day a second injection of 3 c.c. of serum was made. The breathing, however, grew progressively more difficult, and finally tracheotomy had to be performed. For a short time after the operation improvement appeared to take place, but the heart began to fail, and death occurred rather suddenly.

Recognizing the lamentable slowness of our American profession in testing the value of this method, The Medical News has sought to stimulate enterprise by instituting treatment in a too limited number of cases, employing therefor what little serum has been obtainable. The results are partly shown in the report presented elsewhere in the current number of The Medical News. We hope many others will be moved to institute similar experiments, and to make public the closely-scrutinized, accurately-reported results. The News of last week contained the report of a case by Dr. Catlin, which in many respects was an instructive and typical one. Elsewhere in this issue will be found a trustworthy report of the meeting of the Pediatric Section of the New York Academy of Medicine, which, with commendable spirit, has devoted an evening to the discussion of the subject. We also refer with pleasure to a most suggestive report communicated November 9th by Dr. Muehleck to the Surgical Section of the College of Physicians of Philadelphia.

The cases reported by Dr. Muehleck were five in number, occurring in the same family in children from eleven months to six years of age. All the injections were made in from twenty-four to thirty-six hours after the beginning of the attack. For immunization, one cubic centimeter, and for therapeutic purposes from one-and-a-half to two c.c. of Aronson's serum were used. Of the five children

four were attacked. Two of these (one eleven months, one six years of age) were not treated with the antitoxin, owing to inability to obtain it, and these two, although treated by the hitherto generally accepted rules of practice, died. One child that had mingled freely with the other cases, and in whose throat typical bacilli were found, was inoculated with the antitoxin as a prophylactic measure, and was not attacked by the disease. In all of the cases except one, the bacteriologic tests proved the presence of the Klebs-Loeffler bacillus. Of the two cases injected with the antitoxin, both recovered; in one tracheotomy was indicated owing to involvement of the larynx, but the stenosis was markedly ameliorated within twenty-four hours after the injection; in the other the mucous membrane of the tonsils, the soft palate and the pharynx was involved, but without stenosis. After the injections there was a rapid fall of the temperature within twenty-four hours, the membrane became fatty and pultaceous and came away in four or five days.

EDITORIAL COMMENTS.

Ne Quid Nimis.—There is a strange psychologic fatality about the American character that makes it run to excess in whatever it does. The reserve of tact and discrimination, the instinctive knowledge of coming or already-passed limitations, the impossibility of foreseeing the need of the brake until the engine has either jumped the obstruction or has been smashed to smithereens—all this seems to have been left out of our intellectual outfitting. Instead of quietly and moderately plundering the taxpayers of a city, our American methods inevitably end in Tweedism. Instead of exercising and training the body by judicious athletics we have modern foot-ball—a spectacle for gods and men! Instead of a decent party egotism we have in politics an exuberant rabidity that makes an editorial writer roar with laughter at his own assumed virtue and at his own extravagances of mendacity about the other party. Instead of Socialism we have Coxeyism. Instead of temperance we have either dead-drunkenness or prohibition.

Nor in medicine and in pseudo-medicine can we escape "the defects of our own virtues." Here also we note the peculiar power of crazy excess, the lack of restraint, the disdain of Solon's *ne quid nimis*. A patient told us the other day that himself and his family had taken thirty-two dozen bottles of an anti-rheumatic patent medicine. He found that it was as effective against every other disease as against rheumatism! What a roaring farce this of thousands and thousands of newspapers of this country, supported and bribed to publish millions of pages of ludicrous puffs and lies at millions of dollars of expense, concerning quack concoctions in the preparation of which not a spark of therapeutic knowledge or scientific intellect ever had a finger of influence. What silly nonsense, again, for the American medical profession to support two-hundred or three-hundred so-called medical journals, when a half dozen or a dozen is all or more than could be supported with dignity and honesty. What criminal nonsense, once more, to have a hundred or more medical colleges, when a dozen would be all that could be decently endowed and carried on with high standards. The dozen would do a hundred times more good for the science of medicine than the hundred could by any possibility do. Lastly, chiefly as a result of this riotous multiplication of so-called medical colleges, we have a perfectly ludicrous excess of physicians half-starving and competing with each other all over the land. The proportion of physicians to the population is higher with us than with any other civilized people. While France finds one doctor enough to 2000 of the people; Germany, the home of scientific medicine, finds the proper proportion 1:3000; and Sweden, 1:7000. We in our suicidal intoxication run the proportion up to 1:600.

What malignant asinarian bacillus has got into our blood that makes us "whoop" everything to the sheerest and most debauching excess?

The Identity of the Streptococcus Pyogenes and the Streptococcus of Erysipelas.—From the first the close resemblance between the streptococcus pyogenes and the microörganism isolated by Fehleisen as the cause of erysipelas suggested the possible identity of the two; but for a long time the proof of actual demonstration was wanting. A number of cases, however, have been observed in which erysipelas has developed in the sequence of some local suppurative process, so that there is good reason to believe that the streptococcus pyogenes and the streptococcus of erysipelas are identical, differing, perhaps, in pathogenicity by reason of certain yet unknown intrinsic and extrinsic variations. We have referred to this subject upon a previous occasion (see The Medical News, September 9, 1893, p. 300), at the time citing an illustrative case. A parallel observation has recently been recorded by Reed (*Boston Med. and Surg. Journ.*, vol. cxxxi, No. 14, p. 339), who reports the case of a negro, fifty-four years old, dead of carcinoma of the liver, in which, upon post-mortem examination, the pleura covering the upper lobe of the left lung was dull, its surface being covered with a delicate layer of fibrin. Upon section the cut surface was uniformly grayish in color, and studded with numerous slightly projecting granulations. Cover-slips from this part of the lung showed abundant diplococci, many having distinct capsules, while in cultures from the hepatized lobe of the left lung diplococci also developed, together with the streptococcus pyogenes. The pathologist who conducted the autopsy sustained an abrasion of the skin over the left second metacarpo-phalangeal joint, and took no precautions toward avoiding septic infection of the wound during the further progress of the autopsy. Twenty-four hours later he began to experience a sense of languor and chilliness, together with some tenderness in the left axilla, which gradually increased. Finally, a distinct chill occurred, and was followed by fever and headache. The site of inoculation became reddened and a little swollen, and there was a slight escape of pus. Several days later a swelling appeared on the right side of the face near the nose, with

increase of fever, and a well-defined attack of erysipelas developed. The disease ran a usual course, spreading to the left side of the face and involving the ear. The pathologist had never had a previous attack of erysipelas. The time that elapsed between the local infection and the development of the erysipelas was four days.

Hospitals for the Tuberculous Poor.—We need here scarcely dilate upon the advantages to be derived from the establishment of hospitals for the care and treatment of the tuberculous. The experiences of the Brompton Hospital for Consumption and Diseases of the Chest, of the North London Hospital for Consumptives, of the Alexandria Hospital for Consumptive Children, of the Infirmary for Consumption and Diseases of the Chest, of the City of London Hospital for Diseases of the Chest, of the Royal National Hospital for Consumptives, Ventnor, Isle of Wight, afford abundant evidence of the good to be accomplished in this direction by effective organization and intelligent administration. In France, Germany, and Austria, also, plans are under consideration or in process of execution for the establishment of similar institutions, while a hospital for tuberculous patients is already projected for New York City. Our own Home for Consumptives at Chestnut Hill and the Rush Hospital for Consumptives are engaged in a laudable work, but the usefulness of both institutions is restricted by lack of funds and accommodations for large numbers, and more particularly on the part of those unable to contribute for their support and care. Thus it comes about that for the sake of the tuberculous poor, and with the aim of restricting the ravages and spread of a curable and preventable disease, there has arisen the necessity on the part of States and large cities of establishing hospitals for the reception and care of such tuberculous individuals as are unable to properly provide for themselves. City Councils will in a few days be petitioned to make an appropriation of $100,000 to build and equip such a special hospital in Philadelphia, and it is for the purpose of indorsing this petition that these lines are written. The prevention of tuberculosis is no longer a theory, but it has been effectively demonstrated to be a most earnest condition, and a more intimate knowledge of the cause and course of the disease has led to the recognition and adoption of measures calculated to restrict its ravages and prevent its spread. So desirable an end cannot be better promoted than by the establishment of such a hospital as that proposed.

Puerperal Neuritis.—With an expansion of our knowledge of the complications of the parturient and puerperal states, and with a growing familiarity with the lesions of the peripheral nerves, we have come to learn that the intoxications dependent upon infection through wounds and lacerations resulting in the course of childbirth may give rise to a multiple neuritis comparable to that of rheumatic, plumbic, alcoholic, or other like origin. A typical case of this kind was recently reported by Lountz (*Nouvelles Archives d'Obstétrique et de Gynécologie*, 1894, No. 9, p. 419) at a meeting of the Société de Neurologie, of Moscow. The patient was a primipara, twenty-four years old, who passed through pregnancy and labor without complication, the child dying, however, on the fifteenth day. Three weeks after the labor the woman presented swelling of the face, edema of the extremities, difficulty of deglutition, diplopia, pains in the extremities, and then numbness and weakness of the upper and lower members. Common sensibility was little affected, but the muscular sense was impaired. The knee-jerks and the elbow-jerks were abolished, and electric irritability was diminished. These symptoms were progressive for two weeks. To them were added arrhythmia of the heart, acceleration of the pulse and attacks of suffocation. The lower extremities became entirely paralyzed. By and by, however, the symptoms gradually ameliorated, except the paraplegia, which persisted for a long time. It is assumed that this depended upon a polyneuritis due to infection through a laceration of the perineum incurred during labor.

The Treatment of Typhoid Fever with Cold Baths.—As constant dropping wears away the hardest stone, so has the persistence of Brand and his disciples finally overcome the prejudices of the medical profession and established and forced to universal recognition the great therapeutic utility of cold bathing in the treatment of typhoid fever. With a somewhat natural unwillingness to adopt new methods specious technical objections were raised when once it was shown and admitted that the action of the bath was actually most beneficent and innocuous. Of these objections there remain the difficulty of bringing the necessary appliances and assistants to the bedside of patients in private practice and the fears of the family and the sensibilities of the patient. The last two may be considered as purely sentimental, and not substantial, and means have been devised to overcome the first. One of the simplest and most available devices for effectuating the end in view is that described by Burr (*Chicago Medical Recorder*, vol. vii, No. 4, p. 227). A rubber sheet, 2½ yards long by 1¼ yards wide, is slipped under the patient, and drawn up over his pillow, and its edges tucked up alongside of his body. A folding crib-like frame, 6 feet 2 inches long by 2 feet wide and 8 inches deep, is then unfolded and placed over the patient, resting upon the mattress and surrounding the patient, pillow, rubber sheet and all. The edges of the sheet are then drawn up over the top rail of the crib and down the outside to the lower rail, where it is hooked fast by means of rings attached near its edges with elastic tape. There is thus devised a light and perfect tub, with the patient resting undisturbed on his mattress and pillow. The accessories may be a couple of water-buckets, a ⅝ inch rubber hose, six or eight feet long, for a siphon, to which a spray nozzle may be attached, a sheep's-wool sponge of good size, and a bath thermometer.

Negro Physicians.—Apropros of our recent comment upon the urgent need of negro physicians, we are glad to be informed by Dr. Robert Reyburn that the Medical Department of Howard University of Washington, D. C., has endeavored to meet this necessity, almost half (including six women) of its 436 graduates during the twenty-six years of its existence having been negroes. The Dental Department of Howard University also has graduated 40, including 12 colored men, and 62 (36 colored) have received the degree of Doctor of Phar-

macy. The present medical class numbers 117, of whom 75 per cent. are colored. The Dental Department has 7 colored and 3 white students, and the class in pharmacy 13 students, all colored. It is further to the credit of Howard University to have been among the first to adopt a four-years' graded course of medical instruction. During the past year a training school for nurses has been established in connection with the university, with a current attendance of 77 pupils. The action of Howard University as to the admission of negroes is all the more praiseworthy in view of the practice of Southern medical schools of refusing them admission. Besides the two schools supported especially for the education of negroes by the Methodist Episcopal Church, alluded to in our issue of November 3, it is said that no medical school within 500 miles of New Orleans will allow the negro to matriculate.

The Dangers to which Physicians are Exposed in the performance of their professional duty, particularly when required to be out at night, are forcibly illustrated by a recent experience of Dr. A. M. Phelps, of New York. Returning home at about 5 o'clock in the morning, after having responded to a messenger call, he stopped at a public house for a sandwich, and while making payment was jostled by three men, one of whom abstracted a roll of bills from his pocket. With the aid of a policeman the fleeing culprit was caught and placed in durance. At the hearing before a justice the statement was made that Dr. Phelps presented "the appearance of being drunk and was under the influence of liquor." The policeman who made the charge was, however, unwilling to affix his signature to the written statement, which Dr. Phelps indignantly repudiates and which appears to have been entirely without foundation. Dr. Phelps' denial of the imputation against him is scarcely necessary, for in a question of veracity little credence would be given the word of a New York policeman.

"*The Rights, Liberties, Health and Happiness of Homes*" are everlastingly threatened in Massachusetts, so say flaring, glaring, flashing, furious circulars of "The National Constitutional Liberty League" of Boston, by the wicked renewed attempt to secure the passage of a very mild medical practice act by the State Legislature. These are the people that are aided by a Harvard Professor on the ground that medical discoveries often come from the so-called quack. As a study of the motives of the opponents of rational medicine these circulars are interesting; they have their lessons also as regards the mechanism of the methods, and they are a charming study for the observer of practical morbid psychology.

The Banquet-bribe.—Some time since, we believe, considerable amusement was furnished the world by the finding of pockets-full of free railway-passes in the possession of some ialistic enemy of the railroads. The laugh deepens into disgust when we contemplate the spectacle of the American medical editors banqueting at the expense of manufacturers of drugs and other articles used by the physician and advertised by the journals of the editors in question. If this is permissible why shouldn't the trussmen banquet the members of orthopedic congresses in the same way, the opticians attend to the ophthalmologists, etc., etc.? Surely the instrument-makers and the manufacturing pharmacists should "syndicate" their interests, and give all medical societies and congresses their banquets and hotel bills free!

Reform in Relieving Dependency, instead of encouraging it, is shown by the later experience of the Town of Waterbury, Conn., to be brought about by the revised system of administering public alms. This reform was stimulated by the report of a special committee, selections from which were published in THE MEDICAL NEWS of October 27. "Despite the hard times an annual saving of about $8000 is now being made, besides suppressing other gross abuses." Both giver and receiver are thus better off. As has been facetiously said of marriage, almsgiving is a game that two play at and neither wins.

SELECTION.

ATHLETICS.

As regards athletics, what is their aim? I believe what THE MEDICAL NEWS says is the aim: "To give every student a rounded, harmonious physical organization, not to train a dozen or two semi-officials to win matches."—PRESIDENT SCHURMAN, of Cornell University, in Annual Address to the Students, September 27, 1894.

SPECIAL ARTICLE.

REPORT OF THE MEDICAL NEWS.

A CLINICAL REPORT OF FIVE CASES OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

BY WILLIAM M. WELCH, M.D.,
PHYSICIAN IN CHARGE OF THE MUNICIPAL HOSPITAL, PHILADELPHIA.

THROUGH the kindness of Dr. Frese I have had the opportunity to test the antitoxin in two cases of diphtheria in the Municipal Hospital. Dr. Frese received the material from the German Consul at Philadelphia, Mr. Meyer, who obtained the serum from the Institute of Prof. Behring, of Berlin. Besides my two resident physicians, Drs. Bemis and Carman, there were also present Drs. Frese and Kneass, both of the German Hospital, at the time the injections were made. Having selected two suitable cases of diphtheria in which the diagnosis was made from the clinical aspect of the cases, a bacteriologic examination was commenced by Dr. Kneass; but without waiting for the result of this examination, and thus losing valuable time, the serum was at once injected. Twenty-four hours later Dr. Kneass reported that Klebs-Loeffler bacilli were present in both cases. Dr. Bemis, my senior resident, closely observed the cases and made careful notes of their symptoms from time to time.

Subsequently, Dr. Louis Fischer, of New York, kindly visited the hospital and injected three additional patients with Behring's antitoxin, in the presence of several physicians. The clinical histories of all these cases are herewith presented:

CASE I.—F. N., two-and-one-half years old, white, female, of Russian descent, had been ill a little longer than forty-eight hours when admitted to the hospital, October 2d. On admission the tonsils were large, in-

flamed, and covered with an extensive exudate, dark-gray in color, and the breath was fetid. There was also involvement of both nares. The glands of the neck were somewhat enlarged, and the color of the face was pale and sallow. The temperature was 100.2°; the pulse, 124; the respiration, 24. Ten cubic centimeters of the antitoxin were injected at 6 P.M. (the day of admission). During the following twenty-four hours the temperature was recorded hourly, and varied between 99° and 101.4°; the pulse between 100 and 138 beats per minute; the respirations were from 16 to 28. The exudate in the fauces continued unchanged; there was free discharge from both nares; the greater part of the time this discharge consisted largely of blood. There was also oozing of blood from the mouth; the breath was fetid; the pallor was increasing and of a leaden hue. On November 4th the exudate in the fauces was unchanged; there was considerable epistaxis; the glands in the neck were enlarging; the temperature ranged from 98° to 100°; the pulse was 120; the respirations about 36. On November 5th the exudate in the fauces was not diminished; there was continued epistaxis; the breath was still fetid; the glands in the neck were even larger; there were some purpuric spots on the face; the color was very pale; prostration was great; the temperature ranged from 100.6° to 102.6°; the pulse was 140; the respirations, 28. At 1 P.M. of this day a dose of the stronger preparation of Aronson's antitoxin was injected by Dr. Louis Fischer, of New York. At 7 P.M. of the same day the condition of the patient was unchanged. For twenty-four hours after the first injection no other treatment was employed except the liberal use of milk and stimulants. Subsequently tincture of ferric chlorid and mercuric chlorid were given every two hours, and hydrogen dioxid applied locally every hour to the nares and fauces; strychnin sulphate, gr. $\frac{1}{100}$, was also given every six hours, continuing, of course, the free use of milk and whiskey.

On November 6th the exudate in the fauces was thinner, though still dark in color; blood was slowly dropping from the nose; the glands in the neck were somewhat diminished in size; the temperature, pulse, and respiration were unchanged. The pulse had considerable volume. Exhaustion had not increased, and the child took nourishment freely. On November 7th the exudate in fauces had increased since the previous day, and a few small purpuric spots remained on the face. Epistaxis had ceased, though the nose was somewhat moist from blood. A large ecchymosis on the thigh appeared where the first dose of antitoxin was injected, and the temperature was about the same, and the pulse was very weak indeed, just barely perceptible at the wrist, and could not be counted. The extremities were cold, the face pale and livid, and there was great drowsiness. The child was disinclined to take nourishment; there had been no bowel-movement for twenty-four hours. Tinct. ferri chloridi and hydrarg. chlor. corrosiv. were continued every two hours, and hydrogen dioxid was applied to the throat. Strych. sulph. gr., $\frac{1}{100}$, every four hours, and whiskey and milk were ordered at short intervals. At 12 midnight, $\frac{1}{60}$ gr. strychnin sulph. was given hypodermically.

On November 8th the exudate in the fauces had very much increased, covering not only the tonsils, uvula, and the anterior half-arches, but extending forward in front of the uvula. The exudate in the nares was also increasing; the glands in the neck were sensitive but not swollen. The temperature ranged between 97.6° and 99.8°; the pulse was just barely perceptible at the wrist; the heart's action was feeble, and the extremities were cold. In spite of this condition the child appeared bright and took milk fairly well. Strychnin sulph., gr. $\frac{1}{100}$, was ordered every three hours until two or three doses should be given.

At 5.20 A.M., 10 c.c. of Behring's antitoxin were injected. At 6.10 P.M., sulphuric ether, ℥xv, was given hypodermically, also at midnight gr. $\frac{1}{100}$ strychnin sulph. hypodermically. On November 9th the exudate in the fauces was very much diminished; the heart's action was very weak, the pulse just perceptible at the wrist, but could not be counted. The temperature was about the same. The expression of the child was bright, but it took nourishment less willingly. There had been no bleeding from the nose for three days. Injections of strychnin were continued, gr. $\frac{1}{100}$ every four hours, and artificial heat was applied to extremities. At 2 P.M., 10 c.c. of Behring's antitoxin were again injected.

On November 10th there was still considerable exudate in the fauces and also in the nares; the heart's action was feeble, and the pulse at the wrist was still almost imperceptible; the extremities were cold, and the child took nourishment and stimulants somewhat reluctantly. Three hypodermic injections of strychnin sulph. $\frac{1}{100}$ of a grain, were made in the last twenty-four hours. The child's expression, when awake, was quite bright. The heart-sounds were growing less and less audible, and death occurred at 10 P.M. from asthenia.

CASE II.—E. G. T., aged two years and eight months, white, female, born in Philadelphia, was admitted to the hospital October 2d, having a well-marked exudate on both tonsils and in one of the nasal cavities of less than forty-eight hours' standing. At 6.10 P.M. on the day of admission 10 c.c. of Behring's antitoxin were injected. During the following twenty-four hours the temperature varied between 99° and 100.8°, being about the same as before the injection was administered; the pulse-rate was between 120 and 135; the respirations were from 20 to 30. The exudate on the tonsils seemed unchanged, as also did that in the nose, except that the discharge from the nares was slightly less. On November 4th the exudate in the fauces and nares had neither extended nor diminished; the temperature was unchanged; the pulse-rate and the respirations were about the same. On November 5th the exudate in the fauces and nares was unchanged, except that both nares were now involved; the glands in the neck were only very slightly swollen; the general condition of the child remained about the same as when the injection was given, though possibly there was slight improvement. The child received the same internal and local treatment as the previous case, and took nourishment freely.

On November 6th there was but little change in the exudate in the fauces; the temperature had risen to 101.6°, and the rash of scarlatina had appeared. A sister of this child had developed scarlet fever two days previously. On November 7th the exudate was diminishing both in the fauces and nares; the temperature ranged between 100.8° and 101.8°; the pulse was 120. On November 8th the exudate in the fauces had disappeared;

in the nose it was dry and much less distinct; the temperature was 101.° On November 9th there was no exudate in the fauces, and very little in the nose. The rash of scarlet fever was just barely characteristic. The child's general condition was much improved, and she had quite recovered from the diphtheria. The attack of scarlatina was very mild.

On November 12th gradual improvement was noted, and there was no exudate in the fauces, but there was still a very little in one nasal cavity. The temperature was about normal, and, from the time the scarlet fever began, it had not been higher than 101.8°. The pulse was 120. Desquamation commenced on this date. The child took nourishment well.

Case III.—A. J., thirteen years of age, colored, was admitted November 3d, having been ill four days. The exudate in the fauces covered the tonsils, the anterior half-arches, and the uvula completely. The temperature was 101.6°, the pulse 100, the respiration 28. There was only very slight enlargement of the glands of the neck. There was no nasal involvement. Tinct. ferri chloridi and hydrarg. chlor. corros. were given internally every two hours, and hydrogen dioxid was applied locally every two hours. On November 4th the condition of the fauces remained unchanged; the temperature was 99.2°, the pulse 86, the respiration 25. A 1 per cent. solution of formalin was applied to the throat every two hours alternately with the hydrogen dioxid. On November 5th the exudate in the fauces remained the same; there was no increase of swelling of the glands of the neck; the temperature was 99°, the pulse 88, the respiration 20. There was very little exhaustion, and the child took nourishment well. At 1.10 P.M. Dr. Fischer, of New York, injected 10 c.c. of Behring's antitoxin (a bacteriologic examination was made by Dr. Kyle, and typical bacilli were found). Following this the temperature ranged between 100° and 100.6°. On November 6th the exudate in the fauces continued much the same, though somewhat thinner on the uvula. The temperature ranged from 98.4° and 98.8° to 100.8°; the pulse was about 90, the respiration about 20. The same internal and local treatment was continued; the child took nourishment and stimulants freely. On November 7th the exudate in the fauces had greatly diminished; the temperature was 99.4°, the pulse ranged from 80 to 90, the respiration was 18; nourishment was taken as usual, and the patient slept well. On November 8th the exudate was diminishing rapidly, the swelling of the uvula was much less, and exhaustion was not great. On November 9th the exudate was much thinner and had disappeared in part, though considerable still remained. The same local and internal treatment was continued. The patient was now doing very well, and was placed on the regular house-diet.

On November 10th the general condition continued favorable; the fauces were quite free from exudate, but a little still remained on the uvula. Albumin continued in the urine in the same proportion.

On November 11th there was no exudate in the fauces except a little on the uvula; the temperature and pulse were about normal; the child took nourishment well, and strength was increasing. On November 12th there was a mere trace of exudation on the uvula; the temperature ranged between 98° and 100°; the pulse and respiration were about normal. The child was anxious to sit up.

Case IV.—B. M., white, male, aged five years, was admitted October 18th, on the third day of the disease. The exudate in the fauces was very great, covering the tonsils, the uvula, the anterior half-arches, and extending on the roof of the mouth in front of the uvula; there was also nasal involvement. The glands of the neck were enlarged. On October 19th the child was bleeding from the nose and mouth. On November 20th the exudate was unchanged, and there were croupy symptoms. On October 23d the general condition was about the same; the albumin on this date was about 60 per cent. of the bulk of the urine. The temperature had been running from 101° to 102°, the pulse from 100 to 118, the respiration from 22 to 26. On October 25th the exudate had diminished and epistaxis had ceased. The temperature was about 99°, the pulse 100, and the albumin was only 10 per cent by bulk. On October 30th the fauces were almost free from exudate; no albumin was found in the urine; the temperature was about normal, sometimes subnormal; the pulse ranged from 96 to 100. There were marked evidences of toxemia; there was great pallor and weak heart-action. On November 5th the temperature had been ranging from 100° to 102.6°; there was no albumin in the urine; the pulse was from 98 to 112. There was a mere trace of exudate in the fauces, and still some nasal involvement; the pallor and prostration continued; there was a feeble pulse, and the cervical glands were still enlarged. There was a herpetic eruption on the lips. At 1.30 P.M. Dr. Fischer, of New York, injected 10 c.c. of Behring's antitoxin, the Klebs-Loeffler bacteria having been found to be present by Dr. Kyle. On November 9th the patient was gradually improving; the temperature was from 98.6° to 100°; the pulse from 90 to 120; no exudate existed in the fauces, and that in the nares was gradually growing less; the color was also improving, and the child took nourishment well. The general condition was much improved.

On November 12th the fauces were entirely free from exudate, and only a very little remained in the nares; the temperature was 98.6°. No albumin had been found in the urine for several days past. The child was constantly improving.

Case V.—A white male, eight years of age, was admitted November 9th, having been ill seven days. The exudate in the fauces covered the tonsils, the anterior half-arches, and the uvula, and extended a short distance on the roof of the mouth in front of the uvula; both nares were also involved. The breath was offensive; the glands on both sides of the neck were considerably enlarged, and the skin over the swollen glands was red. The temperature was 102.8°, the pulse 136, the respiration 36. Ten c.c. of Behring's antitoxin were injected under the skin on the back at 12 o'clock M. by Dr. Fischer, of New York. The patient was at this time taking internally about 6 minims tinct. ferri chlorid. and $\frac{1}{3\frac{1}{2}}$ gr. of mercuric chlorid every two hours; locally, hydrogen dioxid undiluted, alternately with a one per cent. solution of of formalin, was applied every hour, whiskey ℥ij every two hours, and milk *ad libitum*. On November 10th the temperature was 100°, the pulse 120, the respiration 32. The exudate in the fauces remained about the same, ex-

cept that it presented the appearance of peeling off in some places; in the nares the exudate was unchanged; the glandular swelling also remained about the same. The child at times was drowsy, and at other times restless.

On November 11th the exudate in the fauces and nares remained about the same; it was still dark in color, and the breath was offensive. The glandular swelling had not increased. The temperature was about 100°, the pulse 128, the respiration 32. Albumin was found in the urine in the proportion of about one-tenth part of the bulk of the urine. The child took nourishment well.

On November 12th there was very little, if any, change in the exudate in the fauces and nares; at times there was slight epistaxis. The temperature was 99.8°, the pulse 116, the respiration 26. There was no increase of the glandular enlargement; exhaustion was not great; and the child continued to take nourishment and to rest well.

I append the report kindly furnished by Dr. Kyle, of the bacteriologic investigation made by him.

BACTERIOLOGIC REPORT.

By D. BRADEN KYLE, M.D.

In the examination of the four cases of diphtheria injected with the antitoxin by Dr. Louis Fischer, of New York, the bacillus of diphtheria (the Klebs-Loeffler bacillus) was found in each case, the bacteriologic diagnosis agreeing with the clinical diagnosis, as made by Dr. Welch. One case was examined by Dr. W. M. L. Coplin, and the other three by myself. A complete bacteriologic report will appear in the January issue of the *American Journal of the Medical Sciences* in connection with an article to be contributed by Dr. Fischer.

It may be of interest to add a brief epitomization of the laboratory-technique of the preparation of the culture-medium, etc.

The bacillus of diphtheria grows best on blood-serum prepared after the method of Loeffler. A wide-mouthed jar, with a ground-glass stopper, which has been thoroughly sterilized, is taken to the slaughter-house and filled with freshly-shed blood of the ox or sheep, young animals being preferable. The skin of the neck of the animal to be killed is shaved, washed with soap and water and a brush, then with alcohol or ether, or a 1 to 1000 solution of mercuric chlorid may be used if the skin is again washed thoroughly with boiled water. One of the great vessels of the neck, preferably an artery, is then opened, and the blood is allowed to spurt directly into the prepared receptacle. The edge of the jar is then cleansed and the jar is sealed by means of the ground-glass stopper, and set aside until the blood has clotted firmly. The jar is then removed to the laboratory and placed in an ice-chest for twenty-four hours. It should be examined every few hours, and if the clot tends to adhere to the sides of the jar it should be loosened by means of a sterilized glass rod. While the serum is collecting test-tubes may be cleansed and sterilized. Two sizes of tubes are needed. A tube four inches long and two-thirds of an inch in diameter may be used for the serum, while a tube six inches long and three-quarters of an inch in diameter is used for the cotton swab. The tubes are carefully washed and dried, then plugged with cotton so wrapped that its surface will be smooth, and when withdrawn from the test-tube will not spread out, but remain firm.

The tubes to be used for the swabs are prepared as follows: A stiff steel rod (an ordinary knitting-needle may be used) is passed through a plug of smaller diameter than the tube. The plug is wrapped so as to firmly hold the steel rod, which is passed through layers of cotton until the plug will tightly fit the caliber of the tube. The end of the rod which is placed in the tube is then wrapped with a small piece of cotton, which should be loose and fluffy at the end, but tightly adherent further up the rod. This arrangement can be effected by frilling the cotton and shortening the fine fibers well up on the rod and wrapping firmly toward the end. The swab is now introduced into the tube, which is placed in an incubator and exposed to dry heat at a temperature of 150° C. for at least one hour. This procedure should be repeated two hours before using the tube. The nutrient beef-broth which is mixed with the serum is prepared as follows: One pound of finely chopped lean beef is placed in one liter of water and allowed to stand for twelve hours in an ice-chest. After twelve hours the meat and water are placed in cheese-cloth or a towel and the fluid pressed out. The fluid thus obtained should be heated and again filtered through a towel, and the amount brought up to one liter by the addition of distilled water; to this is added 1 per cent. of peptone, 1 per cent. of glucose, and 0.5 per cent. of common salt. If the fluid has an acid reaction, a few drops of a saturated solution of sodium bicarbonate may be added. The mixture is then boiled for half an hour and filtered through absorbent cotton into sterilized flasks; then sterilized for half an hour. The blood-serum is now siphoned off through a sterilized glass tube and mixed with the nutrient beef-broth in the proportion of 3 to 1. The serum is poured into the sterilized test-tubes by means of a sterilized pipet, which should be inserted to the end of the test-tube so as to avoid the formation of air-bubbles and to secure a perfectly even surface. Two c.c. of the serum are sufficient for each tube. The tubes are now placed in an incubator and kept at a temperature just below the boiling-point, care being taken to have them inclined in order to obtain a wide surface for the growth of the inoculated germs. Great care must be taken that the serum does not boil.

If kept for several hours at a temperature just below the boiling-point, and if the process is repeated after twelve hours, the serum will remain sterile. The serum thus prepared is quite clear and firm. The tubes can be placed in glass jars, sealed by means of a clamp-top, and kept for months.

The swab for obtaining the membrane for inoculating the tubes is preferable to the inoculating-needle, as the infected areas can be quickly passed over, and the secretions are readily gathered in the meshes of the cotton. Besides, the operator is not exposed so long in front of the patient.

The serum-tube may be brought to the bedside and inoculated at once after the swabbing of the throat, or the swab can be returned to the sterile tube and taken to the laboratory, and the inoculation made there, and the serum-tube placed at once in the incubator.

A few words as to the method of obtaining the infec-

tive material from the throat and of inoculating the tubes may not be amiss. With the patient in a strong light, the operator puts one hand on the patient's head, while with the other he holds the tube containing the serum. An assistant depresses the tongue, and with the other hand holds the tube containing the swab. The operator removes the swab and rubs it firmly but gently against any visible membrane, either on the tonsils, pharynx, or uvula. The swab can now either be placed back in its tube, and the extending cotton singed and the whole be taken to the laboratory, or the serum-tube can be inoculated at once. After the swab has been used and the inoculation made the cotton should be burned, while the steel rod can be again sterilized and used. Should no false membrane be visible the swab should be passed over the reddened mucous membrane. Should false membrane be present in the nose, inoculations should be made from it also. Inoculations should not be made after the application of disinfectants to the throat.

After the inoculation has been made the serum-tubes are placed in the incubator and kept at a temperature of 37° C., the optimum temperature of the Klebs-Loeffler bacillus, for from ten to sixteen hours. On inspection the smooth surface of the serum will be dotted with minute colonies which are barely visible, but by slanting the tube and holding so as to look along the level of the flat surface small pin-point projections can be seen. Spreads and stains should be made at once. Care must be taken not to spread the material too thickly on the cover-glass. This can be avoided by first placing a tiny drop of sterilized water on the cover-glass. The platinum needle is then introduced into the tube and swept over the colonies, and the bacteria adherent to the needle are washed off in the drop of water previously placed on the cover-glass and evenly distributed over the entire surface.

The spread is then allowed to dry in the air, and before being placed in the stain is fixed by being passed quickly through the flame of an alcohol lamp. The best stain is Loeffler's alkaline methylene-blue. The cover-glass is left in this stain without heating for from ten to fifteen minutes; it is then rinsed with clear water, dried, and mounted in Canada balsam. The microscopic examination by means of the one-twelfth oil immersion will disclose what at first appears to be a mixed culture. The bacillus of diphtheria assumes many shapes and forms, yet the refractive bodies and the rounded ends are characteristic.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

STATED MEETING, NOV. 8, 1894.

JOSEPH E. WITTERS, M.D., *Chairman.*

DR. A. CAMPBELL WHITE read a paper entitled "Antitoxin Treatment of Diphtheria, Based upon a Series of Cases Treated at the Willard Parker Hospital." He said that many efforts had been made to confer immunity from infectious diseases ever since Jenner demonstrated that this could be done in the case of smallpox. There was, however, some danger in inoculating persons with attenuated bacilli, and for this reason certain investigators had been following a somewhat different line of research. They had found that by first rendering an animal immune, and then injecting the serum of this animal into a human being, the latter could also be made immune to that particular disease, without the danger attending the other method. By this plan of treatment, the person so treated was not only spared a severe illness following the inoculation, but by properly regulating the dose of the serum given the treatment could be adapted to an infection of greater or less severity. These facts are the foundation of the new antitoxin-treatment of diphtheria. Behring has found that not only is an individual rendered immune by an injection of diphtheria-antitoxin, but if the diphtheria has already developed its course will be promptly checked. The serum is obtained from the larger animals, particularly the horse, and the injections necessary to immunize the animal may have to be continued for several months. The only reaction following the injection of this serum into the human subject is that which may be attributed to the introduction into the system of the serum from the lower animals. The strength of each sample of serum is determined by noting its effect in certain quantities on guinea-pigs of a given weight.

In the Willard Parker Hospital the mortality among adults suffering from diphtheria has been less than 3 per cent.; for children between the ages of five and sixteen years, 13.6 per cent.; and for children under five years, 42.7 per cent. Patients dying of diphtheria from the intoxication of the disease, from extension of the membrane, or from heart-failure, do so usually within the first ten days; those dying later than this, usually succumb to pneumonia or paralysis. Among one-hundred-and-seventy fatal cases observed in the hospital during the past year, one-hundred-and-thirty-five deaths occurred within five days after admission; seventeen within ten days, and eighteen after this time. Of these eighteen, nine died of heart-failure, two of septic infection, one of meningitis, and six of pneumonia. The practice had been to keep all diphtheria-patients in a warm room, in the recumbent position, and on a fluid diet; the nose and throat were irrigated with normal salt-solution, and internally large doses of iron were given and stimulants as indicated. In the laryngeal cases the main dependence had been placed on sublimations of calomel and the use of moist heat.

Recently twenty especially severe cases of diphtheria were selected for the antitoxin treatment, no other treatment being employed with the exception of a single irrigation of the nose and throat with the salt-solution just after admission to the hospital. The average age of the patients had been three-and-a-half years, and the average dose of the antitoxin, 11.3 cm. Fourteen in this series had also laryngeal diphtheria; four of these were intubated, and one tracheotomized. One intubation-case, in a child of three years, died on the twenty-fourth day of lobar pneumonia. The tracheotomy-case unexpectedly developed a broncho-pneumonia from exposure to cold, on the thirty-fourth day. Of the six cases in which there was no laryngeal complication, only one died, and that was a child that was apparently well and on the road to convalescence from the diphtheria when it developed scarlatina. In these latter

cases, then, the mortality was 16.6 per cent., while in the laryngeal cases, instead of the usual mortality-rate of 50 per cent. or over, it was 28.5 per cent. The injections of the antitoxin caused no local irritation or reaction of any kind, with the exception of an occasional slight eruption. The temperature was not markedly affected, but the pulse was decidedly improved after the first few hours. The antitoxin treatment did not hasten the disappearance of the diphtheria-bacilli, and it did not markedly hasten the disappearance of the membrane.

Twelve other cases, all under five years of age, were treated with the weaker "immunization-solution" of Aronson, and among these the mortality was 25 per cent.

Statistics compiled from various sources show that out of a total of 486 children, 116 died, or a mortality of 23.8 per cent. in a class of cases in which before the introduction of the antitoxin-treatment the mortality had been 60 per cent.

In conclusion the author expressed the opinion that in addition to conferring immunity from diphtheria for a certain length of time, the antitoxin was a specific for this disease, and was capable of averting death from absorption of its toxins.

Dr. Herman M. Biggs said that during the past summer he had had exceptional opportunities in Berlin for studying this new treatment of diphtheria. It should be remembered that this was not a recent discovery, but the result of years of scientific research. He had been particularly struck with the fact that all of the eminent bacteriologists connected with the Institute for Infectious Diseases in Berlin, after carefully following 500 cases treated with the antitoxin, were unanimous in expressing the opinion that this treatment has already passed beyond the experimental stage. Bacteriology has shown that the constitutional disturbances exhibited in the various contagious diseases are due to bacterial products, and it has been demonstrated by experiment that immunity can be produced artificially by inoculation with these chemic products of the microörganisms. It has also been demonstrated that this immunity is the result of the development of something that neutralizes the chemic products of the bacteria. The strength of these products in diphtheria can be measured biologically by their effect on animals. An antitoxin may be developed in the circulation by inoculation with these chemic products of the microörganisms, and the amount of the antitoxin can be very greatly increased by gradually increasing the quantity of the toxin injected. Clinical experience has shown that the dose of the antitoxin-solution must be adjusted to the age and weight of the patient as well as to the severity of the infection.

Dr. William Hallock Park said that it had been shown by experiment that after the antitoxin had been injected and the power of the toxin neutralized, both the antitoxin and the toxin were still present. If the inoculation of the trachea of an animal with diphtheria be immediately followed by an injection of the antitoxin-solution, the development of the characteristics of diphtheria will be prevented, but if the injection of the antitoxin were delayed somewhat longer, a larger quantity would have to be employed in order to prevent the development of the diphtheria. It does not, however, affect the diphtheria-bacilli: they may be grown on cultures that have been impregnated with the antitoxin. Dr. Park has been able to collect 1180 cases of diphtheria treated by the antitoxin with a mortality of only 20 per cent.

Dr. George F. Shrady said he could recall the time when diphtheria was a new disease in New York City, and when the mortality was as high as 90 per cent. He had followed the cases undergoing the antitoxin-treatment in the Willard Parker Hospital, and he could heartily indorse the method.

Dr. W. P. Northrup said that it should be remembered that there had been no severe epidemic of diphtheria in New York City since the beginning of last July, and that on this account deductions from the few cases so far reported should be made with great caution. He thought the treatment was likely to render the greatest service in fulminating cases that occasionally occur.

Dr. Louis Fischer said that he had spent the whole summer with Professor Baginsky studying this treatment. The practice in Berlin had been to employ the injections in every case proved by bacteriologic examination to be true diphtheria. In his own cases he had not usually observed any change in the local or general condition until about forty-eight hours after the injection of the antitoxin.

Dr. H. W. Berg remarked that the difficulty in estimating the true value of this treatment lay in the fact that we had no way of determining at the outset whether or not a given case of diphtheria was specially severe.

Dr. J. Lewis Smith said he would like to know if the antitoxin-treatment had any beneficial effect on pseudo-diphtheria.

The Chairman replied that Aronson had stated that it had no favorable influence on cases of mixed infection. The ordinary mortality-rate of diphtheria in New York City was not much over 25 per cent. The very fact that most of the recent cases of diphtheria had been very mild, so that many recovered without any treatment, should make us especially cautious about drawing any positive conclusions from the cases presented. This could only be done after the treatment had been on trial for a long time and in the hands of many physicians.

Dr. White, in closing the discussion, said that a sufficient guarantee of the severity of the cases that he had submitted to the antitoxin-treatment was to be found in the fact that in fourteen of the twenty cases the disease involved the larynx, and that the patients, with one exception, were all under five years of age. The ordinary mortality in our hospitals in this class of cases was 40 or 50 per cent., and this had been reduced to 25 per cent. in the cases treated with the antitoxin.

NEWS ITEMS.

Special Course in Bacteriology.—A course of ten lectures on bacteria, by Dr. M. V. Ball, at the Academy of Natural Sciences, Nineteenth and Race Streets, on Fridays at 3 P.M., was begun on November 9th. Medical students and others interested are invited to attend.

Muscular Anomalies and Squint.—A series of lectures and demonstrations, together with clinical work, will constitute a special course upon muscular anomalies and

squint, to be given at the Philadelphia Polyclinic during the week commencing November 19, 1894.

The Value of State Medical Examinations.—At the September examinations for State medical license by the board representing the Medical Society of the State of New York, the number of candidates was seventy-six, of whom fifty-one were successful and twenty-five unsuccessful.

The Statue of Dr. J. Marion Sims.—By an error it was stated in THE NEWS of November 3 that the unveiling of the statue to Dr. Sims took place at Brooklyn instead of at Bryant Park, New York City. It was also said that the statue was the first of a physician erected, while the statement intended was that it was the first statue of a physician erected in this country.

Meetings of Philadelphia Medical Societies:

ORIGINAL ARTICLES.

POPULAR ERRORS CONCERNING INSANITY.

BY R. M. PHELPS, A.M., M.D.,
OF ROCHESTER, MINN.;
ASSISTANT SUPERINTENDENT ROCHESTER STATE HOSPITAL; MEMBER OF AMERICAN NEUROLOGICAL ASSOCIATION, ETC.

INSANITY, though technically held to be a medical subject, has a large border-line of questions concerning its actuality, its essential elements and limiting boundaries, that belong more properly to ordinary or social philosophy; such aspects must be frequently met by legal decisions, and judgments concerning them must be made by citizens having social and legal relations of many kinds with the border-line cases. It is as a question of popular interest, and one deserving of vastly more popular, intelligent thought, that the subject is here presented.

Such consideration is needed to bring more clearness, more rational action in legislation, more of reasonable and less of the blind, perverted malignant criticism of asylums for the insane by the ordinary well-informed classes of society, including its lawyers, ministers, merchants, and most intelligent citizens generally.

And first, we find, oddly enough, that no one is so ignorant or knows so little of insanity that he does not make impromptu very positive judgments in regard to it. Living with and among the insane of a large asylum population we are frequently told that "this one surely is not insane;" that we "ought to let that one out;" that they "know of several cases who are railroaded into an asylum;" that "we have some here who ought not to be here," etc. So coolly and decidedly are we told these things right on our own threshold that after a time we shrink from the long argument which likely, after all, only half convinces, and we are prone to content ourselves with the decided protest, or else at times ignore the reflection altogether, and smile at the thought of how coolly our years of experience and long contact with this special insane case under question go for naught before the five-minute examination. The slight regard in which expert testimony is held is shown no better than by the total disregard of the testimony of physicians expert in judging of insanity in the Prendergast trial. Although quite uniform, good, and unwavering, it was coolly disregarded and set aside by lawyers, by jury, and by newspaper criticism.

A second way in which confusion of thought shows itself is proved by the suspicions of the most unreasonable character that run through the papers and through the popular gossiping conversation at the first misfortune at an asylum. By inference, at least, it is judged that each asylum is kept and controlled by *men of criminal intent*, while lurid pictures of daily happenings are fully and eagerly accredited. Like the preceding criticisms, this contumely has to be accepted coolly and calmly by the officers and employés as part of the *impedimenta* of the business, unless, forsooth, these would in sheer disgust give up their positions.

It is impossible to fight such criticism, and it will only disappear as the future will, by the gradual withdrawal of the seclusion-element, and by the slow spread of intelligence concerning the class, dissipate such clouds of skepticism. Of course also here, as in all lines of work, a steady progress in intelligent care and a true hospital-spirit of nursing will avoid to a more perfect extent the occasional happenings which furnish a basis for such criticism.

We believe that there are some reasons for this popular distrust and misjudgment, and also for the popular unbelief and mistrust of experts and expert testimony. We would outline the first point leading toward clearer ideas in this form:

1. *Insane people are more or less reasonable people.* That is to say, they both use their reasoning powers, and they use them moreover in a reasonable manner. Although few have ever formulated the saying, "insane people know nothing," yet nearly all have made judgments, or have read and accepted judgments having this as its practical basis. The arguments of the prosecution concerning the insanity of Prendergast, accused of the murder of Mayor Harrison of Chicago, all had this as their fundamental error. It was found through newspapers, in conversation, and everywhere. It was argued that because *he was afraid of death he must be sane;* because *he could remember accurately he must be sane;* because *he could plan ahead he must be sane.* This was the drift of the arguments that decided his conviction of murder upon the ground of sanity. But insane people are more or less capable and responsible in business. Peterson reports the case of a switchman doing regular work. The trouble is that every man whose mind works untruly or wrongly in any *one*

discoverable way is denominated insane, though much of ability, intelligence, and responsible action still remain in other ways.

It is evident upon consideration, however, to the most heedless mind that such a one is vastly different from one in a dull, stupid condition of terminal dementia. The first point toward clearing up the fog about the question, then, could be restated about as follows: *In insane people varying degrees of intelligence and ability still remain.*

2. Our second point is to be inferred from the preceding. It is that *insane people grade from very slight mental defects toward the profoundly dull, the overpoweringly depressed, the wildly exalted, or the weakly silly.* This, again, would seem an easy, almost self-proved statement, but as it is practically often ignored, it is needful to make it very prominent here. One person is able to carry on a clear conversation, perceive clearly, reason accurately, to do good business, or what not; while another is too stupid to speak, or too overwhelmed by acute mania, or by the oppression of a melancholia, to have much if any consciousness of what is going on about him. The contrast is great, yet to *both* of these extreme cases is applied in common *the name "insane."* The inference is so clear as seemingly to need little further explanation. The gradual line of increasing ability in a series of cases can be made out clearly in any large hospital for the insane. Ought the man at the intelligent end of the series to be ignored as a man of likes and dislikes, as a man of duties and responsibilities, as much as the man at the other end of the series necessarily is? The answer seems so evident as to hardly need framing.

3. *Not all insanities technically such ought to receive the name insane.* For example, a person in the process of getting drunk goes through various phases of mental impairment or insanity, yet because of its transient character it is rarely so named. If, however, the conditions of mind in many intoxications were *permanent*, it would be easy and just to call such a person insane.

So, too, in the delirium of fevers, the person is practically insane. But the state being transient and of transient causation, the name is not applied. Many drugs produce transient mental perversions to be considered in the same way. From blows on the head, from surgical operations about the head, from gross brain-wounds, similar impairments of a transient nature are noted. Among more chronic troubles the mental impairments of early epilepsy are frequently asserted by good authorities as not to be insanity. The perversions of chronic inebriety are by some spoken of as insanity, by others not. Reform-schools and prisons always hold some cases to whose mental state it is doubtful whether the name insanity would be applicable or not. The fundamental endowment of some people is occasionally so lacking that some of the more critical will call them insane. A little thought, therefore, will show that the word "insanity" is applied to a long, graded series of cases which vary to an astonishing degree among themselves; and, moreover, that the state of the person must be *permanent* enough and *obtrusive* enough in the public mind to make the name "insanity" seem popularly applicable.

4. *The change from sanity to insanity is not instantaneous.*

Even as we watch the slow recovery of an insane person as he gradually discards one after the other of the mental perversions which have crowded his mind, so we can watch the gradual descent along similiar lines. It is only occasionally that a single day brings on the state. Usually weeks, even years, can be included by careful questioning. The practical outcome of bluntly stating the foregoing is manifold.

Prominently it will be seen that during this descent people are doing acts criminal, civil or social, whose responsibility may be afterward called in question. Secondly, this descent may be stayed in its progress at almost any stage, thus rendering less clear the decision of the mental state. For it is easy to throw distrust over the early acts of one who is found *subsequently to be profoundly insane.*

But when the early state of mental weakness *stops as such*, and never becomes openly violent or insane, it will be rarely acknowledged as such by all concerned. But that there are such cases there is no doubt.

5. As a fifth point I introduce with somewhat of hesitation and caution the statement that *we find vaguely outlined in sane people as morbid feelings, hysterical acts, etc., the same mental states "in kind" as are observed among the insane.* I will not criticise anyone for differing with me, but will put this in the form of an opinion rather than a fact. Close introspection, at least with some of us, will reveal moods of depression, perhaps cleared up by fresh outdoor walks, and replaced by a more elated tone of mind. As we compare this morbid, illogical, and practically unreasoning depression with the state of mind of a very mild melancholiac who has not defined delusions, we can see vaguely the same depressed ideas in the latter case only in a more exaggerated form. So, too, hysterical acts in their more intense and less controllable form are found to constitute a type of maniacal state.

But if one cannot find—indeed, if he have not the data to find any such resemblances—many can at least know of and follow more closely the same kind of thinking as manifesting itself occasionally in the father, brother, or some other relative of the patient. Of course, in such case it is no more

strange, probably, to inherit the perversions of mind than it would be to inherit the more natural activity. At any rate, such judgments are made quite commonly to me by those technically ignorant of insanity. They are found in such expressions as, "Well, you will find that trait all through the family." Or again, "Her mother was very nervous and unstable also." Or, "I think she gets this trouble from her father," etc. Indeed, in cases in which heredity is constantly denied by the family, and dare not be asserted by the physician, such relatives often so notoriously show mental peculiarities that even such people as hackmen, landladies, or those who have only transient knowledge will assert, though in inelegant terms, the likeness. In due caution, however, it should be said that such likeness is only an occasional one, for in the large number of cases it cannot be found.

But more clearly than we can trace in different people these resemblances can we follow the *same person* up through the varying degrees of perversion. Take, for instance, a melancholiac as he progresses through the varying degrees of intensity of such depression to a fully defined hypochondriacal or melancholiac state. This occasionally progresses so slowly and deliberately as to exhibit most or all of the intermediate gradations. By all these, as well as in reasoning by analogy, there are *in the sane* outlined vague resemblances to the corresponding *insane* states of mind.

We reluctantly set forth this last point because of the wrong inferences that may be easily drawn from it. We do not mean to speak of everybody as a little insane, but only as *more or less ideally perfect*, and as possessing *more or less of mental ability*, and more or less of mental *stability* as well. Stated in this form, we do not think much of argument is necessary to sustain the statement.

6. It is charged that people send their relatives and friends to asylums to get "rid of them." The point that we would make is that a *large proportion of insane are sent to asylums to* (*in one sense*) *get rid of them*. This is one of the true functions of the asylum as well as of the school for imbeciles, that for the deaf and dumb, for the blind, for inebriates, and for defectives generally. If one stops to think of it he will see that it is *possible* to keep outside every insane person, but that the State policy is to offer its care for them if they get very troublesome. It offers, of course, supposedly better care, both medical and custodial, than would otherwise be obtainable; but the fact remains that one of the chief functions of asylums of all kinds is to relieve people of the burden of their relatives, which burden they can only carry themselves in an imperfect and defective way. And this asylum-care has, of course, more the element of *cure* than has the home-care. This being admitted, the only question remains, "How much of trouble" should be borne by relatives before accepting the care of the State? The answer is very complicated. It needs special consideration in each case. If wealthy, of course a good deal more should be done by relatives than if very poor. The degree of trouble to be borne before sending to the asylum will be seen to vary with varying circumstances, with varying ability, and with the estimated prospect of a cure.

A good many statements with less of the philosophic character than the preceding might be added. For example, it might be said that an *asylum is not full of raving patients*. If it is an asylum of over 1000 of all grades of insanity, both acute and chronic, with approximately one new patient per day (as is the case here), three or four cases of typical acute mania are about all that are liable to be found at any one time. Again, *raving cases do not continue raving*, but most always quiet down quite rapidly. Again, the frequent inquiry for dungeons or cells leads me to say that they *hardly have existence in the United States;* I never saw any of them.

Now, how will these preceding statements, if accepted, clear up the existing confusion of mind spoken of in the beginning, for example, that problem of expert testimony over which so many are honestly stumbling. If two equally able and opposing experts give opposing testimony, does it denote either perjury or incapacity somewhere, as has been hinted? I do not wonder at the question; but in the light of our analysis I would say that the solution would appear fairly easy. The cases that come under question in this way are probably and usually those border-line cases which can be easily decided one way or the other by the same experts, by simply shifting their standard of sanity a little forward or backward. I think the main error common to experts is the assumption of a partisan instead of a judicial attitude. Knowing that the whole case—judge, jurors, and community—demand a verdict of *total responsibility or total irresponsibility* of even the most border-line case, they, impressed as they are by past experience to the same effect, swing from their actual medium position to a positive one, disregarding thus entirely the first and second points made in our analysis.

I think I can conceive of a case, not necessarily imaginary, in which I could with equal justice, and equally valid arguments, maintain either the side of sanity or insanity. Let us take a case to illustrate (of a kind not essentially peculiar, nor perhaps as good as would be the insanity of epilepsy, but chosen as being the most familiar to our readers), of an aged man, who, gradually between the ages of sixty and seventy, becomes more and more feeble-minded, until at the age of seventy actual delusions

have crept in, and he is dull, perceives imperfectly, is querulous and hard to control, vacillating with motor feebleness, and in short, is a typical case of senile dementia. This is a very ordinary picture. Now at sixty he was confessedly sane and quite able. As he grew, first irritable, later garrulous and forgetful, still later selfishly suspicious and more forgetful, until finally delusive ideas prevailed, there must be passed somewhere a time when any expert would be puzzled not over the fact but over the name. One expert might place his standard of sanity near the sixtieth year, and say that the first changes of disposition constituted insanity. Another might place his nearer the seventy-year mark, and say that only when actual defined delusions appeared could insanity be named in the case. Another might say that ordinary early senile changes were normal and physiologic, and ought not to be called insanity at all.

But, pushed logically backward from the age of seventy, every expert, if logical, would find a point of doubtful standing and a place where the name would change from sane to insane, and where therefore he could give either name equally well. Of course, if thus cornered, he would say at once that like the distinction between youth and old age, he could give the facts, and the name would not signify. Yet he would immediately, under our present court-practice, be confronted with the fact that the name does occasionally signify all of the difference between life and death for the criminal. If still of logical mind, he would say the courts then ought to change, and recognize impaired mentality of varying degree, establish various degrees or kinds of restraint or penalty for such cases.

The rationale of this discussion is thus seen to lie in the fact that the law and public opinion do not, as yet (except in a roundabout way), thoroughly recognize any gradation between absolute non-responsibility and absolute responsibility. Consequently, the expert coming on the witness-stand thinks he must give, and in fact is half-obliged to give, one of these two opinions; and he will swing to the one side or the other of his "middle" position as he thinks he most honestly and justly can. Compelling the expert to take a judicial position is the only remedy. Allow him to admit reasons for leniency of judgment in the case of the criminal whom he has adjudged sane, or, on the other hand, for a severe restraint in the case of the criminal whom he has adjudged insane, because of the varying degrees of intelligence and responsibility exhibited. Although a full recognition of this is probable decades in the future, yet we cannot think the problem of expert testimony fully solved until such recognition is made.

By common consent insanity is indefinable; it is difficult to form a definition that is inclusive of all in anity and exclusive of all forms of sanity. As Dr. C. H. Hughes outlined before the International Medical Congress, no definition can be acceptable which leaves out idiocy, feeble-mindedness, and inherited states. To this idea we simply add by carrying our thought out into the world at large, and concluding that no one is ideally healthy, no one is ideally sane. As we say that a person is physically well, in spite of some deviation from the normal, so we can say that a person is mentally sane in spite of some deviation from the normal. And as these physical deviations, growing steadily worse, must sometime take to themselves the name disease, so the mental deviation, if increasing, must take to itself the name insane.

If these are true ideas and in the line of advance, the sooner they are adopted the better. The appeal is to common sense, and to common good judgment we must leave the answer as to their truth. As to the measures that follow their adoption, the main one, of course, will be modified penalties for the criminal insane, and modified restraint for the non-criminal insane; these modifications to be graded to meet the various grades of criminality or responsibility decided upon. But we think no hasty action should be advocated. Our knowledge as yet is not accurate enough to outline more than a few of these gradations. The words "defectives," "cranks," "neuropaths," "perverts," "feeble-minded," etc., indicate, however, a strong tendency to make such distinctions by medical and non-medical men. In the Prendergast trial again, the words "not entirely and perfectly sane" were used by the Judge in his charge as indicating a state still responsible enough to deserve hanging. The world is full of such expressions as "somewhat cracked," "not quite right," "a little daft," "very queer," etc., showing that the common sense of the world has for centuries recognized a multitude of impairments of mind, even while the medical and legal wisdom has refused to recognize such for fear of social disorganization.

The *medical* ideal is to find a point of unsoundness. The *legal* ideal is to find a state which shall be of "so great" mental disorganization as to make it evident that the patient can be held irresponsible without affecting public safety. The two elements are not considering the same question, and, as a matter of course, confusion and contradictions abound. The jury practically said, Prendergast is not insane "enough" to avoid punishment for the safety of society. Of course, in border-line cases the medical and legal views do not come to a square issue, inasmuch as the attorneys will befog the case for their own benefit, and the Judge will be thus the only one left to try and make it clear.

I think the first thing that comes to mind in considering any such doctrine as that of a modified but not destroyed responsibility is, that it unsettles free will and all complete responsibility, leaving us without a firm foundation to which to pin any faith. But this is but a most superficial view; a little inspection will show that we never can know, with even close approximation, a man's mental or moral standing, anyhow. It will show, logically, if man is not considered physically completely well and capable, or, per contra, absolutely incapable, that therefore insanity, considered as a symptom of physical changes, follows the same law of gradations instead of taking a position at one extreme. That to assume some exact and instantaneous line of division between sanity and insanity is to assume something contradicted by facts and by analogy itself.

If modified penalties were provided for the decisions of judges and juries they would decide more cases to be insane when so argued by the physicians. As it is now, the juries all know that it is wrong and dangerous to let such a man as Prendergast free; and they therefore override the testimony of insanity because they believe in some way that society should be protected; and in the latter idea *they are right*. It is evident that all men of homicidal tendencies ought to be restrained somewhere, and it is also evident that an insane paranoiac proved guilty of homicide ought to be committed somewhere for life in spite of insanity. The safety of society demands such restraint, and such provision would be much more wise than to hang some and let others go free after temporary detention.

For a last point, to the person who still fears the effect of admitting the doctrine of modified responsibility, we would seemingly only need to point to the fact that they themselves have admitted such a state frequently and easily, and have not found any disorganization of society to occur thereby. In young children we have practically a partial responsibility. As infants they are regarded at first as not at all responsible—later, as somewhat responsible, yet not suffering penalties by law for criminal acts; later, they become more responsible and receive modified penalties, such as the reform-school or asylum; later still, under the law of penalties, they are judged criminal, yet within allowances made for their youth; while finally, at adult life, they receive the full penalty of the law. If, then, children are so judged, what more of essential difficulty will there be in adopting modified responsibility by reason of *acquired* defect for such defectives as inebriates, the somewhat feeble-minded, and those in the earlier stages of insanity?

In final conclusion, then, we may be pardoned, if we regard the foregoing doctrines as based upon sound foundation, even though so far in advance of the times as not yet to have full recognition. Of course, a full study of the details is only for medical investigation and long medical experience. We cannot see that it will ever be possible that the judgments as to insanity can be given over to any kind of a jury in the place of medical men. For, as students of this special branch, we look back at the vague ideas of insanity which we had before making a specialty of it, and note the gradual growth of perception of accuracy which have come with such study since that time. We realize that it is only by medical and philosophic study of long duration that the greatest accuracy can be obtained.

Yet on the other hand it is manifest that popular ideas are daily overriding or setting aside such principles as are established by such long study, and that there is necessary an advance in popular ideas so that expert opinion will be accredited and accepted.

SOME OBSERVATIONS ON A METHOD OF MULTIPLICATION OF THE AMŒBA DYSENTERIÆ (AMŒBA COLI).

BY H. F HARRIS, M.D.,
OF ATLANTA, GA.

So much has been written during the last few years, both in this country and abroad, concerning the amœbæ dysenteriæ, and so general is growing the belief that they are the main causative factors in the production of certain very important pathologic processes, that every fact connected with their life-history becomes of interest and possibly of importance. Notwithstanding the numerous studies of these organisms that have been recorded, no direct observations, so far as I am aware, have been published concerning any method of reproduction. It is true that Kartulis succeeded in cultivating them in alkaline straw-infusions, and has described non-motile granular bodies that he supposed were spores; but, so far as I am able to learn, this was a mere inference based on no positive evidence. As other members of this group frequently multiply by direct division it naturally suggests itself that the same would also occur with these, but the failure heretofore to observe this seemed to indicate that if such is actually the case it must be of rare occurrence or does not happen out of the body at all.

During the last three years I have very frequently studied these organisms, and, although indications of reproduction were always watched for, never did I meet with more than a suggestion of this until July 16, 1894, when, while examining the fecal discharge from a patient who had relapsed two weeks before from what was apparently a complete recovery from the chronic form of amebic dysentery;

I noticed a large ameba lying in the situation shown in Fig. 1, *a*.

The main body of the ameba was elongated to many times its width and clubbed at either extremity. The lower portion of the body moved down the field more rapidly than the upper, causing a constriction near the middle, which progressively grew smaller and smaller; there had been apparently a pseudopod sent out, and following this, a constriction between its distal end and the body of the ameba,

FIG. 1.

Showing triple division. *a*. When first seen. *b*. After segmentation. *c*. Amebæ, with small and very unusual pseudopodia. *d*. One hour after division.

so that, when first seen there was a small band, not wider than 1 μ, but of considerable length, connecting the two bodies; this band was composed entirely of ectosarc. In perhaps half a minute after the ameba was first seen the thin ectosarc-rod joining the pseudopod with the main body parted near the middle, the ends becoming immediately rounded, and being drawn back rather quickly into the larger masses to which they were respectively attached; a few seconds later the body of the ameba divided at the point of greatest constriction, the ends being at first irregular, but becoming quickly covered over by the ectosarc. Even until division occurred the narrowest point of the body was 4 or 5 μ wide, and the ectosarc was continuous through the center. The two bodies produced by this separation, as the body previously liberated had done, at once became more or less rounded, moved, threw out pseudopodia, and in both movement and appearance in every way resembled ordinary amebæ.

In Fig. 1, *b*, are shown the relative position and form of the organisms about three minutes after segmentation. They seemed to retain but little vitality after division had been completed, which was possibly due to the fact that they had been passed several hours before and were examined at the temperature of the room; the weather, however, was very warm. Notwithstanding that there was but little progressive movement, for a time two of the amebæ sent out many pseudopodia, the character of some of which was very peculiar and like none I had before seen; the peculiarity referred to was first noticed in the ameba resulting from the pseudopod about five minutes after separation, and consisted in the protrusion of pseudopodia composed entirely of ectosarc, of a uniform diameter of about 2 μ, of a length about equal to the diameter of the body of the ameba, rounded at the extremity and sometimes straight, but usually bent at one or two points; they moved slowly from side to side, occasionally lying full length upon the surface of the ameba. After a time they were retracted, except in one instance, when, while lying upon the ameba, fusion took place between the two. From the larger of the two other amebæ similar slender processes were projected, never quite so long as in the other, but often many were thrown out simultaneously, as shown in Fig. 1, *c*; those coming out in near proximity gave a strong resemblance to the villous processes that occur in other varieties of amebæ. Their movements forcibly suggested that their object was the inclusion of food-materials. The large pseudopodia were in every way like those found in other amebæ. The remaining ameba became quiescent immediately after division and gave off no pseudopodia. Their appearance after one hour is shown in Fig. 1, *d*.

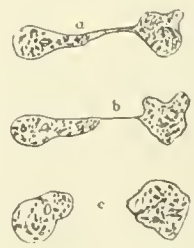
No further examination of the feces was made on this day, the foregoing being regarded merely as a chance-observation, not likely soon to be repeated.

Two days later the discharges were again examined, with the result that several amebæ were seen to divide into two. No other examples of the triple division were seen. In Fig. 2, *a*—*c*, is shown

FIG. 2.

a–*c*. Showing usual method of division.

FIG. 3.



a–*c*. Showing unusual form of segmentation; the middle portion, instead of breaking, slowly fades from view.

the type of division as generally observed. The body of the ameba elongates, a constriction results somewhere about midway between the two ends,

and increases until a mere filament of ectosarc remains, which suddenly snaps asunder. Occasionally variations occur, as in Fig. 3. When first seen the ameba was lying as shown at *a*, clubbed at the ends, somewhat constricted toward the middle, and seemed to be perfectly immovable; however, after some minutes slight alterations in form could be detected, and a narrowing of the intermediate portion, with a movement which was so slight that it was at no time perceptible; the connecting band became smaller and smaller, until it gradually faded from view. The two amebæ resulting scarcely moved after division had been completed.

On the 19th of July division was again observed, but two days later, although the organisms were quite active, the most careful examination failed to show anything of the kind. The patient died on the following day. Unfortunately, no post-mortem examination could be obtained.

It should be stated, in conclusion, that the amebæ from the stools of this patient were, some months before, examined very frequently for a period of over two months, and although they were quite active and very numerous, at no time was the slightest evidence of multiplication seen. The organisms here could in no way be distinguished from those which I have examined from other cases of amebic dysentery, and, with the exception of the related peculiarities, conformed in every particular to the descriptions of the best authorities.

UMBILICAL HEMORRHAGE: ETIOLOGY, PATHOLOGY, AND TREATMENT. REPORT OF A CASE.

By CHARLES F. CRAIG, M.D.,
of Danbury, Conn.

Hemorrhage, occurring at birth or soon after, from the umbilicus may be caused either by loose ligature of the cord or laceration of the same, or from pathologic conditions present in the blood-vessels or blood of the infant. It is with the latter variety, or true umbilical hemorrhage, that this paper has to do. Cases of this kind, unless the hemorrhage takes place from the umbilicus itself, and not from laceration or faulty ligature of the cord, are comparatively rare. The following is a *résumé* of most of those recorded:

Mr. Watts, of Kent, England (*Gentleman's Gazette*, April, 1752), reported one case. Dr. Francis Minot, in April, 1852, reported statistics of 46 cases. Dr. Stephen Smith, in 1855, reported statistics of 79 cases. Dr. J. Foster Jenkins, in 1858, published a monograph giving histories of 178 cases, and Grandidier collected the histories of 202 cases.

Taking all the statistics together, about one-third of the cases occurred in females, and two thirds in males; but it is hardly probable that sex has anything to do with the liability to the hemorrhage.

The time of greatest danger of hemorrhage taking place seems to be after the cord has fallen, as only 18 of Jenkins' cases occurred before this, while the greatest number occurred between the fifth and fifteenth days.

The causes of umbilical hemorrhage are generally either a faulty condition of the blood, especially its feeble power of coagulating, or a pathologic condition of the vessel-wall, or both. The accident is sometimes referable to the hemorrhagic diathesis or hemophilia. As to the cause of the diathesis, syphilis may be said to be the chief one. The disease may not only so alter the blood in the infant as to destroy its coagulability, but also produces inflammatory condition in the walls of the vessels. Sir J. Y. Simpson attributed many of his cases to this inflammation, which he believed caused thickening and infiltration, loss of contractility, and, therefore, a patulous condition of the vessel-walls.

Jaundice is sometimes accompanied by bleeding from the navel, and the icteric hue is nearly always present in umbilical hemorrhage. A condition of ill-health or anemia in the mother, due to any cause, produces a certain degree of a like condition in her offspring, and in this way may be an indirect cause of a liability to hemorrhage. Rarely, no cause can be found either in infant or parents.

The manner of occurrence of umbilical hemorrhage is interesting. Generally, without premonition, the first thing noticed is that the baby's clothes are soaked in blood, although this is sometimes preceded by jaundice. Out of 175 cases, 41 were so preceded. Colic, clayey stools and vomiting may also precede the bleeding. The blood may ooze slowly or rapidly. The most dangerous hemorrhages are those that occur at night, and in which a large amount of blood is lost before they are discovered.

As regards prognosis these cases are nearly always fatal, about ninety per cent. of infants so affected perishing. When jaundice and hemophilia are present the case is almost hopeless, while those cases having healthy parents, and in which the blood flows very slowly, stand a much better chance. Death occurs from exhaustion in from a few hours to three or four days.

The treatment may be summed up as follows:

1. Apply a compress of lint or sponge, soaked in an astringent solution, such as tannic acid, over the umbilicus.

2. If bleeding does not cease, cover the umbilicus with a thick layer of plaster-of-Paris, held in place until it hardens, and then bind this down with a bandage.

3. As a last resort employ the needles and ligature, passing two needles through the umbilicus at right angles, and wind the ligature around each in the form of a figure 8. These can be removed, if the infant survives, in four or five days and an iodoform-dressing applied.

4. A laxative should be given if indicated, and a few drops of brandy in sterilized milk as stimulation is needed.

At 9 P.M., October 5, I was called to attend L. S. in her confinement. She is an American woman, forty-one years of age, and has had four children, all of whom were and are healthy, the youngest being now ten years of age. After a long labor, due to defective pains, she gave birth to a boy weighing about seven pounds. At the time of birth he was nearly asphyxiated, but was finally brought around; the cord was carefully tied and washed, and the child placed in bed, where he was quietly sleeping when I left the house. On my visit next morning I found both mother and baby doing nicely. Early the next morning I was awakened by a messenger who said that the baby's cord was bleeding. I hastened to the house and found the child's clothing soaked with blood, and on removing it, saw that the blood oozed from the point of juncture of the cord and the floor of the umbilicus. I at once applied a compress, and the bleeding ceased in a few moments. The mother said that waking in the night, she lifted the baby, and in so doing felt something warm flow over her hand. Calling for a light, she saw that the baby's clothing was covered with blood, and at once sent for me. The blood was not clotted in the least, nor would it clot. On my call later on the same morning, October 7, I found that the bleeding at the umbilicus had ceased, but was told that the baby had vomited blood several times. For this I ordered grain-doses of tannic acid, to be repeated every hour until the vomiting ceased; and on calling that evening found that no more blood had been vomited. The next morning (October 8), I found that no more vomiting had occurred, but that the child had a jaundiced look. Later in the morning I was again called, and on reaching the house found the baby's clothes over the abdomen saturated with blood, and on removing them, I found the blood oozing rapidly from the umbilicus. I at once applied plaster-of Paris, which stopped the bleeding, but the baby died in a few moments afterward. At the time of death the skin was deep-yellow in color, and there were numerous purpuric spots over the forehead.

I was unable to procure permission for a post-mortem examination. The fault in this case lay in the blood of the child, no doubt, as it would not coagulate.

A remarkable feature of the case was the occurrence of intestinal hemorrhage on stopping that at the umbilicus, and the re-establishment of the umbilical hemorrhage after the vomiting of blood had been controlled by the tannic acid.

I could obtain no history of syphilis or other constitutional disease in the parents.

GUAIACOL EXTERNALLY IN TUBERCULOSIS.

By J. SOLIS-COHEN, M.D.,

PHYSICIAN TO THE HOME FOR CONSUMPTIVES, CHESTNUT HILL; HONORARY PROFESSOR OF LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE; EMERITUS PROFESSOR OF DISEASES OF THE THROAT, PHILADELPHIA POLYCLINIC, ETC.

In The Medical News of September 30, 1893, I published a "Preliminary Note on the Pronounced Effect of the Endermatic Use of Guaiacol in Controlling High Temperature in Tuberculosis." After more than a year of continuance of the treatment it is worth while to add my present satisfactory impressions of the remedy, the result of its use in something under fifty cases, some thirty of them in the Home for Consumptives at Chestnut Hill, and therefore under peculiarly favorable surroundings.

We began in that institution with a dose of ♏ xlv, as had been recommended in the French journals. This dose was far too great in the climate at Chestnut Hill, and sometimes produced positive collapse. So rapidly did the temperature fall that the lips and finger-tips of the patient soon became blanched, the cardiac impulse weak, and the perspiration profuse. We then diminished the dose. We found ♏ xxv a good average. Some patients did equally well with doses of ♏ xx, ♏ xv, and even of but ♏ x.

Free perspiration is a good indication of satisfactory action of the remedy; the temperature falling more rapidly the more free the perspiration. When perspiration is slow, hot milk or other hot drink given just before the remedy is applied, or hot water-bags placed along the surface of the body, will favor the perspiration.

Temperature reduced with ♏ xv of guaiacol does not remain reduced for so long a period as when reduced with larger doses. It will generally rise again on the following day. If a dose of ♏ xx or ♏ xxv is then rubbed into the same patient there will probably be a prompt reduction of three or more degrees, perhaps even a degree or so below the normal standard, with return to normal in a few hours, and continuous maintenance of the normal temperature for three or four days, a week, or longer. This normal temperature was maintained for six weeks in one of our hospital-patients.

Should the temperature fall very rapidly from 103.5° or 104° to below normal, with profuse perspiration, the patient will feel cool and comfortable the cardiac impulse will remain unimpaired, and the lips and finger-tips will continue rosy until the temperature has dropped to about 99°. Then, if the temperature continues to fall, as it sometimes does, to 97°, or even to 96°, the sensations of comfort are replaced by sensations of chilliness, and the rose-tint of the lips and the finger-tips becomes empurpled. A hot drink and a hot-water bag at the side will send the temperature back to normal in a few

minutes, and the patient may fall into a refreshing sleep.

The method of using guaiacol at the Home for Consumptives is as follows: The skin where the guaiacol is to be rubbed in is well washed with soap and water, and then thoroughly dried. The place selected is a matter of indifference, but we have usually chosen a spot over the seat of greatest lesion of the lung. Ten or more minims of guaiacol, as may be wanted, are poured into a dish, whence it is taken up upon a camel's-hair pencil and brushed upon the parts, back and forth, until the whole dose has been absorbed. This will take ten, fifteen, or more minutes. Then the part is rubbed dry with the hand, after which it is covered with a layer of cotton protected by paraffin paper or oiled silk. In many cases the temperature drops a degree or more before the rubbing is completed, and two degrees within thirty minutes of commencing the application.

When the patient is near death, and the temperature elevated in consequence of the approach of dissolution, guaiacol in the doses in which we have applied it had no effect in arresting continuous rising of the temperature.

It may be concluded that the endermatic use of guaiacol, when carefully employed, often promotes the comfort of the patient in a manner which cannot be obtained from its use by ingestion, by subcutaneous injection, or by direct injection through the air-passages.

ORIGINAL LECTURE.

ANTERO-LATERAL SCLEROSIS; POSTERIOR SCLEROSIS; PATHOLOGY AND TREATMENT OF LOCOMOTOR ATAXIA BY SUSPENSION AND BY APPARATUS.[1]

BY DE FOREST WILLARD, M.D.,
SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA; CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA;

AND

GUY HINSDALE, M.D.,
ASSISTANT PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES AND OUT-PATIENT PHYSICIAN TO THE PRESBYTERIAN HOSPITAL.

THE degenerations of the spinal cord, or the system-diseases of the cord, constitute the most hopeless class of affections in spinal pathology. Insidious ofttimes in their onset, relentless in their advance, cutting off one by one the means of progress, the exercise of the senses, and the control of the mind, these diseases have long been treated in vain. Why should we be content to calmly listen to the funeral march as these patients are borne, one by one, to their final resting place? In the language of a distinguished teacher, we are saying to them as they enter our consulting-rooms: "My dear sir, you have a strip of fibrous tissue in the back part of your spinal cord; it is very small, but it will get bigger, and you will grow worse. Why it comes there I do not know, and why I cannot stop it I cannot understand; but I have triangulated your nervous centers, located the lesion, and if I ever get your cord I can dye the affected part a beautiful orange-yellow or a bright carmin-red."

The whole range of the scleroses and palsies of various types has waited patiently, despairingly, at the fountain of science. We can pity the patients, but our outstretched arms seem powerless to save. We are encouraged, nevertheless, to find some faint streaks of light in the East that are beginning to dispel the gloom that has overshadowed us and that are ushering in a day of new things,

Although, as a rule, the scleroses of the cord are gradual in their onset, and although it is customary to ascribe to slowly-operating causes their production, yet cases of acute locomotor ataxia are not infrequently observed. It is quite likely, also, that traumatism is the initial cause oftener than is generally supposed. Careful inquiry will sometimes elicit the fact that the disease dates from an injury to the back, or that a slight accident has hastened or developed an attack. It has happened that a man has received a blow upon the back producing myelitis with paraplegia and sensory disturbances of the lower extremities; the disturbances, let us say, were chiefly on the left side; a second injury was sustained, and ataxia and loss of knee-jerks supervened.

It is probable that in persons of a neurotic predisposition, locomotor ataxia is precipitated by traumatisms of even a slight degree. Spillman and Parisot have analyzed fourteen cases of tabes associated with peripheral injuries of various kinds, and they cite fractures, contusions, and wounds of the extremities, the extraction of teeth, or even the operation for cataract, as precipitating the disease. But here, as elsewhere, the danger is that *post hoc* is not always *propter hoc*.

Acute locomotor ataxia, according to Leyden, may follow acute diseases; it may succeed to diffused neuritis. It may begin as traumatic myelitis or as meningo-myelitis. We are not without evidence that there is a tendency toward secondary degeneration of a particular set of fibers after a local accident to the cord, such, for example, as compression-myelitis. In a recent case of Preston's, of Baltimore (MEDICAL NEWS, March 18, 1893), this was well shown. In this instance a man, aged twenty-three, was crushed by a bank of earth. There was no external injury of note. There was entire loss of sensation and of motion below the level of control over the bladder and rectum. The superficial and deep reflexes were abolished. Bedsores of a trophic nature formed. Death occurred on the fiftieth day, and examination showed a fracture of the last dorsal and first lumbar vertebræ, with compression of the cord. A microscopic examination showed degeneration of the posterior columns reaching into the cervical region. On the other hand, there may occur a degeneration also of the lateral and direct cerebellar tracts.

Following an accident an ascending degeneration of the posterior columns and direct cerebellar tracts may ensue, and at the same time a descending degeneration of the crossed pyramidal tracts of the lateral column. Such a case was reported to the College of Physicians

[1] One of the Mütter Course of Lectures delivered before the College of Physicians of Philadelphia.

of Philadelphia, four years ago by Meigs (*Trans. College of Physicians*, 1890). In this instance a sailor was struck by a wave and dashed against the bulwarks of a vessel, causing him to strike the back of his head and neck against the rail. He at once lost all sensation and power of motion from the clavicle downward, and from the time of the accident he had retention of urine and incontinence of feces. Post-mortem examination thirty-six days after the accident showed that there was neither luxation nor fracture of the spine, but there was a small extra-dural hemorrhage into the spinal canal at the level of the seventh cervical vertebra. Microscopic sections of the cord above the seat of injury showed degeneration of the posterior columns (columns of Burdach and Goll), of the whole of the direct cerebellar tract, and of a portion of the antero-lateral ascending tract, while below the seventh cervical vertebra the crossed pyramidal tracts of the lateral column were degenerated. (See illustrations in article alluded to.) In the lumbar region the lateral limiting layer and the direct cerebellar tracts, together with the enclosed crossed pyramidal tract, were degenerated, though in less degree than the latter. Cases of this kind and other cases in which the traumatism is not so severe show that after the primary lesion has cleared up a system-lesion may be left as a residuum in the cord.

The relation of the different forms of myelitis to the various scleroses has not yet been investigated as it should be, and it offers an excellent subject for special study. How far these affections are a part of the process of inflammation is a matter of dispute. The term is broad enough to embrace the most flagrant febrile process as well as the chronic succession of changes pervading an organ or certain tracts of tissue, and disclosing, after years of existence, simply a hyperplasia of fibrous tissue without any febrile symptoms having been observed.

At the foundation of all inflammatory processes lies the principle of infection, and it is not altogether unlikely that all cases of myelitis and all the scleroses, whether primary or secondary, may in the future be harmoniously related to their respective infections. How far we may be carried by the present all-pervading belief in the microbic origin of these diseases we cannot now say, but I note that no less an authority than Dana has recently published a paper entitled "The Microbic Origin of Chorea, with a Case," (*Trans. Amer. Neurolog. Assoc.*, 1893). Dana found diplococci in the superficial layer of the cortex and in the deep layer of the pia, in which situation there were cellular infiltration and degenerative changes, and in the medullary and upper part of the cord there were evidences of meningeal irritation, vascular disease (arteritis) and nerve-root irritation. At the Congress of American Physicians and Surgeons, in 1891, Dana discussed the nature and causes of the scleroses of the spinal cord, and announced his faith in the newer pathology. The old belief that sclerosis of the cord is a parenchymatous inflammation with secondary growth of connective tissue is giving way. It is a degenerative process, showing under the microscope a gradual decay and death of the nerve-fiber and cell. In some sclerotic processes, like locomotor ataxia, this decay is accompanied by the development of irritating products, leukomains or tox-albumins, which may produce so active a change in the connective tissue as to lead to something resembling a secondary or reactive inflammation. Just what is the ultimate cause of these degenerative processes is not known. As yet no microbe has been discovered. We have simply the toxin theory—a working hypothesis—a disturbance that may be likened to that which has been observed upon the solar system, and which the French astronomer knew was due to an undiscovered planet.

Some believe that this is a steadily secreted poison in the human body, and that it is constantly acting on diseased tissue; they bring in evidence the fact that many degenerative processes follow syphilis and the infectious fevers, and they account for it in the suggestion "that pathogenic germs have poured into the system a poison or have so modified the cellular nutrition that there is a poison constantly thrown out which irritates and destroys certain areas of nerve-tissue."

Then, again, in Friedreich's ataxia, the hereditary form of sclerosis, it has been shown that certain strands of the spinal cord were never endowed with vitality enough to carry on their functions for more than a decade or two. With this premise some have enunciated the view that by the presence of the poisons of certain infectious organisms the nerve-cell is stunned and its growth stunted; it follows that nutritional equilibrum is destroyed and premature senility and death are brought about.

Sanderson in his Croonian Lectures on the "Progress of Discoveries in Relation to Infectious Diseases" (*Brit. Med. Journ.*, 1891) states, that whereas degenerative diseases do not follow those infections which do not confer long immunity, such as diphtheria, sepsis, erysipelas, tuberculosis; and whereas on the other hand, diseases that do confer long immunity, like typhoid fever, measles, scarlet fever, smallpox, syphilis, etc., are most likely to set up degenerative changes, it would, therefore, not seem unlikely that the very thing which protects against recurrence of infection may be the cause of some internal degenerative change? It is probable that immunity is secured through the modification of cell-nutrition and through the continued presence of some antitoxin in the liquor sanguinis.

It is important to bear in mind in connection with researches in the pathologic anatomy of the nervous system that there are important and often misleading changes, both gross and minute, produced in the spinal cord by injury during its removal from the body and its preparation for microscopic study. Attention has been called to this subject by Van Gieson (*N. Y. Med. Journ.*, 1892), who has compared the lesions produced by bruises with the conditions found in a number of reported cases of malformation of the cord. The lesions artificially produced are reduplications of the gray matter, irregularly shaped horns, canals, cyst-like spaces, and misplaced gray matter, and they may be produced any time at an autopsy by careless technique or bruising. It has been shown that just such artefacts have been erroneously described as congenital malformations or as the result of pathologic processes, and have given occasion for extensive and interesting speculations as to their supposed relations to the production of disease-processes.

Among the surgical measures that have been adopted in the treatment of lateral and posterior spinal sclerosis,

suspension has been the most widely employed. The apparatus used was brought to the notice of the profession by Motschutkowski, of Odessa, Russia, and about the same time Charcot reported encouraging results from its use in France. Three or four years previously Dr. Weir Mitchell had adopted the same measures in two cases of sclerosis, but failure to obtain good results prevented further trial at that time. The measure in itself is not by any means a new one, having been used as long ago as 1826 by Prof. J. K. Mitchell in cases of Pott's paralysis; in fact, it has been in use for centuries for various conditions of the spinal column. Motschutkowski made his observations first on a tabetic patient to whom he was applying Sayre's plaster jacket for the treatment of spinal curvature. He noticed a remarkable improvement in certain symptoms. Raymond, of Paris, who was in Russia on a scientific mission called Charcot's attention to the Russian publication.

Without going into the history of this procedure it will be enough to say that an enormous amount of literature appeared upon this subject in 1889. Five-hundred-and-sixty cases are reported in which suspension was adopted, and several valuable papers on this subject were published in the *Transactions* of this College in that year. The treatment has been extensively adopted in Philadelphia since that date, but with varying success. For a time almost every large hospital in this and in other cities gave the plan a fair trial. The various reports claimed improvement in a proportion varying from 30 to 87 per cent., the highest being Motschutkowski's original record, but no cures were noted.

In 1890 Dr. Guy Hinsdale, of Philadelphia, reported twenty-three cases treated at Dr. Weir Mitchell's clinic at the Orthopedic Hospital and Infirmary for Nervous Diseases. Of the twelve cases which had fifty or more suspensions, in seven there was reported a lessening of pain; in two there was no change; one had no pain to start with and none at the end of treatment; while in two the pains were worse. As to sexual power five reported increase; one, lessening; one had always been good; and one not stated. In no case was there such a gain in sexual power as to make a man competent who had been incompetent before the commencement of the treatment. The gait was improved in four cases; in seven it was unchanged. Station improved in six; was unimproved in four, and was good to start with in two. Knee-jerk was unchanged in all the cases. Bladder-control was impaired in four; rectal control was unaffected. In general it was found that many cases feel an indescribable sense of gain from suspension. They feel better, eat better, sleep better, and wish to continue the treatment. Now that the novelty of the treatment has worn off, it is natural to find fewer cases at present being treated by this method.

At the University Hospital suspension has yielded fair results, and by the kindness of Dr. C. S. Potts I am enabled to give the results in the following cases hitherto unpublished. In a total of eleven cases four were very much improved, and the remaining seven, while not sustaining any marked improvement, invariably felt better for some time; and several of them after the treatment had been stopped returned requesting to have it continued. The special symptoms relieved were the pain, incontinence of urine, sexual weakness to some extent, and several in whom muscular weakness of the legs was present felt much stronger after the suspension.

The apparatus used was that of Charcot, as modified by Mitchell, in which the elbows are displaced in slings, a band around the waist preventing the arms from getting away from the chest. In this way the force applied to the head may be easily regulated. The duration of suspension was one-and-a-half minutes at first, gradually increasing to four minutes. The only bad symptoms reported were subsequent attacks of vertigo; one fainted the first time, but bore it well afterward; the patient, however, was in an enfeebled condition. It is proper to state that all but three of these patients took, in addition, internal remedies, potassium iodid, mercury, etc. The treatment was certainly palliative if not curative.

The following are synopses of three cases in which improvement was observed.

Case I.—Mrs. S. was in the first stage of locomotor ataxia, probably of specific origin. She had been treated with anti-syphilitic remedies for some time with benefit, except that severe burning pains in the feet were not relieved. She was then suspended every day for six weeks, and the pains almost entirely disappeared in that time.

Case II.—T. P. had been ataxic three years, and unable to walk without a person supporting him. He suffered from incontinence of urine and gastric crises. After the third suspension he felt better; after the fifth he could walk without assistance, and the bladder-symptoms were much improved. After two weeks' treatment he had an erection of the penis, the first for over a year. This recurred every morning throughout the remainder of his treatment. At the end of a month of suspension he returned to his home, able to control his urine and to walk much better; and his attacks of vomiting and pain were much less frequent. In addition to the treatment by suspension he took silver nitrate for two weeks.

Case III.—The disease was of specific origin. The man had had internal treatment for seven months without much improvement. He suffered pain in the legs, sexual weakness, and was unable to walk a block without sitting down. After suspension his pains ceased, his legs grew stronger, and after treatment on alternate days for four months he returned to his work as a shoemaker. One year later he was married, and since that time a child has been born.

Stewart has reported (The Medical News, Sept. 12, 1891), from the Jefferson Medical College, a case of postero-lateral sclerosis which showed remarkable improvement as to gait, station, and tactile sensation. The patient was suspended three times a week for five months, suspension being made as frequently by the head alone as with the arm and head supports. The duration of each treatment was about five minutes.

That suspension produces a change for the better in many of these refractory cases has been definitely proved, but just how it acts upon the living spinal cord is still a matter of conjecture. Measurements show an elongation of the spinal column amounting in some instances to one-and-a-half inches. This stretching involves in its tension the surrounding structures, the muscles and tendons, and also the spinal cord and dura mater, and spinal nerve-roots. Adhesions from chronic meningitis are broken down, and it is possible, but not proved, that

this allows a freer transmission of nervous influence along the nerve-tubes, more especially those which run on the surface of the posterior columns. Hegar's post-mortem studies show that in the dorsal region the dura of the cord is lengthened 5 mm. by moderate flexion of the spinal column. He produced this by placing blocks under the chest and abdomen, and bending the neck, the legs being free. Strong flexion was found to increase this length to 7 mm. The dura returned to its normal length on placing the cadaver in a straight position. Hegar laid bare both sciatic nerves, inserted threads at different levels and made a strong pull. The distance increased one millimeter; the spinal column was again flexed and the distance increased six millimeters, and in this position the sciatic nerves were strongly pulled and the distance increased eight millimeters. The spinal column was next exposed, and the two threads were stitched into the substance of the cord at a distance of 15.35 c. m. from each other. Moderate flexion lengthened the cord 0.75 c.m., and strong flexion over 1.05 c. m. Thus it was shown that the cord itself allows greater extension than does the dura.—(Douglass Graham, Hegar, *Wiener med. Blätter*, 1884, No. 3.)

Cattani has shown that stretching of nerve-trunks is accompanied by tearing of the axis cylinder, stretching of the medullary sheaths, with subsequent degeneration and regeneration. Such manipulation of the nerve tissues doubtless makes a great change in their vascularity. Just as Swedish movements and massage renovate the muscular system, so it is highly probable that flexion and extension of the cord and the accompanying stretching that occurs combine to alter and improve the nutrition of the tissues affected.

The first surgeon to apply *stretching of peripheral nerves* in a case of ataxia was Langenbeck. This operator stretched the sciatic, and improvement at once followed; the pains were diminished in a remarkable degree, and the incoördination became less. The experience of other operators has not been satisfactory, however, and it is only in cases in which the pain is intense and referable especially to the sciatic nerve that nerve-stretching should be considered. All theories proposed to explain the action of this procedure have failed to satisfy the profession, and "it would seem now to be passing into merited disuse" (Gowers).

One of the remarkable features of the surgical pathology of spinal scleroses, particularly of locomotor ataxia, is an occasional trophic alteration of skin, teeth, bones, and joints. Prof. Charcot's name is identified with the knowledge of these spinal atrophies, while other French writers, notably Ball, Oulmont, Bouchard, and Dejerine, and in this country Dr. H. C. Wood and J. C. Shaw have rendered important contributions to the subject. Charcot depicts on the one hand cases of extraordinary wasting of the articular ends of the bones. In a femur it was found that the head and most of the great trochanter had disappeared; the edge of the acetabulum had atrophied to a corresponding degree. On the other hand, the changes to which attention was first attracted are those of swelling of the joints and thickening of the bones. (Fig. 1.) While it is possible for any of the joints to become affected, the arthropathy is more common in the knees, the ankles, and the small bones of the foot. (Fig. 2.) This typical swollen foot has been characterized by Charcot as "la pied tabetique." The tabetic hand (Figs. 3 and 4), as well as the tabetic foot, may occur, and the example which is shown in the drawing from the publication of M. Ball is characteristic; it is extremely rare, and Dr. Wood, who has portrayed it in his work, says that he has never seen an example.

Fig. 1.

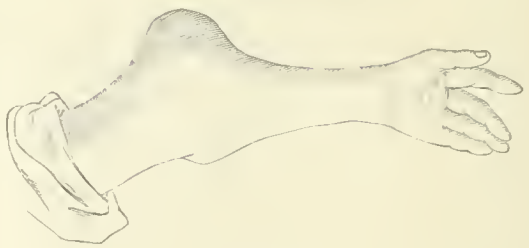


Fig. 2.

Fig. 3.

Fig. 4

Tabetic bones in the stage of hypertrophy have been carefully analyzed in France; the phosphates were found to be greatly diminished, but the fatty matter in the dilated Haversian canals was enormously increased. "The histologic and chemic results show a strongly marked resemblance between the bones of locomotor ataxia, of osteomalacia, and of general paralysis" (Wood). An atrophy secondary to hypertrophy succeeds in advanced cases of tabes, and in such cases fractures of the long bones are liable to occur. When this happens there is apt to be rapid and excessive formation of callus; or again, it is possible to have

atrophy in one limb and enlargement in the other. Thus, in locomotor ataxia, as in general paralysis and allied diseases of the nervous system, the changes in the bones are of a trophic character, tending to atrophy and hardness; or, on the other hand, there may be permanent alterations related to those found in osteomalacia.

Much light has been thrown on the occurrence of atrophy in tabes by the discovery that in some cases of locomotor ataxia the nerves themselves are the seat of the disease. Investigations of the peripheral nerves in tabes by Dejerine, Goldscheider, Shaw, and others show that the ganglion-cells of the anterior horns of the spinal cord are not always accountable for the atrophy, but that the peripheral nerves as far as the atrophied muscles have undergone disease, in cases in which atrophy is the marked symptom.[1] Atrophy in tabes usually affects the lower extremities, and as it progresses the muscles and tendons undergo shortening, giving rise to contractures and fixation of the neighboring joints. Much of this contracture and fixation is due to want of use, as well as to spinal arthropathy. Attempts have been made to produce these bone-changes artificially in animals by operations upon the nerve-centers, so that, if possible, degeneration might occur in the spinal cord with a resultant lesion of the joints. Giacomo (*Soc. de Biologie*, March, 1885, p 156, quoted by Wood), in a very large dog cut the posterior roots of three lumbar nerves between the ganglia and the cord. After some months the joints of the left foot became enormously swollen and edematous, without increase of sensibility or temperature. At the autopsy it was found that secondary degeneration had occurred in the spinal cord at a level corresponding with the joint-changes.

In cases of tabes which extend through a comparatively long period of time, degeneration of the peripheral nerves may involve the patient in another very serious change, to wit: symmetrical gangrene of the toes. I am not aware that such cases have been reported in Philadelphia, but a recent case of Pitres, of Bordeaux, presented this condition in the following history:

The first symptoms of tabes were observed in 1875; five years later lancinating pains in the legs began, and the chief clinical features of the case were well established; ten years later the patient felt as though his toes were dead during cold weather, while in hot weather they became blue and swollen and pained greatly.

In the sixteenth year from the onset of this train of symptoms gangrene became fully developed in all the toes of the right foot and in the great toe of the left foot. The patient dying by accident shortly afterward, the usual condition of the spinal cord was found, together with a very marked degeneration of the corresponding peripheral nerves. Nevertheless, numerous apparently normal nerve-fibers existed. (*Revue Neurologique*, May 15, 1893.) Another case of symmetrical gangrene of the toes occurring in a tabetic patient has recently been recorded by Kornfield (*Wiener med. Wochenschr.*, November 5, 1892.) An interesting feature of the case was a certain resemblance to cases of syringomyelia viz.: in the characteristic dissociation of sensibility; or, in other words, symptoms of posterior poliomyelitis, anesthesia to pain, to heat, and to cold, with preservation of tactile sensibility and of the muscular sense. But, on the other hand, there was no characteristic muscular atrophy. Post-mortem examination showed, besides the sclerosis of the posterior columns, an acute inflammation of both peroneal nerves, fully explaining the occurrence of gangrene. (Fig. 5.)

Fig 5.

Those who have investigated the peripheral nerves in tabes concur in finding the most decided changes in the peripheral ends. The microscope shows the myelin broken up into irregular masses of various sizes; later on absorption of this granular-looking material occurs, and the sheath of Schwann is found empty and shrivelled. The axis-cylinder frequently remains for a long time unaffected, and in some specimens it can be seen very sharply stained by carmin in the sheath with very little myelin around it. (Shaw, *International Clinics*, vol. iii, 1892.)

The view is gaining ground that tabes is a more diffused lesion of the cerebro-spinal axis and of its branches than has hitherto been realized. It would be much better in post-mortem studies of locomotor ataxia if attention were not riveted too closely to the spinal cord, but that more attention be given to the peripheral nerves and to the arterial blood-supply of these and of the spinal cord. Gowers has called attention to this, and lately Preston (Medical News, July 8, 1893), attributes to arterio-sclerosis of the intercostal vessels a diminished amount of blood in the spinal cord, and in consequence of this imperfect supply of nutriment an atrophy and degeneration of the nerve-elements. As a consequence of this degeneration of nerve-matter there starts partly from the sheath of the nerve, partly from the bloodvessel, an outgrowth of connective tissue, which in its turn encroaches upon this often less resistant nervous matter, giving the characteristic picture of sclerosis. Preston shows that the etiologic factors, by common consent conceded to be the most important in the causation of tabes, viz: syphilis, exposure to cold and wet, or rheumatism, and alcoholism, are the exact conditions most

[1] J. C. Shaw, International Clinics, 1892, vol. iii, p. 176.

favorable to the development of arterio-sclerosis. Acting on this supposition, he has suggested the use of nitroglycerin in order that the small branches of the spinal arteries may be dilated and a larger supply of blood be afforded the cord.

In the surgical treatment of these pathologic conditions it is obvious that but little can be done. Contractures occur so late, marking the hopeless progress of the affection, that interference by the surgeon can only avail little. The condition of the limbs can, however, sometimes be benefited by tenotomy when the existing degree of incoordination does not present an insuperable obstacle to locomotion.

CLINICAL MEMORANDA.

A CASE OF GLAUCOMA SIMPLEX.

BY GEORGE M. GOULD, M.D.,
AND
E. M. HEWISH, M.D.,
OF PHILADELPHIA.

THE peculiar interest of the case here reported resides in the progress of an attack of uncomplicated or simple glaucoma to comparative blindness without the usual symptoms consisting in or consequent upon an excess of ocular tension, with no pain, headache, etc. The diagnosis depended solely upon the recognition of the existence of a deep pathologic cupping of the disc.

Mrs. B., seventy-three years of age, an active and, for her age, a healthy woman, consulted Dr. Hewish for a simple defect of failure of vision, in the summer of 1894. Some three years ago she got glasses from an optician, but they had, of course, never proved satisfactory to her. Owing to myosis, examination of the eye-ground was impossible until temporary dilatation of the pupil had been secured through a mydriatic. The pathologic cup was at once recognized, and treatment by eserin was instituted. Vision of the right eye had become reduced to a mere macular perception of light, and of the left eye to a macular counting of fingers. At no time was the tension of the right eye above normal, and that of the left eye, if it were really at all "plus," was only very slightly so. The anterior chambers were quite normal in depth, or but very slightly shallower than normal. There was no injection of the conjunctiva, no sensitiveness to touch, and no marked corneal anesthesia. No headache, pain, or even discomfort of any kind had at any time existed in or about either eye. This statement the patient persistently emphasized.

The patient absolutely refused operation, and under the circumstances we advised a temporary trial of systemic therapeutics. The patient had been confined to the house for a long time, and there was considerable constipation, but beyond this, except as regards some worry and trouble from recent family misfortunes, the woman was healthy, clear-minded, and for one of her age, very active. Laxatives, almost to purgation, and tonics were freely administered, out-of-door rides and walks ordered, and general hygienic reform instituted, but all without effect on the ocular condition. The vision, if possible, got worse. The eserin was continued for the two weeks in which we tried the measures directed to the general condition.

We now determined to have a thorough opthalmoscopic examination, not only for the purpose of establishing the diagnosis, but also to see if mydriasis would increase the vision and the tension, and to test the field,, etc. This had previously not been possible by both of us owing to the myosis. The pupils quickly responded to weak solutions of homatropin, and the disc-cuppings were found to be extreme, "undercut," typically glaucomatous in the highest degree. There was no venous or arterial pulsation of the vessels observable. Neither the tension nor the vision was noticeably increased by the mydriatic. Three days later, operation having been consented to, we performed iridectomy on the left eye. There was no gush of aqueous on opening the anterior chamber beyond that usual in normal eyes. Operation on the right eye was postponed because of the absolute normality of the tension, the almost complete blindness, and also because we concluded to await the results of the operation upon the eye that had some vision left, and that, if at all, was slightly firmer than the other. The operation, *per se*, was successful; *i. e.*, it was almost wholly bloodless and carried out easily, and a fair-sized coloboma was secured. Healing was remarkably prompt and good, no iritis or other untoward symptom supervening. The eye is now as quiet as it has always been, but vision is not improved. All local applications, including eserin, have been discontinued; the pupils have returned to a normal size, show no tendency to mydriasis, and the tension remains as uninfluenced by the operation as it had been by the eserin.

It seems remarkable that a condition essentially glaucomatous, if we may trust the story told by the ophthalmoscope, should exist without what is undoubtedly held to be the essential symptom and characteristic of the disease, that is, increased tension. With the absence of abnormal tension there has always coexisted an absolute absence of the subjective symptoms of pain and irritation. The only trouble the patient has ever remembered or complained of is visual failure. She has never seen rainbow-rings or halos about a light. Of objective symptoms there has been no heightened tension, unless very slight indeed, in the one eye, the other having gone on to blindness without, so far as can be determined, any rise whatever. There has never been any conjunctival or corneal congestion or other disorder, no mydriasis, no marked corneal anesthesia or loss of transparency, no iris-abnormalism, etc.

The case is to be held, therefore, as an extreme and perfect illustration of "simple glaucoma," concerning which Fuchs has written:

> The relation of glaucoma simplex to glaucoma inflammatorium has been the subject of manifold discussions. Since glaucoma simplex, on account of the absence of inflammatory symptoms, is entirely different externally from glaucoma inflammatorium, it was not recognized as glaucoma at all until the discovery of the ophthalmoscope. Even Von Graefe did not originally place glaucoma simplex under the head of glaucoma, but designated it as amaurosis with the excavation of the optic nerve.
>
> Jaeger held to this view until the last, looking upon glaucoma simplex as an optic-nerve lesion *sui generis*—a "glaucomatous" optic-nerve lesion. At the present time, however, the majority of ophthalmologists place glaucoma simplex under the head of glaucoma proper, since it has in common with its most essential symptom, the increase in tension. The inter-connection of simple

and inflammatory glaucoma is also proved by the numerous intermediate varieties which form a continuous transition from simple to inflammatory glaucoma, so that no sharp line of distinction can be drawn between the two.

To these transition-forms belong, for example, the cases of glaucoma simplex with periodical obscuration of vision, and which are accompanied by transient cloudiness of the cornea, and often as well by a dull headache. Even in pure cases of glaucoma simplex, a constant headache sometimes exists, the dependence of which upon the glaucomatous process is proved by the fact that it disappears after iridectomy. A glaucoma simplex, later on in its course, often passes into acute or chronic inflammatory glaucoma, and cases also not infrequently occur in which, after inflammatory glaucoma has developed in the eye first affected, glaucoma simplex is present in the one which is affected afterward.

The inter-connection of the two forms of glaucoma shown from the above-mentioned facts has been doubted because in many cases of glaucoma simplex no evident increase of tension is demonstrable. In these cases we must assume that the lamina cribrosa is particularly yielding, so that it is forced backward by a pressure which does not perceptibly rise above the normal limits. Such cases, to be sure, are not always clearly distinguishable from simple atrophy of the optic nerve with unusually deep excavation. In doubtful cases the testing of the color-perception may furnish a diagnostic guide. In atrophy of the optic nerve color-blindness makes its appearance early, while in glaucoma the ability to distinguish colors is retained for a comparatively long time.

Our principal object in reporting this case is to emphasize two practical points of interest springing from it, and which convey profoundly important lessons:

1. *The ease with which such cases may be overlooked by the physician.* The absence of all objective and subjective symptoms, except the loss of vision and the one shown by the ophthalmoscope, illustrates the necessity of careful ophthalmoscopic examination in every case coming to the oculist. It is to be feared that such an examination is not absolutely invariable, and that the hasty diagnosis of "amblyopia" is, as it were, a garment that may cover a huge sin and lull the patient into a supposed security leading to blindness. It may also be noted that such cases as these make the descriptions of glaucoma in some of the text-books seem very insufficient. A very recent text-book makes glaucoma consist solely in an *increase* or abnormal degree of tension, without regard to the fact that with a highly subnormal power of resistance the process is truly glaucomatous without an abnormal elevation of tension. One cannot help wondering how frequently such cases may not be overlooked, called optic atrophy, etc.

2. *The crime, or what should be held a crime, of the optician in furnishing glasses without a physician's prescription.* The physician *may* overlook such cases, but the optician can by no possibility recognize them. We have personally known several such cases, and so no doubt has every oculist. The present case is a striking example. Had the patient, Mrs. B., three years ago consulted an ophthalmologist she would probably now have good vision instead of being blind. Instead of this she went to a popular optical firm, who if we had proper laws would not have dared to sell her glasses for glaucoma, or, if daring, would now be liable to a suit for heavy damages. Civilization demands that it should be made just as illegal and punishable to sell spectacles without a physician's prescription as it is for a pharmacist to prescribe drugs for any other disease of the human body.

MEASLES AND PHENACETIN: WHICH KILLED THE PATIENT—THE DISEASE OR THE TREATMENT?

By CHARLES E. PAGE, M.D.,
of Boston, Mass.

In reporting a case of measles which proved fatal a writer in a current medical journal prefaces the history of the case with some thoughtful speculations concerning the possibly deleterious effects, at times and under some circumstances, of the coal-tar poisons.

"It would seem," he says, "that the marvellous potency of the pharmaceutical derivatives of coal-tar, at present in such general favor, should be sufficient to arouse the responsible physician to an unusual degree of alertness as to any deleterious effects upon the human organism which, when prescribed internally, they might naturally be expected capable of producing. Taking everything into consideration," he goes on to say, "it is quite remarkable that death in certain cases has not oftener been suspected of being the culmination of their use rather than, on the other hand, that they probably exerted the effect of at least postponing the occurrence of such a dire calamity."

From a purely speculative point of view he regarded it as incredible that these drugs, in doses ordinarily recommended, should be so much less liable to produce evil than good, "were it not for the results obtained from the extensive experience in their employment," in all of which the writer concurs, except in the view that the "results obtained" give us any rational hope that these poisons are ever "less liable to produce evil than good."

"Amid the complexities of a given instance of disease," further remarks Dr. Tyler, "it is practically impossible to clearly define that which may be designated the negative action of remedies employed. Observations and experience have too often avouched the efficiency of the *vis medicatrix naturæ*, for example, to avoid the acceptance of many apparent favorable results from artificial sources in any other spirit than that of extreme skepticism."

The case cited was that of an Italian, "about thirty-two years of age, muscular and exceptionally well-nourished." The historian remarked upon "the striking resemblance the symptoms bore in many respects to those which are quoted as having been observed in poisoning by phenacetin," and he goes even further, in thinking that had the amounts employed been considerably greater the question might rationally have arisen "whether it was directly due to the complications resulting simply from the disease, to the remedy, or to a combination of the two," that death ensued. But the amount of phenacetin was so small (fifty grains with whiskey in five days) that it seemed to him incredible that the drug could have much influenced the result.

But, he states that the second five-grain dose of phenacetin on the fifteenth (the second day of sickness) reduced the fever markedly, from 103.6° to 101°, thus

exhibiting a "marvellous potency" for either evil or good. Moreover, in spite of reduced temperature, "the pulse and respiration, on the other hand, became accelerated." My criticism here is, that a drug which increases the respiration and pulse of a patient, does so by adding to the toxic condition, giving the system still more to contend with, thus forcing it to work more vigorously because of the added load, not from increased strength, which being admitted tells, of course, against such a procedure. In this case, as usually happens—indeed, as it seems to me, must always be the case, in accordance with the laws of the animal organism, whatever the apparent effects at the moment, or the happy chance which allows of restoration from disease, under mistaken treatment the organism was made to work harder while the vital forces were actually depleted, the reduced temperature being, really, evidence of this; and the final and speedy exhaustion of the patient to his death in five days, though he was a muscular man, gives further and unmistakable evidence, as it seems to me, in the same direction.

The patient was a splendid subject for water-treatment, and yet not one word is mentioned of even a cold compress over the region of the inflamed bronchi when, on the third day, "bronchitis became very evident in both lungs, and cough troublesomely aggravated." The constant changing of the cold compress over the chest in these cases (pneumonia, acute bronchitis, etc.,) operates most charmingly. By this is not meant the application of a cold towel to remain for any length of time to become a hot fomentation, but its renewal every two or three minutes in desperate cases, and kept up till the conditions are markedly improved, and returned to at any time when evidence is observed of return of the congestion. Instead of this helpful and most regular (though not popular) treatment the chest was simply anointed with camphorated oil, an expectorant directed, and quinin sulphate prescribed. Moreover, the patient was fed night and day, though he was at the start an exceptionally well-nourished patient and a promising subject for the fasting-cure; though, for that matter, it is my practice never to punish a fever patient with food, whether he be lean, stout, or medium, nor to offer any other nutriment than water, till convalescence is well established and satisfactory evidence observed—improved tongue, lowered temperature, good appetite, etc.—that the food stands a fair chance of being digested; otherwise it can serve no useful purpose, but must always prove a harmful nuisance, with absolutely no compensating effects. It tends to keep the patient's temperature up and going up, for it is so much more waste to be burned and eliminated. On the other hand, during every day of absolute fasting the toxic matters which are threatening life are reduced by about two pounds, and a few days of this sort of house-cleaning, as I have observed in innumerable instances, change the conditions so completely as to seem almost miraculous.

To quote: "At 4 A.M. of the 19th (sixth day of treatment), temperature 104°, phenacetin and whiskey were again prescribed, but failed (as will be seen) of any salutary effect. At 5 A.M. the patient was noisily delirious and uneasy." What an indication for a Brand bath, to tranquillize the patient by means of the refreshing cold water, the effect of which is to strengthen the heart, brace the entire nervous system, prevent or restore from the dreaded coma! The common plan, however, of "silencing the alarm bells, instead of doing anything to put out the fire," was pursued: "Sol. morp. sulph. (U. S. P.), one fluiddram, which small quantity it was deemed advisable to supplement an hour later with Dover's powder, six grains. At 6.30 A.M., patient tranquil, but shortly lapsed into a comatose state from which it was only possible to partially arouse him. Pupils contracted; respiration varyingly noisy or stertorous; countenance cyanosed; extremities cold. Hypodermatic of strychnin sulphate, one thirtieth of a grain, and repeated two hours later (11 A.M.). Patient had become completely comatose and reflexly insensible to puncture of hypodermatic needle. He expired at 12.40 P.M. His temperature, taken one hour previously, was 106.8°"

The only water-treatment mentioned is that "at various times during the progress of the illness the surface was carefully sponged with alcohol and water combined." The general impression, both with the profession and laity, seems to be that a little water will not harm a fever-patient if it be well diluted with alcohol.

I have undertaken the study of this case in no spirit of carping, but to emphasize what seems the inevitably harmful routine procedures employed by the great majority of physicians in similar cases, as well as their lamentable failure in studying and applying the simple, but genuine, aids to nature supplied by the great variety of water-treatments.

From the study of many cases similar to the one here recorded, in treatment and results, as well as not a few which started out in similar fashion, but which under quite contrary methods resulted in speedy convalescence and recovery, it seems altogether probable that had this robust Italian been spared the ingestion of a single poisonous drug, as well as of all food-substances, which, from lack of possible digestion and assimilation, are themselves drugs, loading the circulation with the poisonous products of fermentation; and could he have had the benefit of appropriate baths—not for the purpose of downing the temperature, by any means, but, as has been already intimated, for their invigorating effects upon the entire organism—while the fluidity of the blood was maintained by plentiful supplies of pure soft water, hot and cold, the results would have been altogether satisfactory.

867 BOYLSTON STREET.

THREE CASES OF LAMINECTOMY.

BY CLAUDE A. DUNDORE, M.D.,
OF PHILADELPHIA;
LATE FIRST ASSISTANT SURGEON, STATE HOSPITAL FOR INJURED PERSONS OF THE ANTHRACITE COAL REGIONS OF PENNSYLVANIA.

THE results of laminectomy for fractures and dislocations of the vertebræ are very uncertain, for with our present resources we are absolutely unable to determine the condition of the cord before operation; the symptoms present may be due to hemorrhage, bony pressure, or adhesions, and at times the cord may be either partially or wholly severed; yet with all the light that has been thrown on the surgery of the spine during the past ten years, we are utterly at a loss to diagnosticate the condition of the cord.

But as laminectomy, if performed aseptically, does

not shorten the patient's days, it is our imperative duty to operate, unless the patient is actually in a dying condition. The results are often disappointing (in fact, more so than statistics show, as there is a tendency to report only such cases as terminate favorably), but the patient is given a chance for improvement, with little, if any, danger of shortening his lease of life.

The following three cases, operated upon by Dr. J. C. Biddle and myself, at the State Hospital for Injured Persons, Ashland, Pa., have not been previously reported, and I publish them to complete the list of these cases operated upon at this institution.

CASE I.—Edward E., aged twenty-one years, single, residence Mahanoy City, Pa., was admitted June 17, 1889, suffering from a partial dislocation of the ninth dorsal vertebra. He had been a laborer in the mines, and while working was injured March 18, 1889, by a fall of top rock, and from that date to that of his admission had been under the care of a local physician without any sign of improvement.

At the time of his admission he weighed but ninety-eight pounds; his weight previous to the injury being one-hundred-and-forty-five pounds. He exhibited entire loss of motion in the lower extremities, with the exception of very slight movement in the toes of the left foot; sensation was almost *nil* up to the hips, above which it was normal; he had complete retention of urine, with a severe cystitis. His tongue was heavily coated, the bowels constipated, and there was marked anorexia, with considerable anemia. His temperature varied from 99° to 100° in the morning, and from 101° to 103° in the evening. The time which had elapsed since the accident precluded any attempt at reduction, and his anemic condition would not warrant a more radical method.

He was put on light, nourishing diet, iron and strychnin were given internally, and electricity was applied to the lower extremities every other day; the cystitis was treated by irrigating the bladder each day with Thiersch's solution. By August his appetite and general condition were much improved, and his weight had increased to one-hundred-and-twenty-five pounds; his temperature being 99° or less each morning, and seldom as high as 100° at night. The cystitis had entirely disappeared, and he was able, with some effort, to pass his urine without the aid of a catheter. Sensation in both extremities had slightly improved, and he was able to slightly move the toes of the right foot. This being his condition, an operation was proposed as the only means of further and permanent improvement, and to this he eagerly consented, and, accordingly, on the 25th of August the ninth dorsal vertebra was trephined.

The cord was found to be compressed and greatly congested, but there was no evidence of laceration. The laminæ and spinous processes of the eighth and ninth dorsal vertebræ were cut away, thus relieving all pressure on the cord; the wound was drained and sutured, and a plaster-of-Paris jacket applied, a hole being cut out over the wound for the purpose of changing the dressing when necessary. By September 1st union was perfect, and for the next month the patient remained in excellent condition, but without any sign of improvement as to sensation and motion. Early in October he was able to slightly move both legs, and had full control of urination; from this time on his paralysis rapidly improved; the battery was applied daily, with massage morning and evening, and in November the plaster-of-Paris jacket was removed, and he propelled himself about the ward in a rolling-chair, and shortly after was able to get about slowly on crutches. He was discharged December 23d, and when I saw him, six months later, he walked very well and without effort; he carried a cane, but this seemed to be more from habit than from necessity. At present date he weighs one-hundred-and-fifty pounds, and drives a huckster-wagon for a living, showing very little loss of motion in his lower extremities.

CASE II.—Thomas K., aged thirty-five years, married; residence, Shenandoah, Pa.; a laborer employed in the mines, was admitted May 12, 1889. On January 25th, while at work, a piece of coal weighing several hundred pounds slipped out and struck him on the back while he was stooping. He was taken home, and Dr. Biddle saw him in consultation a few hours later, and found him suffering from a fracture of the tenth dorsal vertebra, with extreme displacement, fracture of the middle third of the right femur, and of the fifth, sixth, seventh, eighth, ninth, and tenth ribs on the right side. He had complete loss both of sensation and motion below the seat of injury.

On the day of his admission the fractured femur had partially united, the ribs entirely so, and his condition being fair it was deemed advisable to operate without delay.

Upon trephining, the cord was found to be completely severed, the cut ends being almost an inch apart. Further procedure was, of course, useless, and the wound was sutured and dressed, the patient being made as comfortable as possible until the date of his death, June 12th.

CASE III.—Frank S., aged twenty years, single, residence Gilberton, Pa., by occupation a brakeman, was admitted December 20th, 1889. He had been doubled up under a train of coal cars while endeavoring to couple them, on December 16th, and when admitted had a fracture of the ninth dorsal vertebra, with total paraplegia of the lower extremities. He was operated upon the following day, and the cord was found to be severely lacerated and almost disorganized; there had been considerable hemorrhage, as was evident from the clots present in the vertebral canal and surrounding tissues. The cord and canal were washed out thoroughly, the meninges sutured in three places, the laminæ and spinous processes of the eighth, ninth, and tenth vertebræ cut away, the cavity thoroughly drained and dressed with iodoform-gauze. The wound had united by the 29th, but the patient never rallied, and died January 5th.

2012 MASTER STREET.

A CASE OF CHRONIC PURULENT OTITIS MEDIA WITH FACIAL PARALYSIS; SEQUESTRA FROM THE AUDITORY CANAL.

BY CHARLES H. BURNETT, M.D.,
AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, ETC., PHILADELPHIA.

IN the following account there is presented the natural history of a neglected case of chronic purulent otitis media, since the patient had never received any treatment for her aural disease.

Mary M., twenty years old, born in Ireland, and resi-

dent in this country one year, came to the Presbyterian Hospital, July 25, 1894, for treatment of ear-disease. The patient stated that she had never had scarlet fever, but, at the age of ten years, she had measles. She had no earache nor any ear-disease at that time, but in the years subsequent to measles, whenever she took cold, she had earache and otorrhea. Three years ago, seven years after the beginning of the chronic otorrhea, she had a very severe attack of earache, and a large collection of pus formed above the auricle, which, however, discharged itself spontaneously through the ear. A year later, *i. e.*, two years ago, the patient had another attack of earache, which was followed by facial paralysis of a high degree, and which has remained unchanged ever since.

She has always worn cotton plugged in the auditory meatus, thus retaining septic matter in the ear, and promoting therein the necrotic process.

When she presented herself for treatment she showed, in addition to the facial paralysis, a large supra-auricular collection of pus extending forward beneath and beyond the line of the temporal artery, above to the limits of the squama, and behind to the upper boundary of the mastoid. Pus could *not* be pressed from this point into the tympanic cavity or auditory canal and out of the external meatus. A very dark-colored, offensive discharge came from the meatus, however, originating from the diseased tympanum and auditory canal. The latter passage was blocked with granulations, and denuded bone could be felt near its meatus. The entire region of the auricle and meatus was extremely sensitive to touch, and forbade all exploration with a probe.

The patient was etherized on July 25th, and an opening was made in the lower posterior part of the abscess-cavity, over the upper part of the mastoid. About two fluidounces of dark, thick, fetid pus then escaped from this opening. No denuded bone could be felt in the abscess-cavity by most diligent search with a probe at this or any other time. This cavity was for two weeks syringed twice daily with a solution of mercuric chlorid, 1 to 5000, and the auditory canal and middle ear were syringed with alcohol twice daily. The discharge of pus from the opening in the abscess amounted to one fluidounce daily for two weeks, but under the use of a drainage-tube, begun in the second week, the pus-cavity grew smaller, until its walls adhered and the opening over the mastoid closed.

The granulations in the auditory canal had now shrunken, and the discharge from the middle ear diminished under alcoholic syringing. A tough, fibrous polypus was now extracted from near the meatus, and with it came a curved spicula of bone. The caliber of the still-narrowed and sensitive canal was blocked by an impacted sequestrum. Under ether, on August 25th, an examination of the sensitive canal was made, and by means of Sexton's foreign-body forceps two sequestra the size of large peas were removed after rather forcible traction. These sequestra came from the region of the mastoid antrum, judging from their cancellous structure.

Denuded but firm bone was felt in all directions in the fundus of the auditory canal, after the removal of the sequestra, but this rapidly covered in, excepting a small spot on the inner wall of the tympanic cavity, and the discharge further diminished under alcoholic syringing. It is needless to say that the chronic facial paralysis remained unaltered.

In this case there is shown the natural course of a neglected chronic suppurative otitis media of ten years' duration, one-half the patient's life. Poor hygiene and septic retention from wearing cotton in the ear resulted, in the eighth year of the disease, in a severe acute attack, marking the advance of the necrotic process and producing an irremediable facial paralysis.

The rapid covering in of denuded bone by new mucoperiosteum, under antisepsis and asepsis, demonstrates that bare bone is not dead bone, and curetting the denuded surface is not necessary, but rather injurious. Dead bone will exfoliate; denuded bone in the ear should be treated like diseased mucous membrane, by antiseptics, and not with the curet.

TONSILLOLITH: AN UNUSUAL CASE AND SPECIMEN.[1]

By W. K. BUTLER, A.M., M.D.,
SURGEON-IN-CHARGE LUTHERAN EYE, EAR, AND THROAT INFIRMARY, WASHINGTON, D. C.

THE following case of tonsillolith is presented on account of the unusual size which the stone acquired before removal, and incidentally on account of a mistake in diagnosis as to its nature.

The patient, a male, twenty-six years of age, applied last August for treatment on account of "something growing in his throat," which he had noticed since the preceding fall, and which he said had been treated by the application of caustics.

Inspection showed a marked bulging of the soft palate just above the right tonsil, with sub-acute inflammation. Thinking that it might be an abscess it was cocainized and incised, when the knife struck the calculus. The incision, which was midway between the uvula and the anterior pillar, was enlarged and forceps used to withdraw the mass, but without avail, as it could not be grasped. It was then shelled out by passing the finger behind the pillars of the fauces and forcing the mass forward.

While tonsilloliths are said not to be very rare, large ones are exceptional, and the one here presented is the largest of which I have seen any record. Burnett, in his recent *System of Diseases of the Ear, Nose, and Throat*, refers to three large ones which have been reported, the largest of which measured 25 mm. long, 5 mm. thick, and 4 mm. broad. This one measures 25 mm. x 22 mm. x 18 mm. Its weight is 85 grains.

Tonsilloliths are of interest on account of the hemorrhage that sometimes occurs when they slough out, and on account of the obstruction they offer in tonsillotomy, one case having been reported in which the tonsillotome was broken by the resistance offered by a stone.

Calculi usually commence as caseous masses in a follicle of the tonsil, which on drying become hard, and may gradually increase in size by accretions.

This one shows very markedly the laminæ of growth. They are usually composed of organic matter, phosphorus, and calcium carbonate.

Dr. Samuel E. Milliken has been appointed surgeon to the Randall's Island Hospital, New York.

1 Presented before the Medical Society of the District of Columbia, October 10, 1894.

BACTERIOLOGIC NOTE.

A NEW-CULTURE MEDIUM FOR THE BACILLUS OF DIPHTHERIA AND OTHER BACTERIA.

BY M. V. BALL, M.D.,
OF PHILADELPHIA.

THE ordinary methods in vogue for the preparation of blood-serum for bacteriologic purposes are complicated, require special and costly apparatus, and often end in failure. The separation of the serum takes several days, during which time contaminations are liable to occur; in transferring the serum so as to prevent entrance of the coloring matter of the blood the use of pipets is objectionable, and in the sterilization at low temperatures spores if present may not be destroyed, so that even under strictest precautions 10 per cent. of the tubes are expected to be lost. Blood-serum is now chiefly used for the cultivation of the diphtheria bacillus, though numerous other germs develop upon it with preference.

For diphtheria a transparent medium is not a necessity. The grayish-white colonies are more plainly visible on a dark background. Therefore, in order to obtain a culture-medium in as short a space of time as possible, and without the aid of laboratory apparatus, and upon which the bacillus of diphtheria will grow as readily as it does upon blood-serum, I use coagulated blood.

The method is as follows: The blood of an animal is collected in a sterilized jar or bottle. As soon afterward as is possible, small sterilized glass test-tubes are filled one-quarter full of the pure blood, before it has clotted, or of the colored fluid portion which has separated if clotting has already begun. The tubes are then placed in a slanting position (a small tin box can easily be constructed for this purpose or improvised so that the tubes will lie nearly horizontal) in a water-bath, and slowly heated until the water in the bath is boiling; the boiling should be continued for ten minutes or more, until the blood has coagulated and become solid. It then has a chocolate color and a moist-appearing surface, upon which a stroke-culture can be made. From a pure culture of the diphtheria-bacillus on agar an abundant growth was visible on the blood coagulum in fifteen hours. It was sufficient to diagnosticate in ten hours. If the tubes are to be kept for any length of time they can be sterilized two or three times at a temperature of 85° C. without injuring the medium.

The preferable temperature for the diphtheria-bacillus is that of the animal body, from 36 to 37° C. As incubators are seldom found outside of the laboratory, and are expensive, a practical and simple way to insure this constant temperature is to place the inoculated tube in a wooden case or other receptacle (to prevent breakage), and keep it in close contact with the human body itself, in the pocket of a patient's night-shirt for instance, or the physician might carry it in his inside vest pocket. This method of incubation has been described before, but it has never been put into practical operation as far as I can ascertain.

The use of blood coagulum, I believe, is original with me. Other bacteria will grow on it, and I am now making cultures of the tubercle-bacilli which have not yet had time to develop. If no new objections arise it will be the most practical of all culture media, requiring the least time in preparation, the fewest materials, and only such apparatus as every household can supply; while for pathogenic bacteria it is the most natural soil, and one well suited for growth. With few exceptions the dark color of the medium brings out the colonies in strong relief, so that they are at once apparent. I suggest the name *nutrient blood-coagulum* for this bacterial medium.

MEDICAL PROGRESS.

A Case of Cystinuria.—HALL (*Quarterly Medical Journal*, vol. iii, part 1, p. 26) has reported the case of a miner, thirty-two years old, who complained of lumbar pains and of having passed stones; but examination with a sound failed to disclose the presence of a calculus in the bladder. The man was of good habits and had lived in the same locality for eighteen years. He had suffered a good deal from sick headache. Ten years before coming under observation he had an attack of what was called pleurisy on the right side, in the course of which he passed a stone the size of a pea. Subsequently he began to suffer from pain in the back on both sides, and twelve months later passed another small stone, which caused much pain. After this he passed various-sized stones every year, more in the spring than at other times; the largest number was four in one day and fourteen in one month. The largest stone was passed a few years before the man came under observation, when he lost also about a pint of blood. The last stone had been passed seven months previously. The pain radiated from the back to the testicles, causing in these a sense of heaviness. From time to time attacks of colic occurred. The urine was clear and high-colored, and deposited a sediment. There was tenderness on pressure over the loins, and well-marked cutaneous hyperesthesia in the middle line from the twelfth dorsal to the third lumbar spine, and passing from this outward in a somewhat triangular shape and ending at the midaxillary line. On the right side in front there were one or two spots of hyperesthesia over the anterior superior spine of the ilium; and on the left one or two spots somewhat higher, also over Poupart's ligament as far as the external abdominal ring.

The patient brought with him seven calculi which he had passed by the urethra at different times. The largest measured half an inch by a quarter of an inch. It was ovoid in shape, of a honey-yellow color, with sparkling crystalline surface; on fracture it presented a yellow, powdery appearance. The other stones were quite small, three being facetted. The calculi were insoluble in water and soluble in ammonia and also in nitric acid. On evaporation large hexagonal crystals of cystin remained, together with rhombic prisms arranged in star-shapedclusters. The urine was alkaline in reaction, and contained neither albumin nor sugar. It deposited a copious sediment consisting of phosphates, together with small round masses with radiating lines not soluble in acid, but disappearing with heat. These latter were believed to be ammonium urate. For a few days the patient was not placed upon treatment, in order that a study of the urine might be made. The quantity passed varied between 40 and 58¼ ounces in twenty-four hours. On several occasions cystin-crystals were found.

Alkaline treatment was then instituted and continued for seven weeks. This consisted in the administration of a combination consisting of potassium bicarbonate 12 drams, citric acid 8 drams 24 grains, and water 12 ounces, of which an ounce was taken in water every three hours. During this time the daily quantity of urine averaged 69.7 ounces. The patient felt much better and suffered much less pain. Throughout this whole period no crystals of cystin could be found, though frequent examination of the urine was made, but as soon as the treatment was suspended the crystals appeared. The patient was dismissed and advised to continue the alkaline medication, but he disappeared from observation.

Successful Celiotomy for Incised Wounds of Liver and Stomach.—BECK (*Deutsche medicin. Wochenschr.*, No. 39, p. 759) has reported the case of a youth, seventeen years old, who in the course of a quarrel received a stab-wound with a knife in the left hypochondrium. The injured man managed to walk a short distance, but finally fell. The wound was closed by means of silk sutures, but the occurrence of vomiting of the contents of the stomach and of blood in considerable quantities necessitated reopening and enlargement of the wound and a search for the source of hemorrhage. The man presented a condition of acute anemia, so that it became necessary to introduce more than a pint of a 0.6 per cent. sodium-chlorid solution into the basilic vein. After the hemorrhage had been controlled by packing the abdomen with gauze, the latter was carefully removed, and it was found that the bleeding issued from a wound in the liver and from a divided artery of the mucous membrane of the stomach. The wound in the liver was closed by means of deep sutures, and that in the stomach by separate suture of the mucosa and serosa. These means sufficed also to control the hemorrhage. The peritoneal cavity was irrigated with a 0.6 per cent. sodium-chlorid solution, and a tampon of iodoform-gauze was introduced between the liver and the stomach. The abdominal wound was closed and an aseptic dressing applied. The post-operative course of the case was uneventful, the tampon being removed on the third day. For a week nutriment was administered by enema; in the second week liquid food was given by the mouth. A small fistula appeared at the site of the tampon, but closed after the extrusion of some of the suture-material used in uniting the wound in the liver. In the course of eight weeks the patient was perfectly well and able to resume his former work and mode of life. To protect the cicatrix he was instructed to wear a soft, elastic bandage.

Physiologic Rest in the Treatment of Prolapse of the Rectum.—BRYANT (*Mathews' Medical Quarterly*, vol. i, p. 513, No. 4), concludes an article upon the treatment of prolapse of the rectum with the following propositions:

The proper performance of the physiologic functions of the rectum contribute greatly to the advancement of rectal disease and to the sufferings of the afflicted.

The complete vicarious discharge of the feces through an artificial anus located in the sigmoid flexure reduces to a minimum the physiologic demands on each structure of the rectum.

The lessening of the physiologic requirements is commonly in direct proportion to the diminution of the fecal flow through the rectum.

The cessation or lessening of the fecal discharge *per rectum* exercises a palliative and curative influence on diseases of the rectum.

In certain cases of obstinate rectal prolapse the formation of a vicarious channel for fecal discharge is justifiable, both as a palliative and curative measure.

The preliminary establishment of such a channel for the purpose of cleanliness and the prevention of infection is justifiable in many grave operations for prolapse of the rectum.

The dangers attendant on the formation of an inguinal anus are much less than those invited by the contact of fecal discharges with large operative surfaces of the rectum.

When cure takes place great care must be exercised thereafter, otherwise the prolapse will return.

The Treatment of Fractures in Children.—LEBLOIS (*Thèse de Paris*, 1894; *Centralbl. f. Chir.*, 1894, No. 38, p. 900) concludes a study of fractures in children and their treatment as follows: Fractures in young persons differ from those in adults by the frequency of their seat at the junction of the epiphysis with the shaft, the preservation of the periosteum and the rapidity of union. This last fact is due to the greater activity of the elements that participate in the reparation of bony tissue. Frequently an excess of this process gives rise to the formation of an undue amount of callus. Such a hyperplasia in the case of fractures about the joints may result in interference with the restoration of normal mobility. Protracted immobilization must be carefully avoided in the treatment of fractures about joints, and should give way to massage and early passive movement. The treatment of fractures in children by these methods is in most cases attended with excellent results, both as to the speediness of recovery and the restoration of function.

THERAPEUTIC NOTES.

The Therapeutic Value of Ice in Ophthalmic Surgery.—MCGILLIVRAY (*Ophthalmic Review*, vol. xiii, No. 155, p. 294) commends the topical employment of cold in ophthalmic surgery. In case of recent injury to the eyeball the eye is bathed with a sublimate solution (1 : 5000), the patient is put to bed and instructed not to open his eyelids, and ice-compresses are applied immediately and continuously. If, after a day or two, no inflammatory reaction has set in, the compresses are withheld. In cases attended with inflammation, the application is continued till the process has subsided. Each compress is removed as soon as it begins to lose its cold feeling, and a fresh one is applied.

For Bronchorrhea.—

SATURDAY, NOVEMBER 24, 1894.

ENGLISH AND AMERICAN TEACHING OF MEDICINE.

WE have received a courteous letter from a great teacher of medicine in the United States, calling our attention to an inaccuracy in our report of the number of students of medicine in England, published in a comment in THE MEDICAL NEWS of November 3d. This error, which we regret, consisted in quoting as the total number of such students (552) in England what should have been given as the number in the metropolitan or London schools. With a population, for example, five times as great, London has about one-fifth the number of medical students as Philadelphia.

Our correspondent further avers the commanding excellence of the English teacher of medicine, and cites many examples to prove the contrary of our contention. In reply we would say that opinions on such subjects must of course differ with the standpoint of the questioner, and that a few or a number of noteworthy exceptions may not change the general truth of a large proposition.

But our critic is more contemptuous of our advice to the American medical student to first exhaust the opportunities of his own country before going abroad. The *British Medical Journal* cannot, surely, be charged with a bias toward our view, and from the editorial columns of that journal, October 13, 1894, we make the following extract. The leader is entitled:

THE BITTER CRY OF LONDON AS A TEACHING MEDICAL CENTER.—The failure of London to attract foreign medical students is at the present day conspicuous and growing. When we read that the 20 medical faculties in Germany numbered among their students no fewer than 3507 foreigners out of a total of 8012, during the last summer session, there is surely room for inquiry why London—with a clinical field so enormous—should number its foreign students by units, while the German universities count them by hundreds. In fact, at some German universities foreigners are in excess of the natives.

There are, no doubt, many reasons for this state of things, and it is difficult to appreciate precisely the weight which should be given to each. Something is due, no doubt, to the bare manner in which the teaching in the London schools is directed to meet the requirements of examining boards. Everything is subordinated to getting the average man through his pass examination, and not a little to cramming the laggards up to a point which will enable them to "satisfy the examiners." There are no endowments; there is no university teaching; the voice of the researcher in London is as of one crying in the wilderness, and overpowered by the howls of the half-penny newspapers, whose phenomenal ignorance is made poisonous with calumny. Another but related reason is the want of facilities and opportunities for clinical research, using that term in the widest sense. Where are we to look for well-organized clinical departments, with adequately fitted clinical laboratories, for the chemical and bacteriological study of cases? The examination of cases at the bedside, which was the watchword of the great school of medicine in England in the middle of this century, needs now to be supplemented by careful laboratory-investigations, and facilities for these must be provided if this country is to continue to hold a leading place as a medical center. A medical center is not merely a place where so many hundred students are turned out to a pattern every year, but a center where the higher, so-called "post-graduate," instruction is given by men of wide experience or special training, thoroughly acquainted with every advance, and where the advanced student can receive the guidance and direction which he requires. The medical journals published in America contain about this time of the year many letters from American visitors to Europe relating their impressions of the medical schools. The criticisms on London are all more or less to the same effect. "There are too many medical subcenters, with no inclination toward centralization," writes a correspondent to the *Occidental Medical Times*. "The distances between the educational institutions are so great that the post-graduate courses in medicine are very poorly attended." He agrees with others of his compatriots that the American student who wants advanced courses will do better in New York. In New York, indeed, the post-graduate classes have reached a high pitch of organization, and possess an immense building which is college and hospital in one. In Vienna, in Berlin, and in other German

centers the foreign student is able to attend courses in special clinical departments conducted by junior members of the teaching staff of the university; and it must be remembered that any graduate who can show reasonable credentials can obtain the status of *Privat-docent*, and as such can claim certain facilities for the use of laboratories and museums for teaching purposes. Teaching there is a profession. The university and the institutes of biology, pathology, and pharmacology are furnished by the State. The professors are chosen almost without exception from the ranks of these young men, who have won their spurs as *Privat-docenten*. There is a greater freedom of inter-university communication, the student and the teacher can, and does, pass from one to the other, and the universities vie with each other in providing the most complete laboratory-accommodation. It is, indeed, an astonishing thing to see the magnificent institutes for pathology, for hygiene, and for clinical medicine, which exist in even the minor German centers, and to turn to London, which in these respects is a by-word among the nations. There is no great medical school in London which has anything to compare with them, and of any great central institution London has nothing to show beyond the laboratories of the Conjoint Board on the Embankment—an institution well enough in its way, but not available for education, and one which, when compared to the immensity of London and its wealth, rather evidences a want than fills it.

The movement for a real university in and for London had its origin, and draws most of its strength, from the schools engaged in what we may call "primary" medical education. The grievous disadvantages which London students labor under, owing to the want of reasonable facilities for obtaining a university degree, is the most glaring defect, due to our want of centralization and the play allowed to conflicting individualism.

The State which gives nothing can, of course, exercise no control, for it has no control, and so royal commissions come and go and leave not a wrack behind. The elements of a university exist, but not the university.

Now it may possibly be contended that this refers mostly to a comparison of English and Continental teaching, and not so much to American as compared with foreign teaching. Of one thing, however, there can be no doubt, it settles the question of the relative value of English and Continental teaching. If the American student is to seek other lands for medical study it is certainly not to London that he will go, but to Germany. But another fact is equally incontrovertible, viz., that instruction in Germany is dependent upon a practical knowledge of the German language. Now, how many American students can afford to spend one or two years in first acquiring such a useful knowledge of German, and then can spend one or two more years in learning medicine in that language?

Not one in a thousand! Nothing is more useless and wasteful than the attempt of Americans without a knowledge of German to go to Germany for a year in order to study medicine. How many thousands now regret having so wasted time and money on the intricacies of "gehabt haben werden" and the Teutonic grammar? "He has studied abroad" may help to advertise the young doctor, with a certain class of desired patients, but only the born-advertiser wishes such helps. For the few who can spend several years in Germany, after they have by previous years of study at home exhausted the opportunities here, it is doubtless wise, and most wise, for them to learn what Germany has to teach. It was not to these few we suggested our advice; it was to the many, the vast majority, indeed, who can give but a few months, a year, or possibly a little more, to post-graduate study. Our own custom, unless in some wretched exceptions, of encouraging instead of discouraging young teachers, of multiplying the laboratories, quizzes, seminars, etc., distinctly ally our methods to those of successful Germany rather than to those of unsuccessful England. We still believe that, as a rule, it is good advice to our young men to stay at home and to utilize the splendid advantages offered by many great medical centers in the United States. These advantages, if not quite commensurate in some respects with those of Germany, will with a little patriotic encouragement quickly rise, after the true American habit and fashion, to meet all the demands made upon them. We see no objection to patriotism when it is true and justifiable and when it is to the advantage of scientific progress.

It strikes us, moreover, as somewhat illogical for a teacher in an American post-graduate medical school to earnestly advise all American post-graduates to study medicine abroad.

We have only indicated some of the reasons for the faith that is in us. We have not alluded to the often-noticed fact that long residence abroad by no means best fits a man for success in the daily practice of medicine here. Not a few examples could be adduced to show that it rather unfits him. In certain specialties we are certainly in advance of European custom. The theory of medicine may possibly be as well or even better learned there. A literary physician may, perhaps, be better outfitted there; most certainly the laboratory physician, and the teacher. We do not advise such. They will follow their own good wisdom. There is yet another disadvantage the student will find when he settles at home after his studies abroad. If, as is probable, he uses here his possibly acquired habits

of brutality toward dispensary and poor patients, he will find himself avoided and "stranded"—and justly so.

AN HYSTERICAL ARM IN COURT.

In a court of justice not far from Philadelphia a suit for damages was fought and won recently, based upon the following circumstances: A young man, walking along a boardwalk at a seaside-resort on a wet day, received a shock from a current of electricity which passed from a low-hanging arc-lamp along his umbrella-handle, the tip of which had come accidentally in contact with the lamp. The damage claimed to have been done was to the arm, which had remained paralyzed for months. The general health was unaffected. It was shown that at the time of the accident the man fell in a fit, which lasted for a long time, during which it was necessary for several men to hold him.

At the trial the arm presented an exceedingly bad appearance. It was totally paralyzed from the shoulder down, and hung limp and flail-like at the side. It was *uniformly* affected, *i. e.*, not only one or a few groups of muscles were paralyzed, as is the case usually from local trauma, but all the muscles of the shoulder, arm, forearm and hand were equally and completely involved. Hence the affection was a monoplegia, and had the features of a *central* instead of a peripheral palsy. The claimant, when he wished to move the arm, took hold of it with his sound hand and swung it about as an inert and lifeless object. There were no contractures, but the hand and forearm were cold, and markedly edematous and blue. The skin was and had been uninjured. The man had been treated in the surgical clinic of a large hospital, because for some reason his case had been regarded erroneously as a surgical one. At the trial an effort was made, of course, to present the injured arm in as unfavorable a light as possible for recovery: it was even intimated to the jury that the nervous and muscular tissue had been "disorganized" by the electric current, and, consequently, that the patient could not recover. Several physicians, including the surgeon, gave testimony, but they did not attempt the formulation of a scientific diagnosis.

On the other hand, the electric company called a medical witness who demonstrated in open court, where alone he had the privilege of examining the claimant, that the neuro-muscular apparatus was not injured permanently. This he did by the use of a faradic battery. Demanding that the patient should be stripped (a demand that was firmly but unsuccessfully resisted by the claimant's counsel), this physician showed that the muscular nutrition was good, and that all the muscles responded actively to the current. He explained to the jury, which was not an intelligent one, that when nerves and muscles are destroyed or "disorganized" the muscles waste, and that among the very first symptoms shown by them is a failure to respond to the faradic current. He explained also that the blue and swollen appearance of the hand and arm is a sign frequently seen in functional, *i. e.*, hysterical palsies.

The jury, as was expected, rendered a verdict for the claimant, and gave him $5000.

The hysterical stigmata in this case were unmistakable. The complete monoplegia, the blue edema, so well described by French writers, the preservation of muscular nutrition and faradic contractility, and the occurrence of an hystero-epileptic seizure at or about the time of the accident, marked the case indelibly. It is more than probable that the arm was anesthetic, presenting the gauntlet, or segmental, type of anesthesia, but this was not tested in court for fear that, if discovered, its effects upon the minds of the jury might be still more disastrous to the case of the company.

This case raises several important questions: First, does a powerful shock of electricity ever leave a permanent injury to nerve-tissue in cases in which it does not kill? In other words, could an electric current expend its force in such a strictly local way as to destroy the neuro-muscular apparatus in a man's arm, sparing the skin,and yet not kill the man? We are not familiar with any such instance. The foregoing case certainly was not one. In such an instance the local traumatic effect would be destructive, and the arm would present symptoms of organic change, such as wasting and the reactions of degeneration. It seems almost inconceivable that a current capable of doing this much local injury should spare the victim's life. Shocks from electricity are now becoming common accidents, and if they can leave permanent, or even enduring, peripheral nerve-changes the fact should soon be making itself evident. The impression is that if the shock does not kill it does not permanently injure. On the other hand, electric shocks, as strokes of lightning, have long been known to be exciting causes of hysteria.

Second, is not a patient suffering from traumatic

hysteria entitled to damages? It seems too often to be rather implied that an hysterical patient is a fraud, and that he or she is entitled to nothing but contumely. This is neither a scientific nor a humane view. The hysteric is *never* a malingerer. His disease is one of the most genuine in nature, and one of the most difficult to simulate. This young man, with his palsied, blue, and edematous arm, had probably never heard of the school of La Salpêtrière, nor had ever read any French effusions in iconography. Yet his arm was strictly according to the type. If he had lost his arm there could have been no question as to his rights. Why then should there have been a question when he had lost *the use* of his arm?

Finally, why are such cases regarded as surgical? In the Paris hospitals it has been found that hysteria is more prevalent among men than among women, and this preponderance is due largely to *trauma* and to alcohol. The Philadelphia hospitals would probably give equally striking results, especially if the surgical wards were searched. But are these cases properly treated, or is their true nature even recognized, in the surgical wards?

EDITORIAL COMMENTS.

The Patent-medicine Disgrace, rampant in the United States, and discouraged and forbidden by foreign governments, proves better than anything else the semi-barbarism of our American civilization. In Germany a nostrum-maker was recently fined $500 for advertising that his "Beard Promoter" was an infallible article for producing a beard. It was tried, proved to be a failure, and the suit was brought and won. Why cannot similar methods be pursued in our country against the horde of wretches who feed upon the gullibility of the public?

Not long since the millionaires who spend millions of dollars in newspaper-advertisements met in New York to celebrate the success of their methods and to elaborate plans for a still greater share of the wealth of the poor. The newspapers are friends of their friends, and gave pages gratis to reporting their doings and publishing their portraits. It seems that a million dollars a year is not an uncommon amount for a single firm to spend in advertisements. We learn that a bill has been introduced into the House of Representatives having for its object the suppression of these advertisements. We wish it might pass, but we have no idea that it will.

And what ludicrous and wretched stuff is the substance of these advertisements, and how they enable otherwise worthless newspapers to continue their useless existence! There is one infallible test of the trashiness and venality of a newspaper. Its reports of news will be unreliable; its choice of news will be vile; its politics will be purchasable or violently partisan, just in proportion as its columns are filled with this greedy, crazy patent-medicine filth.

In England in 1860 the government taxed these concoctions $218,000, and the amount gradually rose till in 1892 it was over $1,200,000, an increase of over 600 per cent. The last sum represents an annual sale of nearly 38,500,000 packages. Think of the hogsheads of this stuff that the English people have poured down their throats! But what immeasurably greater quantities our own people are guzzling every year! Instead of taxing this traffic, if we cannot root it out, we prefer to encourage it, encourage the secrecy of it, give its millionaire owners the protection of the government, nay, let them make our laws, and never a medical society raises its voice or hires an attorney to set some limit to its swinish disease-producing impudence.

Pathogenic Lectures on Hygiene and Medicine.—The world-old difficulty of practising what one preaches is daily illustrated in the unhygienic conditions of the rooms in which lectures or public meetings are held. Since we attended lectures in Germany it may have been that a stray gleam of practical common sense as regards ventilation may have penetrated the atrocious hygienic barbarism of that otherwise civilized land, but we wonder if to-day the lecture-rooms there are as foul and filled with nauseating stenches as formerly. In our country of to-day the theater and public lecture-room not controlled by any hygienic authority but solely by financial interests are often better ventilated apartments than the rooms wherein are held lectures on medicine and hygiene. We have in very recent times attended lectures on biology where the air was deadly to living things and the mind stupefied by the non-oxygenation of the blood. Of what use is it to have only theoretic knowledge if no application of it is to be made? Why teach by word-of-mouth the righteousness of sanitation and illustrate the hypocrisy of the teacher and the valuelessness of the teaching by the unrighteousness of a fetid atmosphere? Why teach the laws of the oxidation and circulation of the blood while hundreds of furious gas-jets are competing with hundreds of hungry lungs for air to use, and also into which to throw the poisonous products of oxidation? Why teach the laws of optics and the physiology of vision whilst the retinæ of all listeners are shamelessly abused and injured by the unshaded, flickering, naked flames of gas-jets, fed with poor gas, at which gas-lights one must stare if the speaker is to be seen or even if the eyes are to be opened at all. It would appear to be a duty of those responsible to endeavor not to kill while teaching the duty of curing, to not create pathologic "specimens" while lecturing upon the sad results of pathologic study, and in the very act of seeking out the causes of certain afflictions of mankind not to encourage other pathogenic conditions.

The Specificity of the Cholera-bacillus.—If incontrovertible proof of the specificity of the cholera-bacillus of Koch were wanting it would be furnished by cases of accidental infection in the laboratory. Such a case occurred several years ago in the Hygienic Institute at Berlin, fortunately with a favorable outcome. A parallel case, but ending fatally, has recently been reported by REINCKE (*Deutsche medicin Wochenschr.*, 1894, No. 41, p. 795). The case was that of a medical man, who, while engaged in investigations of suspected

cholera-water in the Hygienic Institute of Hamburg, was seized with diarrhea and vomiting, passing into an asphyxic condition, out of which he could not be brought, and to which he finally succumbed. That infection took place in the laboratory there was no doubt, although the precise mode of occurrence could not be unequivocally established. The accuracy of the diagnosis was confirmed by the presence of cholera-bacilli in the stools during life, and in the intestinal contents after death. A single case of this kind has more weight as to the specific powers of a given micro-organism than no end of negative evidence. It should also carry with it the admonition of care to be exercised in the manipulation of pathogenic microorganisms in demonstrations and investigations.

The Trolley-gong Nuisance.—In introducing swift-moving trolley-cars it was perhaps necessary that danger should be averted by the ear-splitting gong. It is now a question whether the health of more people is not injured and their deaths hastened, so that the slow deaths are more numerous and indirect injury is much greater than the quick deaths and the direct injuries from running over a few people. The point of the matter consists, however, in the fact that the companies cannot be sued for damages in case of the slow deaths, whilst it costs money to run over and kill people at once. It is the infernal ringing of the gong at nights, on Sundays, and in empty streets, of which we chiefly complain. Why is this mechanical, indiscriminating, stupid nuisance permitted? On Sunday morning, when a poor exhausted worker tries to make up for overwork and for the loss of sleep occasioned by the unearthly noises of six days and nights of bedlam—on the early Sunday morning, when the streets are empty and there is not even a stray cat to run over, why must these gongs be thundered and banged to the banishment of all sleep and rest of thousands of people? It is an outrage our people should not submit to!

From Across the Ocean.—Our readers will remember the interesting article of Dr. Warthin on some physiologic effects of music in hypnotized subjects, published in The Medical News of July 28, 1894. The facts brought out by Dr. Warthin really opened up a new field of psychologic investigation, and we were glad to present the study in our columns. Now, after some months, Continental scientists are repeating and Continental journals are reporting the facts of Dr. Warthin's study, and all as if discovered by them, and of course without a word of credit to The Medical News. The echoes are even returning to our country, and the novel investigations are described as if, like all other good things, they came from the East. How hard it is to get our people to recognize the things they have to be proud of, and how proud they are of some things that it were better to be silent about. Our ingenuity and mechanical inventiveness are acknowledged everywhere, but we are so accustomed to receive our science from the East that we ignore the splendid scientific advances made by the American mind, and do not get the credit from the world of the noble scientific spirit that is alive amongst us, and that in many fields is producing most noteworthy results.

Poor Food in Asylums.—That deficient nutritive value in food supplied to the inmates of hospitals and asylums must interfere with satisfactory treatment of them need not be argued. Doubtless there is a wide field for original investigation as to the influence of diet upon insane and otherwise defective patients. So much distressing evidence of municipal corruption has been exposed lately in the New York investigation that we are not surprised to learn that Dr. Austin Flint has denounced before the State Commission on Lunacy the adulteration of food supplied to some of the asylums for the insane. He pointed out among other things that chicory was mixed in the coffee, and that bad tea was used. He also said that the quantity of food is often insufficient.

A comprehensive investigation into the food-supply of public institutions would yield some surprising results. The use of oleomargarin is not infrequent, although it is doubtless billed as butter, and real butter is furnished for the officers' tables.

Electric Purification of Water—Droun has lately investigated the purification of water by electricity and finds that the method is efficient, but applicable rather to sewage than to water-supply. The purifying action depends on the formation of sodium hypochlorite (chlorated soda U. S. P.), which is an excellent germicide. Much nonsense has, of course, been uttered in regard to the use of electricity as a disinfectant, and terms as "electrozone," "electro-saline solution," etc., are suggested by inventors and promoted by sensational newspaper-reports, but the question of the applicability is merely one of expense and convenience, as the active agent, sodium hypochlorité, is an article of commerce. One objection to chemic purification of sewage, even when the chemicals used are not poisonous, is that all microbes are killed and the cycle of changes in the organic matter is interrupted.

REVIEWS.

A Dictionary of Medicine, Including General Pathology, General Therapeutics, Hygiene, and the Diseases of Women and Children. By Various Writers. Edited by Richard Quain, Bart., M. D. Lond., LL.D. Ed., F. R. S., Assisted by Frederick Thomas Roberts, M.D. Lond., B. Sc., and J. Mitchell Bruce, M A Abdn., M.D. Lond. With an Appendix by Samuel Treat Armstrong, M.D, Ph.D. New edition, revised throughout and enlarged; 2 vols. New York: D. Appleton & Co., 1894.

The first edition of this standard, one might say classic, encyclopedia of medicine was issued in 1882, and, according to the preface, there have been issued more than 33,000 copies since that time. The first edition contained 1834 pages; the present, 2518; and 43 new illustrations have been added. The illustrations might often have been better, and certainly still many more might have been added with much advantage to the reader and without too greatly increasing the size of the volumes.

No one, in view of the tremendous progress of med-

icine in the last twelve years, will dispute the need of such a complete revision and of such large additions as are now made. In the limits to which we are restricted it is manifestly absurd to attempt any detailed description or criticism of this splendid work. As to description, every reading medical man knows well enough its general scope and plan. The term "dictionary" is an unfortunate one, as it misleads. In the usually-accepted meaning of the term it is neither a dictionary, nor a lexicon, nor a word-book, except in the sense that the articles are arranged alphabetically. Many thousands of dictionary-words are omitted altogether. The etymology of words is sometimes briefly given, but very often not, and the philologic and defining aspect is (rightly enough, considering that the book is *not* a dictionary) quite thoroughly ignored. The work is an encyclopedia of medicine and allied sciences, and undoubtedly the best one in the English language.

As to criticism, the mention of a dozen or two minor points we have noticed would seem hypercritical and useless. We have no wish to indulge in the crime of criticasters and give praise in one line of glittering generality and then write a hundred lines of exaggerated and emphasized carping. Such books as this involve years of life-wasting labor. A thousand hours of conscientious searching and drudgery and intellectual toil of the most painstaking kind too often pass with the reviewer unthought of and unpraised, while a few inevitable errors, omissions, or typographic blunders are pounced upon to show the critic's omniscience and superiority.

It is noteworthy that science nowadays is advancing so rapidly that an encyclopedic work like this, dated 1894, contains not a line or word as to the antitoxin-treatment of diphtheria. How old are our youngest books! Enzymes, ferments, and fermentation, etc., are also omitted. Dr. Stevens will never forgive the authors, we fear, for omitting all mention of exophoria—all the 'phorias—graduated tenotomy, etc.

We cannot forbear also to add a word about the old, old story of English illogicality as to orthography. It is an amusing and characteristically English sin to abuse the deplorable ignorance displayed in "American" iconoclastic spelling, and in doing so display a profundity of ignorance of the very a, b, c of etymology and philology. Thus, as in this work, we have, of course, a clinging for dear life to some of the ancient ways, as in *hæmorrhage*, *diarrhœa*, *ætiology*, *œdema*, etc., but we find *gangrene* instead of gangræne ("γραίνω"), *hemianopia* instead of *hemianopsia* (though quoted as derived from ὤψ—a typographic error makes it ἀψ), etc. The writer escapes inevitable criticism in omitting the derivation of *thyroid*. If he had quoted the Greek origin and still written *thyroid* instead of *thyreoid* (the correct form), he still would have been doubly guilty of etymologic crime. The etymology of diphtheria is given, and yet the adjectival form *diphtheritic* is used instead of the more proper and shorter form *diphtheric*. The authors will receive the gratitude of Dr. Greenhill and Mr. Tweedy for espousing their cause and heightening the wretched confusion as to the meanings of the words *hemeralopia* and *nyctalopia*, two words that henceforth must be banished from scientific usage.

The American supplements add to the value of the work. We are glad to notice the generous and just praise accorded to the assistant editors, Drs. Roberts, Bruce, and Harold, for their most important share in bringing out the volumes. We trust American students will show a hearty appreciation of this great work.

A Practical Treatise on Orthopedic Surgery. Designed for the Use of Students and Practitioners. By James K. Young, M.D., Instructor in Orthopedic Surgery, University of Pennsylvania, etc. Illustrated with 285 woodcuts. Philadelphia: Lea Brothers & Co., 1894

The frequency with which text-books and brochures on orthopedic surgery and allied subjects come from the press is a gratifying testimonial to the interest in this important branch of surgery. Very few text-books on general surgery deal satisfactorily with deformities and diseases of the joints. The chapters devoted to orthopedics are usually brief abstracts gleaned from literature.

The present volume is certainly a credit, not only to the publishers, who always bring out books in excellent shape, but to the author as well, who has been known for a long time as a thorough, painstaking, conscientious student in this neglected branch of surgery.

His classification in Chapter I is commendable, and will certainly be regarded as standard. In studying the different chapters one is impressed with the thoroughness of the work, and it is difficult to bring against the author any charge of one-sidedness or of neglect of the teachings in current literature. The illustrations are sufficiently numerous to make the book thoroughly practical. The criticism might be offered that a certain number are taken from text-books in general surgery and in neurology, and might better be replaced with illustrations more to the point. Yet it is difficult to secure adequate illustrations, and the temptation of the publisher to make use of cuts already in stock sometimes overrides the wishes of the author. The style is clear and the chapters are well arranged.

Taking up the subjects more in detail, one finds that the lines of treatment which are still *sub-judice* are not urged dogmatically, but in a modest way that leaves the student free from any temptation to adopt such procedures.

The author's teachings in the use of plaster-of-Paris are not quite up to date, simply because he is not an ardent advocate of this method, and hence is not expected to be thoroughly familiar with the details that in many hands contribute to a success which he has not attained.

In treating of knee-joint diseases he has made a very careful study of the subject, and one can detect a more thorough knowledge of statistics furnished by some of our German authorities than he would get from a personal study of a large number of cases under his own observation.

In the chapter on lateral curvature of the spine there is a lack of dogmatic teaching which is probably pardonable. The author states the various methods fairly, yet his own recommendations are in the line of medical gymnastics. The various forms of apparatus for crowding the ribs into better position are abundantly illustrated.

In the chapter on infantile spinal paralysis the space given to the faradic and galvanic reactions may not be unduly criticised, yet one hardly expects in a work on orthopedic surgery so much neurologic material, and

is likely to question the propriety of the value placed upon electricity. The prognosis given is sufficiently guarded, but when he comes to treatment and says, "The treatment will depend upon the stage or period during which the disease is seen," one understands that the author has not had a very large experience in the management of this affection, which is accompanied by so many deformities that come within the scope of the orthopedic surgeon. Still, the medical treatment given is to be commended. In like manner his advocacy of mechanical appliances that will protect joints and prevent straining of ligaments unsupported by muscles is certainly worthy of admiration.

The foregoing criticisms are not meant in any way to detract from the value of the book as a whole, and the author is to be congratulated most heartily on the presentation of a work so free from injudicious advice and so full of practical suggestions.

Transactions of the Southern Surgical and Gynecological Association. Vol. VI, Sixth Session, held at New Orleans, La., November 14, 15, and 16, 1893. 8vo., pp. 392. Published by the Association. Philadelphia: W. J. Dornan, 1894.

This handsome volume, while it affords evidence of the activity and earnestness of the body from which it emanates, can scarcely be regarded as an important contribution to surgical literature. Besides the Annual Address of the President, and a eulogy of Ephraim McDowell, by Dr. McMurtry, of Louisville, it contains twenty-nine papers on scientific subjects, most of which would appear to have evoked free discussion. None of these essays is of very high grade. Perhaps the best is one entitled "Intra-cranial Neurectomy and Removal of the Gasserian Ganglion for Intractable Neuralgia," with a report of four cases, by Dr. Tiffany, of Baltimore. Dr. Hunter McGuire, of Richmond, Va., gives a very brief but interesting account of a case of tuberculous disease of the urinary bladder, in which great relief was afforded by supra-pubic cystotomy. A paper by Dr. Parham, of New Orleans, on the bloodless or "skewer" method of hip-joint amputation, would have been far more valuable had the author given the references to the original accounts of all the forty cases collected by him. Dr. Briggs, of Nashville, Tenn., recording his personal experience in the operative treatment of vesical calculus, speaks very highly of the medio-bilateral perineal section, except in cases of large and hard calculi, when the supra-pubic route may be chosen, or in those adapted for litholapaxy. Without questioning the successes claimed by this well-known surgeon, we cannot but think that the simpler procedures are to be preferred; that in the hands of the average operator supra-pubic section is safer than either of the perineal methods. This seems also to have been the view taken by those who discussed Dr. Briggs' paper.

Of the gynecologic essays, the most important is by Dr. Engelmann, of St. Louis, in advocacy of the vaginal route in pelvic operations; his ideas met with strenuous opposition.

We note in a paper by Dr. Keily, of Baltimore, the term "pelveo-peritonitis." It is not Latin, Greek, or English, and it is awkward as well as unnecessary.

It is stated that sixteen papers were read by title, but as only five of these are published, there is no positive proof that the remaining eleven had any other existence.

By more careful revision of the reports of the discussions, some awkward lapses, sometimes of style and sometimes of sense, might have been avoided.

A Manual of Hygiene. By Mary Taylor Bissell, M.D., Professor of Hygiene in the Woman's Medical College of the New York Infirmary for Women and Children. Small 8vo, pp. xii, 330, and Index. New York: The Baker & Taylor Co.

This work is intended primarily to be a text-book for medical students, but the author expresses in the preface the hope that it may be found useful in higher schools and colleges not connected with medical institutions. In the main it will doubtless be a great improvement over the manuals of hygiene which are favored by school-boards, but it is certainly not without demerits. In the chapter on water, for instance, we are told that the consensus of experts has fixed the limits of "bacterial permissibility" in water to be anywhere from fifty to five hundred per cubic centimeter. Apart from the inference that water containing less than fifty per cubic centimeter would not be permissible, the statement gives currency to the now exploded view that the number of bacteria in a sample may be taken as an index of purity. On page 100 we are advised that ammonia salts may be detected in water by adding Nessler's reagent to a small quantity of sample, a method of testing that is never used by competent analysts unless there is reason to believe that the quantity of ammonium salts is quite large. In fact the two pages devoted to the analysis of water show a failure to consult the recent literature on the subject. The same may be said of the chapter on milk, in which it is stated that oleomargarin is much lower in price than butter, a statement that is quite erroneous in the sense in which the author intends it to be understood. We note in this chapter that Flügge gives one hundred thousand bacteria per cubic centimeter as the maximum permissible limit in milk (probably as preposterous a statement as Flügge ever made), and we also note a reference to Mr. *Earnest* Hart. Mr. Hart undoubtedly merits this amendment to his name; still we question if he would be pleased by it. The book is well printed, and the illustrations as a rule good. It is difficult to see why, in the brief article on the bacteriologic examination of water, the only illustration should be that of the ruled-square for colony-counting.

Transactions of the Medical Society of the State of Pennsylvania at its Forty-fourth Annual Session, held at Philadelphia, 1894. Volume xxv. Published by the Society. Philadelphia: The Edwards & Docker Co., Printers, 1894.

A better idea of the contents and value of the *Transactions of the Medical Society of the State of Pennsylvania* for 1894 can be obtained by reference to the News of May 19 and 26, containing a report of the proceedings of the last annual session of the Society than could be given within the limits of a brief review. We have but to add that the work reflects credit upon the Society and is up to the high standard already established.

CORRESPONDENCE.

THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

To the Editor of THE MEDICAL NEWS,

SIR: In the report of the discussion at the New York Academy of Medicine in your issue of November 17th, page 561, the question of Dr. J. Lewis Smith as to the effect of the antitoxin upon pseudo-diphtheria was put to me, and not to the chairman.

I replied that treatment with the antitoxin was not instituted by Prof. Baginsky unless the diagnosis was positively established to be diphtheria by the well-known bacteriologic methods. The antitoxin being an inert substance, however, really could do no harm even when injected into the body of a healthy person.

Dr. Berg then asked whether we recognized a streptococcus-diphtheria as distinct from a Loeffler diphtheria, and what results were achieved? To this I replied that we recognized only as diphtheria that form of disease in which Klebs-Loeffler bacilli were found.

In the discussion I cited a case of malignant laryngeal diphtheria which arose in the Messiah Home for Children, and which I sent to Willard Parker Hospital. The case was injected by Dr. Shrady, and got well.

Sincerely,

LOUIS FISCHER.

187 SECOND AVE., NEW YORK.

NEWS ITEMS.

The Antitoxin of Diphtheria.—The immunization of a horse in the process of preparation of the antitoxin of diphtheria was commenced on November 5th at Washington by Passed Assistant Surgeon Geddings, of the United States Marine-Hospital Service, by the subcutaneous injection of 0.5 c.c. of the toxins of the diphtheria-bacillus. The operation was followed by little local and constitutional reaction. The injections are to be repeated at intervals, and the whole process should be completed in the course of from eighty to ninety days.

Dr. William P. Spratling has been elected Superintendent of the Craig Colony for Epileptics, of New York. The choice was made by competitive examination. Before entering upon his duties Dr. Spratling will visit the famous colony for epileptics at Bielefeld, Germany, and also other colonies of a smaller scale recently established in England.

Smallpox in Washington, D. C.—During the week ending November 14th, five new cases of smallpox were reported in the District of Columbia. One occurred in an employé at the smallpox hospital, the remainder in private families.

Smallpox in Wisconsin.—From October 22d to November 5th, 117 cases of smallpox were reported in Milwaukee, with 43 deaths.

FURTHER OBSERVATIONS UPON THE ETIOLOGY, DIAGNOSIS, AND TREATMENT OF ACUTE AND CHRONIC APPENDICITIS, WITH THE REPORT OF SIXTY-ONE CHRONIC CASES OPERATED UPON, WITH ONE DEATH.

BY JOHN B. DEAVER, M.D.,
PROFESSOR OF SURGICAL ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

SINCE the publication of my last papers on appendicitis, which appeared in THE MEDICAL NEWS of May 19, May 26, and June 16, my further experience has more than convinced me that the views then expressed have been borne out by the results attained by the measures then advocated. Further, I am prepared to express myself more strongly than ever in favor of early operation in acute primary attacks of appendicitis, and of operation in all cases of chronic appendicitis, including under this heading the sub-acute, the relapsing, and the recurrent varieties.

As regards etiology, I would emphasize the views I have already expressed regarding the importance of foreign bodies as a factor in the causation of a large proportion of acute and of a smaller number of chronic cases. In the great majority of the latter the condition found is that of a chronic catarrhal inflammation, while the bulk of acute cases is due largely to foreign bodies, *i. e.*, fecal concretions and extraneous substances. I have only seen two cases in which real foreign bodies were not found. In one, an acute case, the appendix contained a large number of strawberry-seeds; in the other, a chronic case, the appendix had contained a date-seed which had escaped at the point of ulceration. It was found above the tip of the appendix, which pointed north and lay behind the colon.

I believe that all cases of appendicitis begin as a catarrhal inflammation, in which the bacterium coli commune plays an important causative rôle. After this inflamed condition of the appendix has been established, the future outcome of the case, pathologically, very frequently depends upon the presence of a fecal concretion or foreign bodies and bacteria of suppuration other than the bacterium coli commune. No definite rule can be laid down, because there are cases that illustrate both conditions. It has been my experience that in acute perforative, and frequently in non-perforative, cases fecal concretions were found to exist either within the organ or in its immediate neighborhood.

I have already made the statement that the diagnosis of appendicitis is not difficult in the vast majority of cases. I am now more than ever convinced of the truth of this statement and of the importance it bears to successful treatment. The history of the case and the localized signs that center around that most valuable landmark known as McBurney's point are always sufficient to establish the diagnosis either directly or by exclusion. The acute cases that go on to suppuration, and in which there is the greatest tendency for the pus to become circumscribed, are those in which the appendix points toward the northern end of the appendiceal compass and lies between the layers of the mesocolon.

The palpation of the appendix in chronic cases is a valuable and reliable means of diagnosis. Of course, in those cases in which the organ lies behind the cecum the method is less valuable, although it is even then of service, because when the cecum is distended the condition is due to flatus and not to feces. This has been my experience in the sixty-one chronic cases upon which I have operated, to say nothing of a much greater number of acute cases. I have been able to diagnosticate and demonstrate by operation a thickened appendix, giving its direction and location and its depth from the anterior wall of the abdomen. Women are better subjects, but the method is applicable to men, especially if they have been the victims of repeated attacks of appendicitis. In chronic cases I have noted that upon palpation over the base of the appendix the pain is referred in a direction corresponding to the long axis of the organ, *i. e.*, when the pain is referred to the liver the appendix points north, and so on, corresponding to the different positions that the appendix holds.

The difficulty attending the differential diagnosis between chronic appendicitis and incipient psoas-abscess, that is before the pus has passed any distance down the psoas-sheath, I have had forcibly brought to my mind recently in two cases. The chief points in favor of a forming psoas-abscess are the appearance of the patient, usually that suggestive of tuberculosis, the information to be obtained by an examination of the spine, a complete temperature-record, and a tendency to flexion of the thigh of the affected side. While the last-mentioned sign may

be and is present in some cases of chronic appendicitis, it is a far more frequent accompaniment of psoas-abscess. Palpation will, in the great bulk of cases of chronic appendicitis, determine the presence of a diseased appendix, while deep pressure over the right iliac fossa will in case of psoas-abscess, although revealing tenderness, fail to disclose the presence of either a diseased appendix or the characteristic rigidity of the flat muscles of the abdominal walls.

As regards treatment, my rule is this: Given the case of a patient who suddenly develops severe abdominal pain, at first referred either to the epigastrium or about the umbilicus, and later to the right iliac fossa, accompanied by nausea and vomiting, and following some dietary excess or indiscretion, and preceded as a rule by a history of intestinal dyspepsia, and when examination reveals rigidity and tenderness over McBurney's point, I at once administer a purgative, preferably castor-oil or salts. If this is not retained I give calomel. If after the purgative has operated satisfactorily the symptoms continue, along with an increase of intensity of the localized tenderness, I at once operate. The three cases that follow will illustrate my statement and prove my theory to be sound, and the procedure a life-saving measure.

Case I.—On the evening of June 26, 1894, I was called to see Dr. J. H. B., aged forty-five, one of our leading practitioners. I found him suffering with acute abdominal pain, most intense in the right iliac fossa, the character of which I recognized as that of appendicular colic. He gave a history of chronic intestinal dyspepsia extending back for a period of years, also a vague history of having suffered in the past from a slight attack of appendicitis. Three days prior to my visit he had suffered from an acute attack of indigestion, the result of indiscretion in diet, which had been somewhat relieved by active purgation. The day of my visit he had had several bowel-movements, yet the pain in the right iliac fossa, which was paroxysmal, was increasing in intensity, notwithstanding the fact that he had taken, upon his own responsibility, one-fourth of a grain of morphin. Physical examination of the abdomen convinced me that the man was suffering from an acute, progressive attack of appendicitis. I advised immediate operation, and at 8 o'clock the following morning I removed the acutely inflamed appendix, the mesenteric attachment of which was gangrenous in its distal half. Recovery was uninterrupted.

Case II.—Dr. J. C. R., aged twenty-two, resident physician in the German Hospital, while on duty was taken sick on the evening of August 30, 1894, with severe general abdominal pain, soon becoming localized in the right iliac fossa. Under active purgation he was somewhat relieved, but the appendicular pain persisted. On the evening of the 31st I was asked to see the patient by Dr. Frese, the chief resident physician of the hospital, who informed me that in his judgment the doctor was not so well, and he feared the case was progressing unfavorably. I confirmed Dr. Frese's diagnosis of acute appendicitis and advised immediate operation.

The operation was done at 8 P M. The appendix occupied the southwest position and was bound down by adhesions. It was gangrenous and about to perforate; it contained a small collection of pus at its tip. Recovery was uninterrupted.

Case III.—During the early part of the past summer I was called to see Mrs. B., the wife of a prominent Philadelphia physician, who was suffering from what was believed to be appendicitis. She was at the same time suffering from uterine hemorrhage, which from its severity and from the fact that it was associated with acute paroxysmal abdominal pain, raised the question of extra-uterine pregnancy. Vaginal examination demonstrated a point of excessive tenderness high up and to the right, but otherwise was negative. I confirmed the diagnosis of appendicitis, and we decided upon active purgation. This not being followed by abatement of her symptoms, operation was advised. The appendix lay southwest, was adherent, very much enlarged, and contained a considerable amount of pus. The surrounding tissues were covered with inflammatory lymph. Recovery was uninterrupted.

In this connection it is interesting to note that this was the third member of the family upon whom I had operated for appendicitis.

Case IV.—I recently saw in consultation a young lady with appendicitis in whom the symptoms had not yielded to purgation; the appendix was so palpable that it was believed to lie in contact with the anterior parietal peritoneum. Operation was advised. The appendix was found acutely inflamed and in contact with the anterior parietal peritoneum. Recovery was uninterrupted.

I report the following two cases of acute appendicitis to illustrate the frightful rapidity with which such cases may go from bad to worse if not operated upon very early. The only possible hope of recovery in such cases lies in immediate operation, as they that do not show decided improvement with marked amelioration of all symptoms, especially of tenderness, after the administration of purgatives.

Case I.—Mr. R., twenty-eight years of age, was attacked fifty hours before operation. The symptoms grew steadily worse in spite of all medication. When the belly-cavity was opened pus welled up in the wound in quantities. The appendix, which pointed northeast, was gangrenous and had separated from its attachment to the cecum, which also was gangrenous, leaving a large hole in the latter, through which fecal matter was escaping. The opening in the cecum was closed with difficulty. The peritoneal cavity was carefully and thoroughly washed out and drained with glass tube and gauze. The patient died on the third day following the operation.

At the post-mortem examination the external wound was found in good condition, and the glass and gauze drainage still in position. The omentum was congested and infiltrated, presenting the appearance of a cock's comb, and was adherent to the lower end of the cecum around the drainage-tube. All the tissues in the right iliac fossa were in a semi-gangrenous state. The cecum around the opening found at the operation was gangrenous; the stitches, however, were still in position. To the inner side of the row of sutures the bowel was perforated, allowing the escape of feces and pus. The general peritoneal cavity was infected, but contained very little pus; there was no pus in the pelvis. The intestines were covered with lymph. The cause of death was septic peritonitis.

Case II.—Mr. K., aged twenty-three, was attacked May 23 with severe abdominal pain, referred to the epigastrium, and soon becoming localized in the right iliac fossa. Tenderness was marked and persistent, and on the 25th was intense, accompanied by exaggeration of all the symptoms, local distention, vomiting, and constipation. Operation was undertaken on May 28th. When the peritoneum was opened a considerable quantity of pus escaped. The cecum was distended with gas, and the small intestines were injected, but not paralyzed or distended. The appendix, which occupied the northeast position, was brought into view and tied off. The meso-appendix was short, and was attached to the basal half of the organ; perforation had taken place at about the middle third; the appendix beyond was gangrenous. There were no adhesions, and apparently no attempt upon the part of nature to close off the general peritoneal cavity. The pus cavity was thoroughly washed out, but upon placing glass drainage in the pelvis fully a pint more of pus escaped. The patient made a rapid and safe recovery.

The amount of pus, especially that in the pelvis, and the absence of any apparent attempt upon the part of nature to protect the general peritoneal cavity, and the recovery of the patient, point conclusively to the fact that with proper technique the general peritoneal cavity under these circumstances can be protected against infection, and the case brought to a successful issue.

In connection with this paper I report 61 cases of operation for chronic appendicitis, with one death. The fatal case was the following:

B. K., a female, aged twenty-two, born in Ireland, was admitted to St. Agnes' Hospital, September 19, 1894, with a history of four previous attacks of appendicitis. At the time of admission to the hospital she complained of pain in the right iliac fossa. The tenderness in this region was so great upon slight pressure as to preclude a thorough examination. The greatest tenderness was at the McBurney point. Immediately beneath the right semi-lunar line, and within the abdomen, a large mass was felt. The patient suffered from retention of urine, requiring catheterization.

Upon opening the peritoneal cavity an immense mass came into view, composed of the small and large intestine and omentum, bound firmly together by dense adhesions. The omentum was ligated in sections and cut away. The adhesions were carefully broken up, exposing the cecum imbedded with the appendix in an inflammatory mass. After a tedious dissection the cecum and appendix were freed, and the latter ligated and removed.

I beg to call attention particularly to this case on account, first, of the number of attacks; second, the condition found at the time of operation; and, third, the result. Had the patient been operated upon early in or after the primary attack, the result would doubtless have been different. If the appendix had been removed at this time the inflammatory mass found in the right iliac fossa would not have been present, and such an extensive dissection not rendered necessary.

The rôle the appendix plays in many cases of intestinal indigestion I am sure is important. This has been beautifully shown in many of the cases of chronic appendicitis I have operated upon for digestive symptoms, which were so persistent before the appendix was removed, and entirely disappeared after recovery from the operation. I am so thoroughly convinced of the importance of this fact that I believe a permanent cure can only be obtained in a certain proportion of cases of chronic intestinal catarrh by removal of the appendix, should it reveal tenderness, even when there has been no clear history of an attack of inflammation of this organ.

In my record of operations for chronic appendicitis are included three cases in which was present chronic diarrhea with mucous stools, and in one also blood. In two of these cases the diarrhea, along with other evidences of intestinal disturbance, disappeared six months after operation. In the third case, operated upon five months ago, while there is still diarrhea, it is improving. This case is of special significunce from the fact that, although the patient had received most exhaustive and prolonged treatment, both internal and local, at the hands of expert medical men, yet the diarrhea proved rebellious. I believe this case will, as have the others, entirely recover.

In closing, I wish to emphasize the important deductions that have forced themselves upon me. The first and most important of all is the necessity of early operation for those cases of acute appendicitis, whether in the initial attack or in an acute attack supervening upon a chronic appendicitis not immediately yielding to judicious purgation. The ravages of this affection are so rapid and so fatal that I can hardly express myself too strongly upon this point. I hear so often from medical men and the more conservative surgeons that appendicitis is

amenable to medicinal measures, yet when they call in the consulting surgeon for those of their cases which do not improve, how often are they found beyond surgical aid? How often are we called in at the last moment to see supposed cases of obstruction of the bowels or idiopathic (?) peritonitis, only to find the patient moribund, with cold, blue extremities, in fact profoundly septic, the victim of a perforative appendicitis! I could cite instance after instance in which patients have died of inflammation of the bowels, peritonitis, obstruction of the bowels, and in one instance of "heart-failure," only to discover at the autopsy a gangrenous and perforated appendix, with a belly full of stinking pus. In looking over the weekly mortality-reports of the Philadelphia Board of Health I have often been struck with the fact that appendicitis does not figure as a cause of death. If autopsies were made in the cases in which death is recorded as due to "peritonitis," "inflammation and obstruction of the bowels," etc., I am certain that appendicitis would be found the primary cause of death in a large majority of cases so reported. The honest physician or surgeon who is open to conviction cannot but be convinced of the truth of my statements. One attack of appendicitis is almost sure to be followed by others. Each and every subsequent attack lessens the patient's chances for ultimate recovery—and why? Inflammation of the peritoneum leaves adhesions and inflammatory lymph; leaves an appendix the subject of chronic catarrhal inflammation which forms a fruitful soil for the development of bacterial life. Such an appendix is, in my opinion, the starting-point for a large percentage of the chronic intestinal troubles so commonly seen.

In view of these deductions, and the fact that the mortality of the operation for chronic appendicitis is practically *nil*, I must say that the safest and most logical procedure is operation. The golden opportunity is in the primary attack as soon as the diagnosis is established, thus eliminating the possibility of perforation, gangrene, pus, and general peritonitis. Should this opportunity be lost, and the patient recover from the attack, I strongly advise the removal of the appendix as soon as possible.

By asepsis and careful technique the operation can be done with but little risk to life, as has been proved by such men McBurney, Richardson, Bull, Fowler, and others. In further support of this I herewith tabulate sixty-one cases of operation for chronic appendicitis, with one death.

"AURAL MASSAGE" BY CONDENSATION AND RAREFACTION OF THE AIR IN THE EXTERNAL MEATUS AND MIDOLE EAR; ITS VALUE IN THE TREATMENT OF VARIOUS DISEASES OF THE EAR.

By LAURENCE TURNBULL, M.D., Ph.G.,
AURAL SURGEON TO THE JEFFERSON COLLEGE HOSPITAL, PHILADELPHIA.

"Aural massage," by alternately moving backward and forward the auricle with the opened and closed meatus, by the hands, with associate movement of the sterno-cleido-mastoid and occipital muscles, has been recommended and practised for some time for the purpose of giving freedom to the membrana tympani when adherent and thickened, and with some benefit, also, in certain diseased conditions of the other parts of the ear. Another method is to open and shut the orifice of the canal by pressure on the tragus at its lower part, closing the meatus with the thumb or forefinger; the force may be increased by greasing the canal with vaselin alone or with medicated ointments or oils. There is also a more perfect method of massage, by condensation and rarefaction, by means of the instrument of Siegle,[1] which has for years been employed in the examination of the membrana tympani. It resembles the ordinary hard-rubber speculum, but is more elongated, and its outer opening is fitted with an oblique plate of glass. A small nipple projecting from its side marks an opening to which is attached a small rubber tube ending in a mouth-piece. The instrument is used by inserting the small specular end into the meatus as far as possible (best covered with a section of rubber tubing and anointed). The mouth is applied to the end of the tube, or a small syringe, to exhaust the air, may be employed, or else an elastic valve bulb can be used; through the glass the movements of the membrana can be watched. All these plans were very unsatisfactory and could not be graded until Dr. Charles Delstanché, of Brussels, gave us two improved instruments, only a brief description of which I can give at this time, as they require cuts to fully illustrate them.

Delstanché's instrument for massage, or, as he terms it, his "masseur," consists of a metallic tube enclosing a smaller tube of metal which acts like the valve of a syringe. The recoil of the valve which produces the aspiration and condensation is accomplished by a spiral spring between the valve and the bottom of the metallic tube. The inner tube is graduated in fifths, so that one may determine by a key the amount of power to be employed. Care is necessary in the use of the instrument for fear of rupturing the drum-membrane, causing a great deal of pain, a flow of blood and an interference with the operation. In order to better condense the air in the tube the nipple-like process is covered with rubber. It must then be withdrawn from time to time, but the to-and-fro motion may be kept up for some time to advantage, always examining its effects upon the membra tympani. The other instrument is termed by Delstanché the "rarefacteur." It is provided with a double valve, and has an advantage over the other instrument in that, without removing the stop-cock, one may alternately condense and rarefy the air in the external meatus, or rarefy it alone. It is much more powerful, and with it we can rarefy the air in catarrhs of the middle ear and Eustachian tube, in which there is a sunken membrane, or break up adhesions between the membrana tympani and inner walls of the cavity of the tympanum, or after paracentesis of the membrane, when we have fluid products to be removed.

Several other instruments have been brought forth of late for the same purpose, differing in name, but all of them having the same object in view; they cannot be employed alone, but as an aid to other means, for although they are of value when properly applied by the scientific aural surgeon, they are of limited application, and like all efficient agents can do harm as well as good.

One of the most recent of these instruments has been termed the "vibrometer," which combines massage by sounds, both mechanic and electric, with exhaustion or rarefaction, with a series of musical strings. The first instrument employed was like a violin; the second like a guitar; the last is in the form of a banjo. This latter instrument is termed a vibrometer. A medical friend made a series of experiments with the first one hundred cases[1] of tinnitus aurium and deafness, but only 2 per cent. were successful in relieving the patients, and my own efforts have been as resultless. Ten cases out of one hundred will be reported. These will be sufficient for our purpose; they have not been selected, but are like the ordinary cases that present themselves to the aurist every day for treatment.

The following are the rules for the use of the instrument employed, after making a careful diagnosis, and correcting, as far as we are able, defects that would interfere with the successful use of the instrument:

The length of the sittings is from five to twenty minutes, and the number two a week. For tinnitus, like the ringing of bells, the chirping of insects, the singing of birds, the sounds of escaping steam, try the highest notes of the instrument, say twenty thousand vibrations a second. Draw the fine musical string of the vibrometer very tight and shorten it with a clamp to obtain high notes; to obtain low notes

[1] Siegle's pneumatic otoscope or speculum.

[1] Private statement; the cases are not yet reported.

elongate the strings. When the tinnitus gives a deep sound like the sewing-machine, the humming of a saw-mill, and for all low-pitched sounds, use the low-toned strings, say of fifty vibrations a second, and the pounding arrangement with the so-termed exhausting wooden plate. When the tinnitus is high, increase the vibrations up even to thousands. When the right pitch has been obtained the patient should only hear one sound, and the noises which he hears continually should be gone. In the case of a physician who suffered with constant tinnitus he was able by the use of the vibrometer to get rid of it, but he required the constant use of the instrument, as the tinnitus would return. He, therefore, desired to have the instrument in his office. Numerous physicians tested the instrument, and most of them would report the disagreeable effects on their ear. One wrote as follows: "So far, since your treatment by electricity, I have noticed no effect whatever. If anything, the hearing has been a little more dense, but I attribute that to the dampness."

CASE I.—An old gentleman, eighty-two years of age, was subject to gout, but had generally good health. The tuning-fork C, 500 v., was heard five inches from the left ear; in the right ear, three inches, as a musical note. The Weber test showed obstruction in the middle ear; the Eustachian tube was opened by the Valsalva method. Inflation by Politzer's air douche improved the hearing. The watch was heard by the left ear 5/36 in., right 3/36 in. The ordinary voice was heard with the left ear. Tinnitus aurium existed in the right ear, from catarrhal disease of the middle ear, and was increased by the use of quinin, which had to be taken in large doses at varying intervals owing to malarial disease. He had for years suffered from intermittent fever. The form of tinnitus aurium was of a puffing character, and was increased when he arose from a sitting or lying posture. He has had almost all the time an intermittent pulse (at the present time, 10 A.M., it intermits once in every thirty beats) improved under $\frac{1}{40}$ grain strychnin. I opened the Eustachian tube by the Politzer method on Thursday, May 18th. Applications of the vibrometer gave the puffing and drawing sensations for some five minutes, a feeling of fulness in the right ear, and sounds in the ear not so loud. On May 22d I made a second application after he had just arisen from a short sleep; it left a musical note in the right ear, drowning the hissing noise, but it did not last long. On May 19th the man stated that since the use of the vibrometer he had never suffered so much from the noises, which prevented him from sleeping at night. He was not willing to use the instrument any more. As the character of the noises indicated that they were from the heart or bloodvessels, he was ordered a preparation of caffein, pepsin sacch., bismuth citrate, and strychnin, to be taken when the noises were very troublesome and when he had dyspeptic symptoms, from which he was suffering.

CASE II.—Mrs. L. P. S. was eighty years of age. She had been a sufferer from scarlet fever of a severe type, and had a second attack; she was still able to hear imperfectly. Subsequently she suffered dreadfully from grief and mental conditions, and contracted catarrhal inflammation of the middle ear. She had almost entirely lost her hearing. On testing, on May 18th, she could not hear the 0/36 inch watch in either ear, nor the tuning-fork in air in the left; the tuning-fork was not heard on any part of the right side, or by the Weber test when the ear was shut. I opened the Eustachian tube of the right with the catheter, and inflated the tympanum with chloroform. This improved the hearing of the voice. Her tinnitus aurium was like the sound of a sewing-machine. I arranged the vibrometer for a similar sound, and employed it several times. At the conclusion she was able to hear the tuning-fork "A" when it touched the auricle. The voice was heard better across the office. She disliked the effect of the vibrometer, and was not willing to continue treatment.

CASE III.—Mrs. G. H., aged thirty-five, applied for treatment, April 9, 1894. She had had deafness and distressing noises in the head for one year. She suffered from coryza and melancholia, with irritation of the bladder and inherited pulmonary tuberculosis. Pharyngitis and chronic inflammation of the turbinated bones, with discharge of blood and pus, were present, and she had to breathe through the mouth. Bone-conduction was good, air-conduction diminished; the left Eustachian tube was normal, the right narrowed. The meatus was normal, the membrana tympani adherent on the right, with connective-tissue deposit. The nostrils were narrowed and deformed, and drawn upward from an ulcer. The former treatment had been by Seiler's tablets, to make a wash, and the use of Politzer's air-douche. The subjective sounds at her first visit were very distressing, chiefly of a boiling and whistling character. The treatment was by cleansing the nostrils and then applying a solution of silver nitrate, on cotton, with a bent wire, a saturated solution of potassium iodid, five drops, three times a day, increasing until the stomach was disturbed; I then substituted strychnin, $\frac{1}{35}$ grain daily. I used cleansing and pressure, and opened the tubes by catheter. Delstanché's masseur was used. The nose was improving and more natural, and there was improvement in general condition. She described her hearing as better, yet certain tones were not heard. Hearing distance was, right ear 36/36 left, 36/12. The description of the noises, as written by herself, was, on May 18, as of rushing in the right ear and roaring a little. I employed the vibrometer (which she described as being very disagreeable), either faint or drawing a musical note. On May 31 the noises were less, but were like the rumbling of passing coal-cars. I sought to give her a sound as like it as possible for five minutes. On June 4 noises were still less, and she felt very much better. She took the vibrometer treatment for five minutes, "pounding," and then the musical string. On June 5 she stated that she was decidedly better. I ordered the syrup of hydriodic acid in place of the potassium iodid, which disturbed her digestion, and also gave ten minutes' treatment with the vibrometer. On June 7 the patient reported some trouble with her heart, and repressed respiration. She had neglected the strych-

nin, which was again ordered. She would not use the vibrometer, as it gave her "a stuffy feeling," and was unpleasant to the ears. On June 13 she had improved hearing, and the noise was much less. The Eustachian tube was free and the nose all right. I used massage to the ear. On June 20 the nose was not so well, and there was a slight dropping, which was relieved by application of silver nitrate. I opened the Eustachian tube and injected vaselin, and applied massage to the membrane tympani and the ossicles. There was some pain and irritation of the kidneys, and I ordered the free use of Bedford water. My patient left for the summer decidedly improved in every way.

Case IV.—James C., aged fifty-three years, was an insurance-agent. He had been deaf for twenty-five years; with the left ear he could not hear his watch on contact; he heard his own watch on the right, on contact, but not mine. There was no inheritance of nasal trouble. He had been in the army, and had contracted rheumatism with naso-pharyngeal catarrh, but this had been cured. He had a low buzzing sound, but no otorrhea or pain. He had no headache, no vertigo, and no discharge from the ear; hearing was best when everything was quiet, of the left, in air quiet close, best on contact on right; the watch of thirty-six not in contact with left ear. Under treatment for three months, I used the Politzer spray of carbolic acid and Dobell's solution. I introduced the Eustachian catheter in both ears, and inflated with chloroform, with no benefit. I then employed the vibrometer, and directed strychnin granules, one-fortieth of a grain, and syrup of hydriodic acid. Just before leaving he informed me that previous to becoming an insurance-agent he had all his life worked in a foundry; he evidently had foundryman's deafness. On May 24 he stated his hearing was somewhat improved by the treatment of May 21, but he had lost it since. The sounds were of a low buzzing character, and I arranged the vibrometer for the use of the lowest tones, and he received the application for twenty minutes. At the conclusion I found he could hear his own watch on the right, half an inch, and on the left on contact. Hearing for voice was better; tuning-fork in air, left ear, one inch; right, two inches. On May 28, the patient desired the "pounding and exhausting" arrangement; this he had for several weeks, and I then opened the Eustachian tube with catheter and chloroform vapor, and also injected a 20 per cent. solution of pilocarpin. His hearing in the right improved to two inches; in the left he could not hear the watch on contact. On June 1 he stated that any improvement only lasted twenty-four hours. I found he was both a chewer and smoker of tobacco, and had the peculiar yellow mucous membrane and laryngeal catarrh from tobacco. He took the vibrometer for fully four weeks after he could still hear its peculiar sound in his ear. He ceased his attendance.

Case V.—Miss K. F., was a school-principal, with otitis media catarrhalis chronica, from childhood, due to cold, coryza, and rheumatism. There was no discharge, no pain, but she had subjective sounds, singing, etc. There was no inheritance of deafness; she was subject to sick-headaches, and the menses were painful and exhausting. The Eustachian tubes were opened in both ears by the Valsalva method and the catheter. There was good bone-conduction, but air-conduction was diminished. The meatus was normal but dry, the membrana tympani opaque, sunken and adherent. The air-douche improved the hearing for distance. Bone-conduction was good. The nostril was occluded, the septum having been operated upon, but still defective. She had been under the treatment of a careful aurist for six months, but was not improved. By careful treatment since November 25, 1893, by inflation with catheter and chloroform, and Delstanché's massage, she has improved from almost deafness to left ear 10/35, right, 4/36 but it is still difficult to hear the voice, especially in certain words. I employed the vibrometer fifteen minutes, May 19, and fixed it as nearly as possible to the sounds she heard. Some time afterward the ordinary sound was replaced by the vibrometer-sound in her best ear, while in the right ear she only perceived a beat in the ear, while in the other it was a pricking and sounding. On May 30 she returned very much distressed with the noises in the left ear, and thought the vibrometer increased them the last application, but upon examination I found the Eustachian tube blocked up with mucus and the throat inflamed. I cleansed this all out and opened the tube with the Politzer air-douche. I then applied the vibrometer on the very deaf ear by using the "pounding and exhausting" impression. Hearing returned to 10/36 left, 10/36 right. On June 13 the noises were on the increase, and I washed out the nose and throat, opened the Eustachian tube and directed $\frac{1}{200}$ of a grain of nitro-glycerin daily, which proved of advantage to all the symptoms. She left for her summer vacation.

Case VI.—M. O., aged fifty-five, has suffered from catarrhal otitis media, with obstructed and narrowed meatus, and narrowed Eustachian tube, and deafness of several years; improvement followed the introduction of the catheter, with chloroform-vapor and Delstanché's masseur. I applied the vibrometer with exhausting diaphragm, and found it very agreeable to the patient, producing a sound resembling a machine-shop. On May 29 the throat was found to be inflamed and filled up with mucus; it was sprayed with antiseptic wash, and later with liquid albolene (f℥v), camphor and menthol (āā gr. ijss) in solution. I introduced the catheter and opened both Eustachian tubes, and also touched the throat with a solution of potassium iodid (gr. xx), iodin (gr. x), and glycerin (f℥j). The patient was not willing to use the vibrometer, the weather being damp and rainy. On June 6 the hearing was very much improved, also the condition of the nose and throat. He liked the vibrometer and thought it would improve him. He now left for Europe, returning in September; but was then so well that he is satisfied with keeping his Eustachian tube opened without the vibrometer. He calls only when his hearing becomes impaired.

Case VII.—Mrs. I. B. S., aged thirty-nine, had deafness with blowing sound in the back of the

head and ears, of twelve years' duration; she had sore-throat and headache, and was gradually becoming deaf; there was no discharge and no pain; she had various subjective sounds, such as boiling, buzzing, roaring, beating, etc. Bone-conduction was weak on the left, and there was diminished air-conduction on the right. The Eustachian tube was narrow, the meatus normal; hearing was improved under catheterism, the hammer-handle not seen. The treatment before coming was by the Politzer, etc. Under careful treatment of the throat, the nose, the use of Delstanché's masseur and the Eustachian catheter with vapor of ether and iodin at home, she gradually improved, for right from 6/35, left, 12/35 until May 3, it was right, 18/36, left, 12/36; on May 23, right, 10/36, left, 13/36. On May 26 I used the vibrometer, the musical note of two strings, and after the massage and exhaust it left loud noises in the right, and the following day I received the following note: "So far in your treatment by the vibrometer I have noticed no effect whatever. If anything I have been a little more deaf than usual, but attribute that to the dampness after a severe storm." On May 28, hearing after treatment was, left, 15/36, right, 12/36, with sounds of hissing. I gave her that form of motion by the vibrometer, and she thought the noises were less. I exhausted the middle ear and touched the membrane with a solution of silver nitrate, also treated the throat with a solution of compound iodin. On June 4 she was much improved in hearing. On June 8 the patient stated that she thought the vibrometer had made the noises worse. She had the roaring, pounding, and also the musical note. After using the exhaust, massage and opening tube with chloroform-vapor, she was able to hear 12/36 inches, right, and 15/36, left. She heard a clock eight feet off, but general conversation she was not able to follow. Her nose and throat and Eustachian tubes were in perfect order; she had no more severe headaches, and her pelvic organs have been attended to by her regular physician. On June 14 I added to her other treatment hypodermic injections of pilocarpin, a 2 per cent. solution, four drops. Right ear, 12/36, left, 18/36. She left for her summer vacation, and returned in October, but was not willing to use the vibrometer; her hearing continued about the same as when she left.

Case VIII.—Mrs. G. T., aged twenty-five, has had deafness since a miscarriage, and also an attack of influenza. The right ear heard the watch 36 inches on contact, left 1/36. On May 30th, after prolonged treatment in which I treated the nose, throat, and ear with various applications, up to June 6th, the right ear was 7½/36 and the left 8½/36. On June 12th, right ear 8½, left, 10/36. After the use of the vibrometer hearing was clouded for a time; after this it was better. She returned in the middle of October, having lost almost all she had gained, by a severe cold; after treatment she began again to improve.

Case IX.—Mrs. Isabella R., aged thirty-seven, had been deaf for eighteen years, caused by confinement, followed by a great deal of mental distress, as her daughter was born blind. The pain was intermittent, and the subjective sounds were of a boiling or buzzing character. She heard better in a noise, had diminished air-conduction and bone-conduction; the Eustachian tubes were opened by the Politzer air-douche; the meatus normal, the membrana tympani of a light color, clear, with deposit, and adherent. She heard a loud voice, the lips almost touching the auricle. With speaking-trumpet she only heard certain words. She has been under treatment of many physicians, aurists, and quacks; not improved, but was rather worse. I gave her treatment with the vibrometer without apparent effect. This was a case of true labyrinthine deafness.

Case X.—Miss R. E. C., thirty-six years of age, had been deaf for many years; so much so as only to be able to hear words spoken close to the ears in a very loud tone. The left, she stated, had been operated upon. The membrana tympani, then the malleus and incus, were first removed, and the oval window was elevated to relieve the stapes, but no improvement in hearing followed any one of these operations. The parts were filled by what is termed a pseudo-membrane. When standing by the vibrometer she could not hear the sound of it until the tubes were pressed deep into both ears, then she could hear it, even the low tones. The auditory canal of the right hear was normal, but the membrana tympani was thickened, depressed, and attached; the location of the attachments could be noticed after inflation. Her throat was sclerosed with atrophic pharyngitis, and there were many bands of adhesion in the left nostril; some of these, projecting entirely across the nostril, were removed. On introducing the Eustachian catheter the tube could be partially opened under chloroform-vapor. After removal of hypertrophic tissue she was not improved in her hearing and not able to hear her own watch, but, after the application of the vibrometer and opening the Eustachian tube, she could hear mine only now and then, but only on close contact. She suffered from frontal and occipital headaches, the lungs were weak and there was a family tendency to pulmonary tuberculosis. She had had diphtheria of a very severe character, followed by an otitis media purulenta, and her life had been despaired of. I applied the vibrometer for two weeks, every other day, with massage of the membrana tympani. On June 25th, there was no real satisfactory change. I applied then the solution of pilocarpin, intra-tympanically. She now uses the vibrometer fifteen minutes, and thinks she has improved. The only improvement from the first operation was the checking of the purulent discharge. She thinks she hears voices better, and is desirous of continuing the treatment.

Conclusions: 1. Imperfect hearing depends on so many causes that no treatment by any one of the mechanical means should be employed until a careful diagnosis has been made.

2. "Aural massage," with the use of condensation and rarefaction of the air in the external aural meatus and middle ear, will give mobility to the parts and cause absorption of foreign materials interfering with the hearing.

3. Pneumatic massage is useful in middle-ear disease in which there are adhesions to be removed or stretched.

4. No treatment of this kind will take the place of operations, for when all other means fail they must be resorted to, and with wonderful success in *properly selected cases.*

I have endeavored to condense the cases as much as possible, yet I desired to show that nothing was left undone to place the patient in a favorable condition for the action of these mechanical agencies. These details are necessary for the reason that so many cases have been published as *cured* recently without any details, while others use the same means and fail.

There are three other methods now in use for stimulating the deaf ear, all of which I have examined and employed alone with no better success: namely, the vibrophone, audiphone, and the musical-box and pressure-probe.

To stimulate the deaf ear. When "very deaf" patients cannot bear rough, grating, or shrill sounds, a pleasant agency is a small musical box (Cohen), on which is placed a cushion, and upon this the patient places the deaf ear, so that contact with it occurs every day for ten or fifteen minutes; this is to increase the mobility of the ossicles. Lucae has recommended an apparatus for increasing the mobility of the auditory ossicles in cases in which there is stiffness (ankylosis) accompanying a form of deafness in which the patient is not able to hear general conversation, and Rinne's experiment yields a negative result. It consists of a steel rod or pin at one end of which is a small conical depression for the reception of the short process. The pin goes through a conducting tube, and its other end touches a spiral spring fixed into the handle of the instrument, and yielding readily to pressure. In employing this "pressure-probe" or feathered sound, the patient's head is first fixed and the instrument introduced under a good light along the upper wall of the auditory canal toward the short process of the malleus. The latter is received in the hollow at the inner end of the probe, and sharp taps are then made against it—at first, one or two only, later, up to ten, to be repeated if the result is favorable. Lucae asserts (Gruber) that after the employment of this instrument the air-douche may be used with success. As almost all patients suffer pain on the slightest touch with a fine probe, a solution of cocain must be employed prior to the operation. The tip should also be covered with delicate oil-skin, else it will be found that excoriations will be produced. This operation is only justifiable in the hands of the competent aurist who is perfectly familiar with the parts. Improvement, which in some cases takes place after this painful operation, cannot be relied upon without treating the middle ear at the same time.

SYPHILIS AND "APEX-CATARRH."

BY HOWARD S. STRAIGHT, A.M., M.D.,
OF CLEVELAND, OHIO.

CASES of syphilis and apex-catarrh are of frequent occurrence and of great importance. My knowledge of this class of cases has been obtained by observation. There is, I think, little literature upon the subject. The importance of an early recognition of all the factors in such cases was impressed upon me a number of years ago, and a longer experience has only confirmed my opinion. No better name for this class of cases has suggested itself than that chosen. The term, mixed infection of syphilis and tuberculosis, has been suggested, but the catarrh at the apex or apices of the lungs is non-tuberculous, and remains so in the majority of cases. If the catarrh at the apex lowers the vitality and resistance of the cells sufficiently to admit the growth and development of the tubercle-bacillus a localized tuberculosis results. As I have observed, the great majority of these cases of apex-catarrh recover, and the most reasonable explanation of their pathology is that they are simply catarrhal in character. Why such a small proportion of cases of apex-catarrh become tuberculous is not explained. Most cases recover within a few months. The explanation may be that the vitality of the cells is not sufficiently lowered to make possible the growth and development of the tubercle-bacillus.

CASE I.—Four years ago I was consulted by a woman forty-five years of age, who had separated from her husband fifteen years before on account of his bad habits. Her sister, a few years younger, had been under my care for three months with an apex-catarrh, and had improved very much. Upon comparing symptoms they concluded that they both had the same disease. The elder sister had been under the care of two very competent physicians for about two months. She had had a large specific ulcer on the pharynx, and a syphilitic periositis of each tibia. Her suffering from the pain had been intense in the beginning. The ulceration of the pharynx had healed. The active manifestations of the periostitis had also disappeared, but the part was still tender on gentle percussion. Her medication had been mixed treatment with anodynes when necessary.

Within three months she had lost fifteen pounds in flesh. She was slightly anemic, and her tongue showed a disturbance of the gastro-intestinal tract. Her pulse was 96, and the temperature was 99.6°. Examination of the chest revealed in the left infra-clavicular region a well-marked apex-catarrh. At the right apex much less could be detected, although she had transference of heart-sounds and suspicious auscultatory signs. The specific treatment was not changed, and in addition she was given creosote, at

first in doses of ℥jss, four times a day, and later in double this dosage. She improved promptly. She was kept under continuous observation for five months, during three of which she had a slight rise of temperature in the afternoon and evening. After this time she ceased her visits, as she considered herself well. After discontinuing her medicine for two months she began to feel badly again, and returned, and she was again put upon the old treatment, with prompt improvement, and her treatment was continued for two months. For two years she would occasionally return whenever she began to feel badly again, and would take her medicine for a few weeks, and then would cease her visits. When last seen her chest-signs had completely disappeared.

Slight fever in late syphilis occurs, but it disappears within a few days under anti-syphilitic treatment. This patient had had such treatment for weeks, and my treatment was not different as far as the specific disease was concerned. The disease at the apex had simply been overlooked.

Case XI.—An intelligent woman, twenty-five years old, married one year, came under my care in the John Huntington Dispensary in May, 1894. She had lost flesh markedly, was quite anemic, had felt depressed, and had tired easily for six months. Her menses had been regular and normal. She made no special complaint except as to the throat; the temperature was 100°; and the pulse 108. She had an ulceration as large as a quarter-dollar at the upper part of the oro-pharynx, and also an induration of the upper lip. Four years before she had had an ulcer and an induration of the lip, which had never altogether disappeared. The induration and enlargement had become more marked during the two months before she came under observation. They were undoubtedly specific, but this fact had been overlooked or had escaped notice, and she had received no constitutional treatment. When the induration upon the lip first occurred she had had no other manifestations of syphilis, nor at any time later until the ulcer appeared. She disclaims any knowledge as to the mode of contagion. When first seen the induration of the lip was as large as the tip of the little finger, and this and the ulcer in the throat were the only manifestations of the disease. Chest-examination revealed a bilateral apex-catarrh, most marked on the left. She was given mixed treatment and creosote. The improvement in the specific manifestations was rapid, but it was a number of weeks before the depression became notably less marked. The improvement of the ulcer and induration of the lip was as rapid as in an uncomplicated case. The temperature continued at about 100° for three months; the pulse was slightly rapid for a few weeks, and at the present time pulse and temperature are normal. She has gained a few pounds in flesh and very much in strength; and the chest-signs have become stationary. She still has transference of heart-sounds, slight cog-wheel breathing, shortened inspiration, etc. She should continue the creosote for months, as well as the mixed treatment. She will recover so far as the chest-complication is concerned. My reason for this statement is that the catarrhal process began at the left apex, and progressed to a certain point; it then began at the right apex, and the progression at the left ceased and has begun to clear up. When a case of apex-catarrh becomes an incipient pulmonary tuberculosis the physical signs at the apex at which the disease first occurred always continue more marked than at the other apex. I have watched this class of cases for years, and have never seen an exception to this rule.

Case III.—A girl twenty-two years of age was sent to my department in the Dispensary, April 23, 1894. Six weeks before, she had been admitted to the Infirmary Hospital of Cleveland, and for a month before going to the infirmary she had had two ulcers upon the genitals. When admitted she still had the local sores and rheumatism in the right knee. The ulcers healed in a short time under local treatment only. She took something for the pain in her knee, but when the symptoms passed away the medicine was discontinued. Upon obtaning this history my conclusion was that the lesions upon the genitals had been considered chancroidal. She came complaining of her throat, presenting a general slight inflammation of the pharynx and larynx, but nothing characteristic of syphilis. The temperature was 99°, the pulse 90. She had no other manifestation of syphilis. Examination of the external genitals yielded only negative evidence. She still complained of some pain and tenderness in the right knee, worse at times, and she was slightly anemic. Up to the time of entering the infirmary she had felt well. Since that time she had felt tired and less vigorous than usual. The chest-examination revealed next to nothing, but the condition of the left apex was suspicious. Whether there was a slight transference of heart-sounds was doubtful. The diagnosis made was subacute rheumatism of the right knee and pharyngo-laryngitis. Whether the inflammation of the pharynx and larynx was a local manifestation due to rheumatism, or the local manifestation of a developing syphilis, or the local catarrhal condition that so often precedes any positive chest-signs in a developing apex-catarrh, or a local inflammation simply, was the question to decide, and it was impossible to decide it. As far as the possible syphilitic element was concerned, I concluded to wait. She was given sodium salicylate and creosote, and the throat was painted with silver nitrate. The case was seen daily for a short time. The second day the pulse was still 90, but the temperature was 99.3°. The slight rapidity of the pulse and the slight rise in temperature continued on succeeding visits. The pain in the knee promptly disappeared, and the throat-symptoms were somewhat relieved; but after watching her for a few days I became convinced that there was something more in the constitutional condition than had yet appeared. Whether it was a developing apex-catarrh, or syphilis, or both, could not be decided. After observing the case for ten days the patient developed unmistakable syphilitic manifestations: an eruption about the mouth, a mucous patch upon the right tonsil, and an ulcera-

tion and induration in the fourchet. The sodium salicylate was stopped and mercuric chlorid was substituted. A reëxamination of the chest revealed nothing positive. The question still concerned the left apex. Temperature and pulse remained as before. There was no change in either after the patient had taken anti-syphilitic treatment for two weeks. The local specific manifestations rapidly disappeared, but the throat-symptoms remained much the same. There was a loss of five pounds in flesh the first three weeks after the woman came under observation. The chest was examined every ten days. The creosote had been continued because the temperature did not fall to the normal after the ordering of the bichlorid. Five weeks after the first visit the physical signs at the left apex became positive. She had an apex-catarrh. From this time the catarrh at the apex pursued the ordinary course. After two months the patient began to gain flesh and strength. She had, however, slight fever and rapidity of pulse for fully four months after first presenting herself. Her medication has consisted of mercury and creosote. The chest-signs have nearly disappeared. The specific manifestations disappeared according to the rule.

The diagnosis in this case was certainly very much mixed. Viewing the case after five months' treatment the course adopted in the start was certainly wise. The slight fever was important, as it occurs in patients with a developing syphilis, but it subsides within a week after the administration of a mercurial. It also occurs in patients who are developing an apex-catarrh, although the pulse may be normal. While the slight fever in syphilis disappears almost at once under mercury, the slight fever in an apex-case continues for weeks, perhaps months, in spite of every treatment. Patients with a developing apex-catarrh also have slight fever sometimes for weeks before a positive opinion can be given as to the physical signs.

Whether there is necessarily any connection between the syphilis and the apex-catarrh in cases like these is a doubtful question. It would be a reasonable inference to believe that the apex-catarrh developed because of the depressing effects of the syphilitic poison. Apex-catarrh certainly occurs as a result of lowering conditions, but only in a small proportion of syphilitic patients. I see so many cases of apex-catarrh in patients in whose life and surroundings no adequate cause for such development appears that I have wondered whether its occurrence in the syphilitic patient might not be a coincidence. It has also been questioned whether the local inflammation of the capillary bronchial tubes might not be due to the efforts of Nature to eliminate the poison due to syphilis through this part of the body. This does not seem reasonable, because an apex-catarrh only exceptionally occurs in syphilitic cases. I could much more easily understand how the catarrh at the apex in Cases I and II could be due to the specific poison than in Case III, in which the manifestations seemed almost earlier than the specific manifestations. If this condition of mixed infection occurred most often in delicate patients, one could better understand how the one might be due to the other. But this has not been my experience. The prognosis as to the apex-catarrh seems to be as good as in an uncomplicated case.

Although this statement does not seem reasonable, I have yet to see, however, a case of apex-catarrh in a syphilitic that did not recover. Each condition ought to be treated as if the other did not exist. Creosote, or one of its derivatives, is the best remedy for the catarrh. Patients recover, however, under any form of tonic treatment. Creosote relieves the subjective symptoms better than any other remedy with which I am acquainted, and is a brilliant remedy in such conditions. The physician who treats these cases of mixed infection with antisyphilitics and tonics, and knows nothing of the catarrh at the apex, will, perhaps, have as good results as any one; but the attendant who discovers all the factors in the case is certainly in a better position to deal wisely with his case. If the temperature and pulse are not carefully observed the physician may not even suspect any chest-complication. The slight anemia and all the other symptoms of an apex-catarrh are so easily accounted for in a patient who has syphilis that one's eyes may be blinded to any other constitutional condition. The complications noted in these three cases certainly explain the reason why a certain proportion of syphilitic cases pursue an unusual course.

A NEW AND RAPID METHOD OF DEALING WITH INTRA-LIGAMENTOUS FIBRO-MYOMATA.

By WILLIAM R. PRYOR, M.D.,
of New York;
Visiting Surgeon to the City Hospital; Adjunct Professor of Gynecology in the New York Polyclinic; Fellow of American Gynecological Society.

So satisfactory has become our technique in removing the diseased uterus that there is apparently not much room left for improvement. Any modification must be trivial; but the one I offer for trial has proved of such value to me that I am induced to publish it. In removing intra-ligamentous fibro-myomata three elements are present which do not require the surgeon's attention in ordinary cases. There is great risk of wounding the ureter. The sinuses over the tumor are huge, and give rise to disagreeable bleeding when the capsule is split, and because of inherent difficulties the operation is generally much longer than is desired.

The method I have to describe is simplicity itself, and reduces the time of operating so materially as

to appeal at once to the surgeon who has dealt with these cases. These tumors imperatively demand radical procedure, and preclude the possibility of adopting any procrastinating and so-called conservative measures. If I am right in my conclusions as to the merits and applicability of this operation, much of the incentive for Kelly's very beautiful ureteral work will be absent, even though the passage of ureteral sounds as guides were so easy of execution as to become a definite part of our routine in the treatment of these tumors.

Operation. The ovary and tube on the free side are tied off between two ligatures, which are not locked. The broad ligament of this side is then cut between these two ligatures down to a point approaching the uterine artery. The posterior cul-de-sac is now opened and the vagina entered. Through this opening the finger of the left hand is inserted. This is a great advantage, as it enables the operator to guide his Deschamps needle and to more accurately appreciate the exact anatomy of the parts. The bladder is now dissected away from the tumor, and the vagina entered in front. The uterine artery of the free side is now secured between two ligatures in the usual way. So far the operation has proceeded as in any ordinary ablation of the uterus.

The next step is to secure the ovarian artery over the intra-ligamentous nodule. So variably situated is the tube in relation to these growths that no one fixed plan can be adopted in all cases. In one of my cases, for example, the tube was very long, with a broad mesosalpinx. I tied the tube close to the uterus, then its mesentery well out over the intra-ligamentous nodule. The mesosalpinx was then cut to the side of the uterus, the ovary and outer ligature being left over the tumor and never removed at all.

The really important step is the next. We have controlled both ovarian vessels and the uterine artery on the free side. The vagina is entirely dissected from the cervix before, behind, and on the free side. The uterus remains attached by the intra-ligamentous nodule to the broad ligament, the vagina and the pelvic floor. Heretofore it has been the custom to split the capsule of the tumor above and shell out the nodule from between the severed folds of the broad ligament. In doing this there is much time lost, a good deal of hemorrhage developed from the large sinuses that cover these nodules, and very often has the ureter been wounded. This latter structure may lie beneath the nodule, over it, in front of it, or even posteriorly. We never know just where to find it, and there is always great risk of wounding it. There is, however, one spot in which it is never found, and that is directly against the cervix, in the sulcus formed by the junction of the tumor and the uterus. The position of the uterine artery to those growths is fairly constant. Usually it lies beneath the tumor. Should the nodule spring from below the internal os, in all probability it would cause complete obliteration of the uterine artery, for the periphery of these growths is against the internal iliac artery from which the uterine artery springs. I have never met with such a case. All the specimens I have examined showed the uterine artery entering the uterus below the tumor. Discovering this, and in order to save time, as well as to avoid splitting the capsule of the tumor, I conceived the operation which, in three cases, I have successfully carried out.

The uterus having been freed, as described, it is tilted far over to the involved side by an assistant, and the large Deschamps needle is passed through the vaginal mucous membrane, so as to sweep around all the tissues between the vagina and the tumor. Great force is necessary, as the needle must hug the cervix closely, and must pass right up to the tumor. It is made to emerge into the vagina, and the uterine artery is tied by one ligature. The tissues are cut close to the cervix up to the sulcus, between the tumor and the cervix. It is now a perfectly easy matter to peel the fibroid out of the broad ligament with the fingers alone. It will come out of its bed as easily as a mandarin-orange can be divested of its rind. Apart from the absolute freedom from any danger to the ureter, this procedure will commend itself to the surgeon as most valuable in that it will shorten the time of operation very materially. It will not be necessary to ligate veins in the broad ligament or to suture the rent made in it. It renders most easy an operation heretofore very difficult and fraught with great danger to the patient, owing to hemorrhage and the risk of wounding the ureter.

If the tube is spread out over the capsule it may be tied close to the uterus, and left in the body with the capsule.

A further advantage of this operation is the ability to render all raw surfaces extra-peritoneal.

The ligatures on the uterine arteries are left long and turned into the vagina. The vagina is packed with iodoform-gauze in such a way that its upper end is as high as the cavity in the capsule.

The great point, let me repeat, is to secure the vessels above and below the tumor close to the uterus, and *before* enucleation is begun. When the enucleation is made it is from below, and the tumor is shelled out of an intact capsule, without bleeding, as the attachment of the broad ligament to the tumor is very loose. At most, five ligatures are needed.

CLINICAL LECTURE.

IDIOPATHIC MUSCULAR ATROPHY.[1]

BY CHARLES W. BURR, M.D.,
CLINICAL PROFESSOR OF NERVOUS DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE, PATHOLOGIST TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

I PROPOSE to study with you to-day a disease, or rather a group of diseases, characterized by progressive muscular wasting and paralysis, caused by degeneration of the muscles themselves, and not by a lesion of the nervous system. The affection, therefore, does not properly belong, in a strictly scientific classification, among nervous diseases, but since its symptoms are all nervous and its differential diagnosis is from diseases of the cord and nerve-trunks, we have full justification for its study.

At first glance the boy, D. F. (Fig. 1.), looks remarkably robust. The calves are large, the bony frame well developed, the facial expression intelligent, and the complexion ruddy. But, as you see, he cannot stand, can, indeed, scarcely move the legs at all, and while in the arms power of movement in all directions is preserved, yet the movements are awkward, and cannot be made against even slight resistance. The neck-muscles, on the other hand, are fairly strong, and those of the face perfect, so that he can smile, and frown, and wink without difficulty. On examining the muscles more closely we find that while some are enlarged, are apparently hypertrophied, others are small, are distinctly atrophied. The calves, loins, and infra-spinati are large, hard, and firm. The thighs are soft and flabby, but not small while the shoulder-muscles, the lower part of the great pectorals and the muscles of the upper arms are distinctly softer and smaller than normal. The forearms are wasted but little, if any, and the intrinsic muscles of the hands not at all. Many of the muscles, those enlarged most and those most atrophied, give no electric reaction to either the faradic or the galvanic current, and in those which do react the reaction is reduced to both currents. Reaction of degeneration is nowhere present. Your first thought, no doubt, was that the tremendously enlarged calves and loins indicated great strength, but you can now see that these are the weakest parts of the body.

The mechanical reflex of the muscles, the contraction obtained by percussion of the muscle itself, is everywhere abolished, even in the great pectorals, in which in health it is ordinarily most marked and most readily obtained. Not only is there no contraction of the muscle in its entirety, but also the local contraction at the seat of percussion, the "humping" of a few fibers, is absent. The knee-jerk, and indeed all the tendon-jerks, are absent. Nowhere do we observe any fibrillary twitching. Sensation is normal to touch, pain, and temperature. The special nerves are good. The patient has complete control of the bladder and rectum. There are no trophic changes in skin, bones, or joints. There is slight talipes equinus on both sides. Subjectively the boy complains of nothing but muscular weakness. He eats well, digests well, sleeps well, and suffers no pain.

I have here a second boy affected in the same way,

Fig. 1.

Pseudo-hypertropic muscular paralysis.

Fig. 2.

Simple idiopathic muscular atrophy.

[1] Clinical Lecture delivered at the Medico-Chirurgical Hospital, September 10, 1894.

but to a less degree, so that he is still able to walk, and I wish you to watch his gait and method of getting up from the ground and lying down, for it is characteristic. You notice as he stands his feet are placed widely apart, his shoulders thrown back, and his abdomen forward, producing a large anterior curvature of the lower spine. His gait is waddling, duck-like, the body being twisted and thrown to one or the other side, corresponding to the foot which is upon the ground. Most characteristic of all, watch him as he rises. He rolls over on his stomach, plants his toes firmly against the floor, gets "on all fours," and then putting his hands with a jerk, one after the other, on knees and thighs, pushes the trunk up. As has been well said by Gowers, he climbs up his own legs. On lying down he goes through precisely the reverse procedure, as you see.

The third boy, L. X. (Fig. 2), presents a striking contrast to the others, and is an example of a much rarer condition. He looks like a living skeleton. The skin is too big for the body, and hangs loosely from it. The wasting is well-nigh universal, affecting not only arms, legs and trunk, but also (and note this particularly) the face, as is shown by the projecting eyeballs, the slightly protuberant lower lip, the inability to pout, the curiously dull expression called "the myopathic face," due to the absence of some of the facial lines. Except for the absence of enlarged muscles and the involvement of the face, his symptoms are similar to those of the other boys, and his condition the same.

Since now we have learned all we can from examination of the patients, for I know nothing of their previous lives, let us consider for a few moments the causation and mode of progress of the disease. You probably wonder why I have presented the third case as an example of the disease affecting the other two. Great as the contrast is, the dissimilarity is to a large degree superficial, and in all the underlying cause is the same. Clinically, however, we separate them, calling the one pseudo-hypertrophic muscular paralysis, the other simple idiopathic muscular atrophy. The latter has been subdivided into several types according to the distribution of the wasting. Thus there is the juvenile type of Erb, in which the muscles of the shoulders, upper arms, and thigh, and the gluteal muscles are affected; and the facio-scapulo-humeral type, in which the face is attacked first. Other subdivisions have been made, but we may without loss disregard them. No hard-and-fast line can be drawn between any of the types, since mixed cases are met with.

The disease is developmental, due to a fundamental defect in the tissues that form muscle, but what the defect is and its cause we do not know. The affection is not congenital in the sense of showing symptoms at birth, but it is congenital in origin. It occurs far more frequently in family groups than in isolated cases. In the hypertrophic form there is never, or almost never, direct inheritance from parent to child, but transmission is through the healthy female line; that is to say, women who are themselves not affected may yet, if one may say so, possess the potentiality of the disease. In the simple form there is greater possibility of direct inheritance, and females are far more frequently affected. Pseudo-muscular hypertrophy begins in late infancy or early childhood, idiopathic atrophy a little later, and sometimes, though rarely, in adult life. The course of events in pseudo hypertrophy is as follows: The child, who has before walked, will begin to stumble and may complain a little of pain. He tires easily, and says his legs are weak. Now, at the first, this is all, and no diagnosis can be made, though by the exclusion of other diseases we may be able to more than shrewdly guess what will be forthcoming. Later, the calves begin to be enlarged and firm, and muscular weakness increases slowly but surely, until a child, apparently a young giant, is in truth a helpless weakling. All muscles do not enlarge. The pseudo-hypertrophy is usually in the calves, the extensors of the legs, the glutei, the loins, deltoids and infra-spinati. In rare cases the tongue is affected. Certain muscles, as for example the lower part of the great pectorals and the latissimus dorsi, atrophy without previous enlargement. As time passes the enlarged muscles also atrophy, and contortions and contractions appear, the legs being flexed upon the thighs, the thighs upon the abdomen. In the simple form the symptoms may begin, as already stated, in the face, shoulders, or legs.

To sum up, we may say that idiopathic muscular atrophy is a chronic, inherited, developmental disease characterized by progressive wasting and paralysis, with or without muscular hypertrophy, gradually diminishing tendon-reflexes and muscle-reflexes, gradually diminishing electric reaction, without trophic changes, with normal sensation, and with complete control of bladder and rectum.

Using this as a working definition, let us see how we can differentiate this affection from wasting due to other causes. What are the other causes? First, and for our purpose least important, is wasting due to cerebral disease. For a long time it was denied that this existed, but of late years several cases have been reported in which tumors of the motor area, without disease of the anterior cordal gray matter, were accompanied by wasting in the palsied parts, and I do not mean the merely slight wasting due to disuse, but distinct atrophy. We are absolutely ignorant of the cause of this condition, but its distribution, hemiplegic or monoplegic, and the preceding palsy, make it impossible to be mistaken for idiopathic atrophy. Wasting from bulbar disease also needs only to be mentioned. Its accompanying symptoms differentiate it. Most important and most difficult is the diagnosis from atrophy due to spinal-cord disease, the so-called myelopathies. Any disease involving degeneration of the motor cells in the anterior gray matter will show wasting in the muscles with which those cells are connected. Hence it follows that wasting is found in many cordal diseases and with varying accompanying symptoms, according to what other parts of the cord are involved. All in which increased tendon- and muscle-reflexo jerks and fibrillary twitching occur can be at once excluded, since, as we have seen in idiopathic atrophy, the so-called myopathies, the reflexes gradually diminish until they become extinct. The affection that most nearly simulates a myopathy is chronic anterior poliomyelitis, or progressive spinal muscular atrophy. But this is a disease almost exclusively of adult life. The wasting begins in the thenar and hypothenar eminences, or deltoid muscle, and while the tendon-jerks are abolished unless the lateral tracts be affected, in which case they are exaggerated, the muscle-jerks are increased and fibrillary twitching is common. There may be one of several

changes in the electric reactions, including reaction of degeneration. Acute anterior poliomyelitis may, if first seen some time after the attack, deceive at first sight, but the acute onset, the reaction of degeneration, and the distribution of the palsy, in one leg or arm, or two or even three extremities, suffices to differentiate it. In chronic multiple neuritis the method of onset and progress, the distribution, the frequent sensory symptoms, the possible ataxia, the palsy more intense than the wasting, are all points in differential diagnosis.

In myopathies there is ordinarily an inheritance; there are likely to be several cases in a generation; the onset is early in life; trophic changes never occur, while in myelopathies inheritance plays no part; the disease almost invariably begins later in life; trophic changes are not infrequent, and hypertrophy never occurs.

Senator has described a form of subacute or chronic myositis—an inflammation, you understand, not a degeneration—in which there is paralysis and wasting, but the the intense pain from pressure on the muscles and the course of the disease differentiate it.

Lastly, to complicate matters, there is a type of wasting likely to occur in family groups, and beginning early in life in the extensors of the big toe, appearing later in the common extensors and peroneal group, and thence extending. Reaction of degeneration and fibrillary twitching may or may not be present, and hypertrophy never occurs. It is the so-called peroneal type of Charcot and Tooth. It is probable that the situation of the lesion is not constant, but it may be in the anterior motor cells of the cord, the nerve-trunks or the muscles, since on no other grounds can we explain the varying electric reactions and reflexes.

The prognosis as to recovery in pseudo-muscular hypertrophy is absolutely bad. Death is almost inevitable within a few years after the patient becomes bedridden. In simple atrophy the course of the disease is longer, and there may be arrest, and the patient may reach old age.

Treatment is absolutely without curative influence. Electricity and massage will, however, do much to keep patients in the best possible condition, and gymnastics, when possible, may stimulate the development of what little muscular tissue is present. Drugs so far have proved useless.

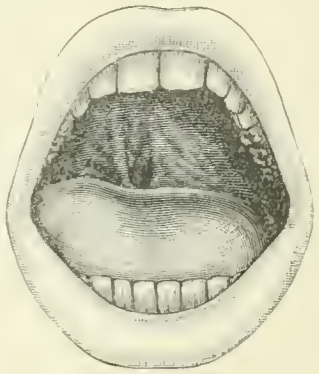
CLINICAL MEMORANDA.

A CASE OF SYPHILITIC CICATRICIAL ADHESION OF THE TONGUE TO THE PALATE AND PHARYNGEAL WALLS, WITH NOTES OF OPERATION.[1]

By E. LARUE VANSANT, M.D.,

ADJUNCT PROFESSOR OF DISEASES OF THE THROAT AND NOSE IN THE PHILADELPHIA POLYCLINIC; SURGEON TO THE THROAT, NOSE, AND EAR DEPARTMENT OF THE HOWARD HOSPITAL; PHYSICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

The patient, Michael B., aged forty-five years, miner by occupation, gave a history of syphilis contracted in October, 1877, followed by secondary symptoms. Syphilitic ulcers occurred on the shins, elbows, and back during the winter of 1877–78. In 1885 ulceration of the dorsum of the tongue and of the soft palate occurred, and this continued with occasional periods of healing, followed each time, however, by renewed ulceration until the autumn of 1889, when it rapidly extended from the dorsum to the sides of the tongue and to the internal



surface of the gums, and severely attacked the palate. This condition was shortly followed by cicatricial adhesion of the tongue to the inner surface of the gums and to the palate. The adhesion commenced first on the right lateral border of the tongue, and extended from the left to the center, then from the left lateral border, extending from the right to the center. After commencing, the adhesions progressed very rapidly, so much so that after six weeks the only opening left in the scar was a small one, about one-eighth of an inch in diameter, situated just above the middle of the tongue.

In December, 1889, the patient presented himself to Dr. W. L. Estes, of South Bethlehem, Pa., for operation. Dr. Estes has kindly furnished me the following notes of the operation performed at that time: "I passed ligatures or sutures through the anterior pillars of the fauces, and with scissors and cautery made an extensive dissection of the cicatricial tissue, working back to the epiglottis. I cut through both anterior and posterior pillars, and sutured the cut surfaces, so that I hoped to prevent further adhesions, and then dissected the tongue away from the gums, and turned the raw surfaces in on the sides of the tongue by sutures, while the tongue was drawn forward by a ligature passed through its tip. When I operated there was a little round opening scarcely a quarter of an inch in diameter. As soon as the patient returned home the adhesions or contractions began again. For several weeks I kept a good fine opening by stretching and another snipping. The man, however, drifted out of my hands, and I was not allowed to do any further operations."

In the spring of 1890 the patient consulted Dr. Frederick G. Ibach, of Mauch Chunk, to whom I am indebted for the following notes of his operations: "I operated on him under cocain with the cautery-knife, removing the greater part of the mass, which at this time filled up all the pharyngeal space. He was put on iodid with bichlorid, and about eight weeks after the first operation the mass had again formed, leaving an opening—through which he breathed and took nourishment—not a quarter of an inch in diameter. From that time up to

[1] Read before the Section on Otology and Laryngology of the College of Physicians of Philadelphia, November 6, 1894.

the time he came to you I gave him relief with the knife —at least once every ten weeks."

During 1890 ulcerations, followed by adhesions, occurred in the pharynx and on the posterior surface of the soft palate, and in October of the same year the patient found he could no longer breathe through the nose.

In January, 1893, the patient was sent to me by Dr. Ibach for treatment. His condition at that time was very pitiable; he was thin and haggard, suffering from insufficient nourishment, and breathing with great difficulty. The opening was so small, and at times so obstructed by secretion, that each respiration was accompanied by a loud whistling, wheezing sound; indeed, at times the man seemed about to be strangled. The tongue was found bound to the internal surface of the gums and to the roof of the mouth by a thick cicatrix, which extended across the dorsum of the tongue opposite the back molar teeth. A little to the left of the center of this cicatrix there was a small circular opening three-eighths of an inch in diameter. Passing a probe through this opening it was found that a narrow canal, some three inches long, ran somewhat diagonally from left to right, and communicated with the pharynx to the right of the epiglottis. This canal was so constricted at points that an ordinary grooved director of a pocket-case could barely be passed through it. Upon examining the nasal cavities they were found to be free and in fairly normal condition. A probe passed through the nostrils would meet an obstruction in the pharynx, and could not be carried lower. The patient was unable to breathe through the nose, and the only channel for nourishment and respiration was the narrow canal before mentioned.

Physical examination of the chest showed nothing abnormal, except the stridulous breathing through the narrow opening in the mouth, and which could be heard all over the chest.

Prof. Wm. S. Forbes and Prof. J. Solis-Cohen kindly saw the case with me in consultation, and it was decided that an operation, consisting of the entire removal of the scar-tissue, be performed. The operation was done by Prof. Wm. S. Forbes, with the assistance of Dr. A. Hewson and myself, at the Jefferson Hospital; tracheotomy was first performed, a hypodermic injection of cocain over the trachea producing sufficient local anesthesia to permit of this. General anesthesia was then obtained by administering chloroform through the tracheotomy-tube. A semi-circular incision was then made under the chin, separating the soft tissues from the internal surface of the lower maxilla, and the tongue was drawn forward and downward through this opening. This procedure gave the operator a clear field of operation through the open mouth. The scar-tissue was first separated at its upper border; in order to do this it was found necessary to extend the incision to the hard palate. The sides of the tongue were then dissected from the gums and the tongue drawn further forward; four abscesses, two on each side, were then broken into; these abscesses seemed to be gummatous remains of the tonsils, and contained each about one ounce of a foul greenish pus. The scar was then dissected from the tongue, the necessary incision reaching to and laying bare the transverse muscle of the tongue. Back of the abscesses a second scar was found, forming another almost imperforate barrier or diaphragm. This scar, which attached the base of the tongue to the posterior and lateral walls of the pharynx, extended down to just above the level of the epiglottis and above to the palate, together with prolongations that ran up the sides of the pharynx to the vault. Careful dissection was again made, and the entire cicatrix removed. The edges of the wound in the palate and tongue were then thoroughly united by sutures, and the opening under the chin closed. A ligature was passed through the tip of the tongue and carried out of the mouth to prevent the tongue from falling back. After the operation the patient improved rapidly in strength and weight, developing an enormous appetite. The tracheal wound entirely healed in about eight days. At the end of three weeks the scar-tissue commenced to re-form along the left wall of the pharynx; efforts were made to prevent adhesion by stretching and breaking the newly formed cicatrices; the patient, however, was rebellious, and at the end of five weeks insisted upon returning to his home.

On the 12th of April, 1893, he again consulted me, his condition being pretty much the same as before the operation in January. The adhesion, he said, had returned in six or seven weeks from the time of operation, and the throat had threatened to close entirely. In March, he said, his breathing had become so difficult that he had heated a table-knife in the fire and burned an opening through the scar. Upon examining the patient I found that the scars had completely re-formed, the tongue being adherent as before. The opening, however, was somewhat larger, being about three-fourths of an inch long and perhaps one-eighth of an inch wide. Several days later another operation was undertaken by Prof. Joseph W. Hearn, with my assistance, at the Jefferson Hospital. In this operation cocain was injected into the cicatrix, and no general anesthetic was given. An inverted V-shaped mass about three-fourths of an inch long and one inch wide was removed from the scar just above the opening; it was hoped that the rest of the scar would retract, and thus keep the opening free. After-treatment was again instituted to keep the opening from closing, but after five weeks the patient again insisted upon leaving the city. In about eight weeks the cicatrix had again returned to about its former condition. The adhesion in each instance recommenced at the sides of the tongue and extended toward the center. After this operation I did not see the patient again, but Dr. Ibach writes me that he presented himself about every two months at his office to have an incision made in the scar. In August, 1894, his condition became very desperate, the gradual closing of the opening producing great debility from insufficient nourishment and want of air. He was advised to have a tracheotomy done and wear a tube permanently. This and further proposed operations were refused by the patient, and in the latter part of August he died.

In considering the results of the different operations it will be noticed that the time necessary to replace and reunite the cicatricial tissue was about the same after each operation—namely, from six to eight weeks—and this, notwithstanding the great difference in the extent and character of the operations. In fact, the contraction began as soon as the process of repair from the operations commenced. The necessity for a long-continued after-treatment in such cases is thus made forcibly evi-

dent. Such after-treatment should consist in dilating the orifice, and perhaps destroying any newly-formed cicatrices from time to time, until cicatrization should cease, leaving a sufficient opening; this would require many months' treatment.

It was my intention with this patient to try some form of dental plate after the operation that would act as an obturator, and perhaps such an obturator associated with stretching, etc., would have given a permanent opening, but it was impossible to keep the patient under treatment.

MEDICAL PROGRESS.

Secondary Suture of the Sciatic Nerve.—Freeman (*Medical Record*, No. 1247, p. 409) has reported the case of a colored boy, nineteen years old, who received a cut across the left thigh, the incision reaching to the bone, and extending two inches below the trochanter major and backward and downward for a distance of about five inches. The wound soon healed, but sensation remained absent from the foot, and the leg could not be used freely. Twenty-five months after the original injury the muscles of the leg and foot were paralyzed and wasted, and there was also some atrophy of the thigh. Sensation was wanting on the entire outer side of the leg and on the sole and dorsum of the foot, except in a line about one-and-a-half inches broad along the upper and inner aspect of the leg. The anesthetic area was dry and covered with scaly, whitish epithelium, and was clearly separated from the adjacent soft, dark and moist skin. There was edema of the foot, and the nails of two or three toes were missing. A large, deep trophic ulcer occupied the under surface of the heel.

Operation was proposed and acceded to. A longitudinal incision, six inches long, was made, with the line of the old cicatrix as the center. The inferior segment of the nerve, owing partially to its atrophy, was only found with some difficulty. The superior segment revealed itself at once by the spindle-shaped bulbous enlargement, the size of an English walnut, which occupied its extremity. This was removed by a wedge-shaped incision with its apex well within the normal nerve above. Below the old injury the nerve was much atrophied, its fibers spreading out and losing themselves in the cicatrix. These stringy fibers were separated as thoroughly as possible from the surrounding tissues, and the end of the nerve resected. The distal and proximal nerve-sections were then repeatedly and forcibly stretched with as much force as was considered safe, in order to bring them closer together. On flexing the knee and extending the hip it was possible to approximate the ends of the divided nerve, the separation between which had at first been at least four inches. Catgut sutures were employed, some being tied to portions of the neurilemma and others being introduced through the body of the nerve itself, the end of the distal segment being dovetailed into the V-shaped incision in the end of the proximal segment.

The wound united by first intention, the knee being retained in flexion and the hip in extension by plaster-of-Paris. On the third day after the operation it was found that sensation in the leg had returned. On the eighth day sensation had improved, and the scaly appearance of the skin over the entire leg was leaving. The ulcer on the foot also began to improve. At the end of two weeks the plaster splint was removed and the patient was instructed to straighten the leg slowly and carefully a little each day. On the outer surface of the foot, and more especially about the little toe, the power of feeling remained markedly deficient. In three or four days more sensation began to return in the foot, and in about three weeks the patient was walking on crutches. In the course of a month from the date of the operation the skin of the leg had recovered its softness and smoothness, while the ulcer had nearly healed. In places sensation was abnormally acute. Nearly a year after the operation the ulcer on the foot had not entirely disappeared. Two years after this the condition of the ulcer had become aggravated, while a second had appeared on the outer edge of the foot near the little toe. The condition was so troublesome that amputation of the foot was resorted to in order to relieve the patient of his encumbrance.

Extensive Resection of the Bowel for Tuberculosis; Implantation of the Ileum into the Colon; Extirpation of the Excluded Bowel.—Körte (*Archiv für klinische Chirurgie*, Band 48, Heft 4, p. 715) has reported the case of a man, twenty-five years old, who came under observation with symptoms of purulent peritonitis, operation evacuating large quantities of offensive pus. A fistula leading to the vermiform appendix remained, for the relief of which a secondary operation was performed, the appendix being removed. The appendix was in a state of chronic inflammation and presented two perforations communicating with adjacent adhesions. No evidence of tuberculosis could be detected. Nine months after the first operation a sausage-like tumor was detected upon the right side of the abdomen extending from the cecal region toward the costal arch. A third operation was performed, and the cecum and ascending colon were found thickened, while upon the serosa a small number of gray miliary tubercles were seen. Extirpation of all of the diseased structures was undertaken. The ileum was divided between two ligatures several centimeters above the ileo-cecal valve. Then the cecum and ascending colon were freed almost to the hepatic flexure. The intestinal wall was friable and tore in places, and the mucous membrane presented polypoid hyperplasias that were suspected to be carcinomatous. The mucous membrane was not healthy at the point of division, and, as there was a fear that a healthy surface might not be reached, the operation was suspended and an artificial anus created, to which the two ends of the bowel were sutured and surrounded with iodoform-gauze. Microscopic examination of the removed portion of the intestine disclosed tuberculosis of the mucous membrane. Seven months later a fourth operation was performed, 21 centimeters of the colon being additionally resected. Still, healthy mucous membrane was not reached. The opening in the colon was closed and an anastomotic communication established between the ileum and the colon. As matters did not improve three further operations were undertaken during the following seven months. Finally in the eighth operation the entire extent of diseased intestine was removed, including the remainder of the trans-

verse colon and the loop of the ileum sutured in the fourth operation, as well as a blind sac in the ileum remaining after the sixth operation. Thereafter there were no further complications, and with the aid of a truss the patient was able to engage in light book-binding.

Successful Gastrotomy for the Removal of Three Pocket-knives.—BECK (*Deutsche medicin Wochenschr*, No. 39, p. 760) has reported the case of a laborer, thirty-two years old, addicted to alcoholism, who for a period of five years indulged in the practice of swallowing indigestible bodies. At first these consisted of tacks, and somewhat later the man swallowed a rod of iron. These feats were usually followed by retching and epigastric pain, which compelled desistance for a few days, when they were again resumed. On one occasion the man, imitating a sword-swallower, swallowed a closed pocket-knife, without ulterior results and without a knowledge of its extrusion. Some time later, as the outcome of a wager, he swallowed two closed knives and a long lead-pencil. He complained of no bad effects, and failed to notice their passage by the bowel. Some months after this, under similar conditions, the man swallowed three knives. For two days he suffered no discomfort, but at the end of this time he began to complain of malaise, sweating, chilliness, loss of appetite, eructations of metallic taste, increased thirst, and pain in the epigastrium. Several days later the vomiting of bloodstained matter set in, with aggravation of the other symptoms. Palpation was attended with painfulness, and yielded a sense of circumscribed resistance in the epigastrium. The stomach was dilated and atonic, and an esophageal sound introduced into the stomach encountered a firm, movable body. The administration of laxatives being unattended with the passage of the foreign bodies, celiotomy was undertaken, and on exposure of the stomach the presence of the three knives was confirmed. The viscus was opened, and the foreign bodies with some difficulty removed. The cavity of the stomach was irrigated with boric-acid water, and the wound closed with silk sutures in three stages. The abdominal wound was then closed, and the usual dressings applied. The knives were respectively 4¼, 3½, and 2¾ inches long. All were somewhat corroded by the action of the gastric fluids. The progress of the case was perfectly afebrile and free from reaction, so that in the course of five weeks the patient was dismissed. It was not a long time, however, before he renewed his former practices, and swallowed two knives, one 4 inches and the other 3¾ inches long. These, however, it was impossible to expel by the administration of a soft, mushy diet, followed by laxatives.

Successful Celiotomy and Resection of the Bowel for Perforation in the Course of Typhoid Fever.—NETSCHAJEW and TROJANOW (*Bolnitschnaja gaseta Botkina*, No. 23; *St. Petersburger med. Woch.*, 1894, No. 36, Supplement, No. 8, p. 46) report the case of a man twenty-five years old, who came under observation, presenting the symptoms of a general peritonitis. He had been sick for about three weeks and had without known cause been seized with severe abdominal pain and a feeling of weakness. By exclusion, a diagnosis of peritonitis from perforation of a typhoid intestinal ulcer was made, and celiotomy was performed seventeen hours after the onset of the symptoms. The abdominal cavity was filled with sero-purulent and flocculent exudate. The serosa of the small intestine was turbid, hyperemic, and in places covered with flakes of fibrin. Some twenty centimeters from the ileo-cecal valve a small, round, pin-point opening was visible upon the free surface of the ileum, and from this gas and liquid feces escaped. An elliptic area, about four centimeters long, was removed from the bowel and the wound closed with Czerny-Lembert sutures of thin silk. After careful cleansing of the abdominal cavity with dry sterilized gauze all empty spaces were carefully tamponed. The abdominal wound was not sutured. The dressings were first changed on the seventh day, when the tampons were removed. The general condition continued good, and the temperature declined gradually in the course of three weeks. After the lapse of nine weeks the margins of the abdominal wound were freshened and sutured. The wound healed by primary intention and the patient made a good recovery.

The Presence of Diphtheria-bacilli in the Lungs of Children Dead of Diphtheria.—KUTSCHER (*Zeitschr. f. Hygiene*, xviii, 1; *Centralblatt f. Bakteriol. u. Parasitenk.*, Bd. xvi, No. 19, p. 791) made a study of the tissues from ten fatal cases of diphtheria, and found diphtheria-bacilli in the foci of broncho-pneumonia. The organisms were most abundant in the alveoli containing large numbers of cells, and were usually inclosed in the cells. Frequently streptococci were also found. The diphtheria-bacilli were also found in the perivascular lymph-spaces, and in smaller number in the bronchi. The organisms were found in the lungs in eight cases, in one instance in the kidneys, and in one instance in the liver.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—SCHIPPERS (*Week-bl. van het nederl. Tydschr. voor Geneesk.*, October 27; *British Medical Journal*, Epitome, No. 1767) has reported the case of a boy, five years old, in which in the course of a severe attack of diphtheria tracheotomy seemed urgent as a last resource. At this time, although the case appeared hopeless, an injection of Behring's antitoxin was made, the previous treatment with quinin and ferric chlorid, applications of ice and inhalation of steam being continued. In the course of twenty-four hours decided improvement had set in, and in a few days more the child was on the way to recovery.

SIMPSON (*British Medical Journal*, No. 1767, p. 1070) has reported three cases of diphtheria in the same household, one of which received 20 minims of Aronson's antitoxin on the third day and 40 minims on the fourth day. This one recovered; the other two died.

LEES (*British Medical Journal*, No. 1767, p. 1071) has reported the case of a child, two and-one-half years old, in which on the sixth day of an attack of diphtheria characterized by stridulous breathing, croupy cough, cyanosis and albuminuria, 10 minims of Aronson's antitoxin were injected, and later in the day 15 minims more; on the seventh day an injection of 10 minims was given. Improvement soon set in, and the case progressed to ultimate recovery. The belief is ex-

pressed that death would have taken place under any other method of treatment.

PHILLIPS (*British Medical Journal*, No. 1767, p. 1072) has reported a case of laryngeal diphtheria in a child four years old in which the performance of tracheotomy followed by an injection of 10 minims of Aronson's antitoxin led to a favorable outcome.

For several months Aronson's antitoxin has been employed in the diphtheria-wards of the St. Bartholomew's Hospital with distinctly good results.

ROMER (*Lancet*, No. 3715, p. 1090) has reported a case of diphtheria fatal from cardiac failure in a boy thirteen years old treated with the antitoxin. The treatment was, however, begun only on the tenth day, when 5 minims were injected; 6 minims more were injected on the eleventh day; 15 on the twelfth day, and some on the thirteenth day.

ROUÉ (*Lancet*, No. 3715, p. 1019) has reported a case of diphtheria in a child four years old in which tracheotomy became necessary and was performed for the relief of dyspnea. The temperature, however, rose, and it was feared that the false membrane was extending. An injection of 5 c.c. of the antitoxin was shortly followed by a decline in the temperature and amelioration of the other symptoms. The case is used to illustrate the combined effects of tracheotomy and the antitoxin. It is believed that the antitoxin alone would scarcely have been sufficient to relieve the dyspnea, but when the respiratory difficulty was removed by tracheotomy the antitoxin proved an indispensable aid.

VON RANKE (*Münchener medicinische Wochenschrift*, 1894, No. 45, p. 882) relates that from 1887 to 1893, inclusive, there came under observation in the Children's Hospital at Munich 1048 cases of diphtheria, of which 516 terminated fatally, a mortality of 49.2 per cent. Of the whole number 575 required either tracheotomy or intubation. Of the 473 treated exclusively with medicinal measures 136 terminated fatally, a mortality of 26 per cent. Of the number treated by operative measures 375 died, a mortality of 65.2 per cent. The cases that came under observation were principally of a severe type. It was at first determined to employ the antitoxin only in cases of laryngeal diphtheria, in order to obviate surgical interference. Investigation showed that from the beginning of the year 1889 to the close of the year 1893 intubation had been practised in 441 cases, of which 288 terminated fatally, a mortality of 65.3 per cent. The mortality had ranged in different years from 59.5 per cent. to 71.3 per cent. The supply of antitoxin (Aronson's) was at first so small that only doses of 1 c.c. were employed, cautiously increased to 5 c.c. Eight cases were thus treated with a fatal result in all but one. From May 1 to Setember 24, 1894, among 64 cases of diphtheria treated by ordinary methods there had been 43 deaths, a mortality of 67.1 per cent. Of 30 cases treated medicinally 13 died, a mortality of 43.3 per cent. Of 32 cases in which intubation was practised death took place in 30. An adequate supply of Aronson's serum was now obtained, and its employment continued from September 24th to October 12th. During this time 10 cases of diphtheria came under observation, and of these 9 were treated with the antitoxin, doses of from 5 to 15 c.c. being employed. Of these latter 7 recovered and 3 died; the one treated in the ordinary manner also died. Of 12 cases that came under observation from October 14th to October 28th 10 (grave) cases were treated with Behring's antitoxin, the other 2 being mild cases. Of the former 5 recovered, 1 died, and 4 were still under treatment, 3 with a favorable prognosis and 1 with a dubious prognosis. Of the 2 mild cases 1 recovered and the other was yet under treatment.

PÉRIGNON (*Journal des Sciences Médicales de Lille*, 1894, No. 45, p. 442) has reported a case of diphtheria in a child two-and-one-half years old in which on the second day an injection of Roux's antitoxin of 20 c.c. was made, and on the third day an injection of 15 c.c. The injections were speedily followed by a striking detachment of the membranes, and the case progressed to recovery.

The Treatment of Diphtheria with Antitoxin derived without the Intermediation of the Animal Organism.—SMIRNOW (*Wratsch*, Nos. 23, 24; *St. Petersburger medicin. Wochenschr.*, 1894, No. 42, Suppl., No. 9, p. 49) undertook to determine the possibility of inducing by oxidation and reduction in the serum of normal and diseased animals changes similar to those peculiar to the serum of immune animals, and finally succeeded with the aid of electrolysis. He found that injections of dogs' serum that had been exposed to electrolytic action for from three to four hours induced elevation of temperature. Injection of cows' serum treated in the same manner acted similarly, though inducing a slighter elevation of temperature. The employment of such serum in the treatment of animals inoculated with diphtheria-bacilli appeared to exert a curative action.

For Erysipelas.—GAGEE (*Medical Record*, No. 1252, p. 566) has successfully employed local applications of a 5 per cent. carbolic dressing in the treatment of erysipelas. Cheese-cloth which has been saturated with a carbolic solution is applied to the affected parts and for some distance beyond, and over this a sheet of rubber tissue or oiled silk, and the whole dressing kept in place by means of a bandage. If the area of infiltration has encroached upon the beard or the head, the hair of the affected region should be shaved. The eyes, even though not affected, are closed and covered with a fluffed pledget of wet gauze. If the ears are involved, a small portion of the dressing should be placed back of each, so that they shall not be pressed against the head by the bandage. The mouth and the nasal cavities are, of course, left free. The dressing is permitted to remain in place for twenty-four hours, when it is removed and replaced by another. The treatment should be continued until all suspicion of redness of the skin has disappeared.

For Amenorrhea.—

R.—Hydrargyri chloridi corrosivi . gr. ¾.
Sodii arseniatis . . . . gr. j.
Ferri sulphatis exsiccatæ . . gr. xxx.
Potassii carbonatis . . . gr. xv.
Extracti nucis vomicæ . . gr. v.
Misce et divide in pilulas xxx.
S.—One pill to be taken before each meal.

SATURDAY, DECEMBER 1, 1894.

CHARACTER.

IN a general way, it is doubtless true that the great mistake of men, of all men, consists in the failure to estimate the value of character. Everybody is prone to put the good of life in something gained or done, in knowledge in some objective thing, as wealth, power over men, ability to make much of self, etc. But apart from this general injudiciousness of mankind there are certain ages or peoples which thus err especially and grievously. It is an error, for example, markedly common in a young nation or people, when great public works are to be carried through and tremendous energy is to be put forth or utilized. The man who can win battles, who can plan and build a railroad, who can procure needed legislation, organize and manage manufactories, he is the man people want, and they care little or not at all whether he be honest, pure, high-minded, unselfish, or whether he be the reverse of these things.

By and by, however, with a better civilization, there comes the knowledge, gained by bitter experience, that the emotional and moral make-up of a man, his character, as contra-distinguished from his ability to do things, have as much, or more, to do with our trust of him, with his "success" even, as his ability to do things. As more and more men compete for the same office or work to do it is found that the larger type of personality, the man who has character as well as ability, is the better man to endow with trust and power.

It is just in such a condition that we Americans now find ourselves. We have heretofore been content to give over our cities, States, manufactories, banks, and institutions of a thousand kinds to the persons who by hook or crook could get hold of them, or who could do the work required. Now at last we are finding out that upon the quality of a man's personal character, in a word, upon his morality, will depend the success or failure of the thing done, quite as much as or even more than upon executive ability, knowledge, or will-power. It is not the most expert bookkeeper or cashier that is the best one to put in charge of millions of dollars, but it is the most loyal and honest. It is not the best, most successful administrative ability that now makes the best administrator. In every walk of life, from governing the nation, the city, or the push-cart, we are daily admonished that the perfection of a man's work depends upon the honor and honesty of the man's character. The power of the mere doer, the knowledge of the knower, the skill of the executor, are growing less important, and are coming more and more to depend upon how the thing is done, upon honor and conscience in the doer. In the long run nowadays the man, honest but stupid, if we must drive the comparison to its rather absurd extreme, gains upon the brilliant scoundrel. But as almost no American can be called stupid, so it follows that the combination of conscience with ability now constitutes the highest type of man.

These rather trite truths have their apt and striking application to medicine—but with the proviso that we are hardly yet beyond the first stage of the evolutionary process. We have hardly begun to be more than half-conscious of our barbarism of caring nothing for a physician's character, providing he is said to cure disease, or wins "success." The consequence is that we have plenty of medical Tweeds and Tammanies, our thousandfold quackeries, etc., all dependent upon the custom of not considering a man's character, but only considering his ability to get official position, or a big practice, to write a book, to deliver lectures, to attract the public eye, etc.

Now we contend that it is high time that we undertake the real work of genuine medical civilization. Sincerity and honor are as much needed to make a good physician as trickiness and smartness. The smart man, who is also a trickster, however infernally smart he may be, is henceforth to be more and more avoided. Whatever he says or does he is only after self, and medicine is his ladder and tool. The man whose laboratory-experiments are untrustworthy, who is always appearing in the daily papers under some pretext or other, whose language is habitually a nasty mixture of slang, oaths, or vulgarity, whose private life is filled with trickery and politics—such a man, however "sharp" and "able," is no longer fit to be a teacher of young men; patients should not be sent him, and office should not be given him. A man who makes, derives profit from, or indorses secret preparations should be practically disowned by his fellows in all ways by limiting his power. A man who fleeces the public, and thus injures the reputation of the profession, by charging fees farcically outrageous for inconsiderable operations needs to be incontinently squelched. The man "with a pull," who hoggishly gobbles up and uses for selfish purposes dozens of hospital-positions, excluding other quiet, modest men of equal ability, nay, even holding them in menial subserviency—such men should be avoided by trustees and other dispensers of power. The ringsters who unite into a clique for mutual advantage and profit by all the scheming and politically vile means in their power—they also need disgracing. The huckster, the schemer, the politician (usually he is one person), is to day the worst enemy of medicine. He corrupts at the source; he is the big quack in the better disguise.

In many ways we need to begin the task of discrimination and of rewarding men of modesty, honor, gentlemanliness, and conscience, instead of neglecting them and filling positions with the schemers, the self-puffers, the newspaper-doctors, and all the "pushers" who use medicine as a mere tool to further self. This is because the method of learning a diagnosis, or of treating a patient, or of doing anything, is often as important as the thing itself, and is indispensable to correct results. The best therapeutist, the best curer of disease, is not he who only knows best, but he who is most conscientious, sympathetic, and self-forgetful; the best surgeon is not the most expert operator, but he who will not operate when operation is not necessary. The most successful physician is not he who has most patients and makes the most money, but he who most successfully cures disease. The best teacher is not necessarily he who talks the glibbest or who is the most "popular," but he who helps his pupils to learn the best and most accurate knowledge, and who inspires them with the enthusiasm for knowledge and for the relief of human ills.

Are you a trustee or a dispenser of office or of power of any kind? There are hundreds of self-respecting, earnest, capable, honest, quiet men who deserve your consideration, and who will fill the position you have to give far better, more to the honor of the profession, more to the good of humanity, than the "hustler," the famous infamous fellow who fills your mail with splendid testimonials of his attainments and capacity, and who cronies with newspaper-reporters, "works the club-racket," and is as careless of medical ethics as he is careful of self-advancement.

If you are no appointment-giver you at times require a consultant. Do you believe you or your patient will secure better advice from the business-doctor, the consultation-hunter, the man with much fame, savory or unsavory? Or, is it not more likely you will do better by consulting with one who studies deeply, who is most scrutinizing, accurate—in other words, whose acts and life bespeak intelligent conscience as the ruling characteristic, and not egotism, "business," or love of fame. At least you are a member of some medical society. Can you not help to refuse office to the office-seeker and the politician? Can you not detect and estop the ringsters when they try to refuse membership to the worthy, and when they try to "run in" the unworthy. Blackballing the good man, receiving the bad man, are too common as they are too frightful mistakes.

In no way can we mold the future and make the world better for our children, freer from disease, than to encourage the formation of noble medical character by helping to office and by rewarding and consulting with those who are seeking to keep their characters pure and clean. In no way are we more recreant to our trust than by giving attention to the advertiser, by helping a despicable character to power simply because he has enormous effrontery and egotism coupled with more or less of flashy superficial medical knowledge and fame.

THE TOXINS OF MALARIA.

As is well known, the connection between the parasites of malarial fever and the symptoms of the disease has not yet been satisfactorily explained. The probability that toxic substances are formed during the growth of the parasites, which produce many of the symptoms of the paroxysm, was suggested by DOCK in a paper in THE MEDICAL NEWS (June 6, 1891), and in that article certain experiments of ROQUE and LEMOINE were mentioned which gave support to the supposition. These investigators tested the toxicity of the urine in three cases of malarial fever, and came to the following conclusions:

"Malaria produces a large quantity of poisonous products. These are excreted mostly by the urine, and the excretion reaches its maximum immediately after the paroxysm.

"Sulphate of quinin favors and increases this excretion.

"The severity of the paroxysm and certain pernicious forms stand in inverse proportion to the quantity of excreted toxin, and appear in consequence to depend on disturbances in the liver and kidneys."

DR. J. H. KELLOGG (*Modern Medicine*, October, 1894, p. 250) has recently made some independent experiments in the same line, and with results that confirm those alluded to. DR. KELLOGG'S patient had a severe attack of malarial fever, with crescents and endoglobular bodies in the blood. The precise variety of the latter is not mentioned. The method of experimenting was that of BOUCHARD, and was carried out as follows:

Obtaining the urine for twenty-four hours, or calculating the amount for that length of time, the urine is neutralized and filtered. The filtrate is injected into the ear-vein of a rabbit, previously weighed, and its temperature taken. The weight of the patient is also noted. The injection is continued at the rate of about one c.c. per second until the animal dies. The amount of urine required to kill the rabbit, and the symptoms produced, are carefully noted. The number of c.c. of urine required to kill is divided by the weight of the animal in kilograms, in order to show the number of c.c. necessary to kill an animal weighing one kilo. This gives the "urotoxy" of BOUCHARD. The total amount of urine for twenty-four hours, divided by this, gives the number of urotoxies produced in twenty-four hours, or in other words, the number of kilograms of rabbit which might be killed by the poison produced in twenty-four hours. This result divided by the weight of the subject, in kilograms, gives the weight of rabbit that would be killed by one kilo of the patient's body, or the "urotoxic coefficient." The normal coefficient, according to BOUCHARD, and confirmed by KELLOGG, is 0.44. Three specimens of the urine from the malarial case were tested. The first was collected for eight hours just before the beginning of the paroxysm. The temperature ranged from 97.2° to 100.6° F. The amount of urine was 400 c.c., its toxic coefficient 0.76. The second portion was collected for three hours during the paroxysm. The amount was 300 c.c. The temperature was from 103° to 101° F. The coefficient for this was 2.36. The third portion was collected for eight hours just following the paroxysm, the temperature being from 100° to 99°. Its coefficient was 0.78.

In DR. KELLOGG'S words: "It appears that during an attack of malarial fever the urine is always more toxic than in the normal state. The degree of toxicity was practically the same before and after the paroxysm, being 0.76 before and 0.78 after, this being far above normal. During the paroxysm, however, there is a much greater increase in the toxicity, amounting to more than five times the normal.

"The conclusion from these observations seems very clear and positive. A toxic substance is produced in malarial disease, which is eliminated in greater quantity during the febrile than during the non-febrile stage. The nature of the toxins is a matter which must be left to physiologic chemists to determine. The symptoms produced by the urine collected at different periods differed somewhat. The urine passed before the paroxysm produced powerful tetanic spasms, with dilatation of the pupil. That passed during the paroxysm, as well as that passed afterward, produced equally powerful spasms, but with strong contraction of the pupils.

"During the period preceding the paroxysm urea was secreted at the rate of 30 grams for twenty-four hours, during the paroxysm at the rate of 48 grams, and succeeding it at the rate of 13.5 grams for twenty-four hours."

As DR. KELLOGG says: "It is hoped that others with more favorable opportunities for the study of malarial disease will take up this line of inquiry, and that still further light will be thrown upon the question."

EDITORIAL COMMENTS.

Abolish the Words "Nyctalopia" and "Hemeralopia."—For several hundred years the word nyctalopia has been used to designate the symptom of "night-sight," a condition in which the vision is better by night or in semi-darkness than by daylight. During the same time the term hemeralopia has also been used to designate the opposite condition of night-blindness—a symptom particularly of retinitis pigmentosa, in which vision is worse at night or in poor illumination than in daylight or poor illumination. There are but two or three inconsiderable instances out of the hundreds in which modern ophthalmologists and lexicographers have used these terms wherein the definitions have been the reverse of those given. The words have thus acquired a desirable and necessary certainty of meaning that is at present universal.

But there are two classes of critics or criticasters in the world, the one composed of men who wish to air philologic knowledge or who are ludicrous sticklers for an impossible idealism of philologic accuracy, the other class composed of those who simply wish to find fault. Both are finical, fine, and flimsy in their arguments, and they unite to say that the foregoing words as now universally defined and understood are not used in the sense that they were used by the ancient Greek and medieval Latin medical writers, and that the true etymology of the words demands that they should be used with exactly the opposite sense to that now and for several hundred years ascribed to them.

Indeed! And are we now using words for the benefit of the ancient Greeks and Latins, or are we using them for the people of to-day? Did students of philology never hear of words changing their meaning? The word *idiot*, for example (and in the example we expressly abjure and deny any personal application) meant in Greek a private gentleman in contradistinction to a politician or one in public life; it has slightly changed its meaning since that lightful day. In Germany to-day, *selig* means *blessed*, but in English the word *silly* has quite another significance.

Indeed! And what man of sense cares two beans about the etymology of most medical words? The modern word-minter first gets his fact, his idea, and then he thumbs his dusty Liddell and Scott for some dried roots out of which to make a term that shall express his idea. There has been no historic or evolutional growth, no living nexus between the dead language or the dead Grecians and the new word. The lack of such an historic nexus is shown also by the fact that the meanings of the two words *could* have become reversed. Two to one, in fact, the new word philologically merits only the derision of erudite men, and it would have been just as well if the "bow-wow" theory had been followed in making it as the pseudo-scholastic jumble.

A scientific word has value only upon the absolute condition that its meaning shall be exact and unexceptional. A word that may mean one thing or that may mean its exact reverse; that requires a definition to follow it whenever it used; that may mean one thing to οἱ πολλοὶ and the reverse to scholars—such a word must simply be forever buried. Dr. Greenhill and Mr. Tweedy, of England, are responsible for an attempt to reverse the definitions of the two words in question and to make them conform to the usage of the ancients. In so far as the attempt is successful it can only serve to bring a contemptible confusion into all text-books and dictionaries, and to utterly kill the words. For what man of scientific mind will henceforth dare to use such nonsensical terms?

It did not matter a pin which one was called Tweedledum and which Tweedledee, so that each always had the same name. Mr. Tweedy thinks differently, and he has frightened both of them and us also to death in trying to get an answer and to revive lapsed habits. The twins were not very healthy babies at best, but these overactive and injudicious attempts at artificial respiration have certainly killed them forever.

We Must Educate our Teachers!—Our genial contemporary, *The Medical Record*, seems to think that refraction may be turned over to the optician if he is only "modest and genuine." It says: "There is no reason, however, why a modest and genuine refracting-optician should not perform a useful service to society. Many people suffer from hypermetropia, myopia, and astigmatism who cannot afford to go to a specialist. They must, therefore, either rely on their family physician, go to a dispensary, or to the R. O. Now we advise such to go to their family doctor and let him decide whether the optician is sufficient, and we advise the family doctor never to send his patient to the refracting-optician who proclaims his ability and readiness to diagnosticate almost every chronic abnormality of the eye." We are grateful that at least the immodest and non-genuine are excluded, but we cannot help asking as to the validity of the judgment and the appointment of the judge in such matters. Upon our bended knees, we would ask our good Democritus a dozen plain questions, to which we beg twelve categorical, monosyllabic answers:

1. Is it of advantage to medicine and to humanity that the druggist has been legally forbidden to practise medicine?

2. Do you advise your patients to go to druggists and ask them for something for "a pain in the back," or to the instrument-makers if they say they are crippled?

3. Is the eye as valuable a structure as the ankle or the "back"?

4. Do you advise refraction to be carried out without the use of a mydriatic?

5. Do you advise opticians to use mydriatics and other drugs in the eye?

6. Do you think all eye-strain due to errors of refraction alone, the muscle-balance playing no part?

7. Do you consider the optician capable of treating muscular anomalies?

8. Do you think the general physician capable of deciding whether the optician "is sufficient" or not—*i. e.*, can the general physician decide whether the case is solely one of an error of refraction, or whether muscle-troubles, diseases of the fundus, glaucoma, paralyses, etc., may complicate it or not?

9. Do you think that poor patients with eye-troubles will get better advice *gratis* from the optician than from ophthalmic surgeons at hospitals, or in their private offices?

10. Which advice will be the least expensive in the long run?

11. Is it in the line of medical science and progress to advise patients to leave the physician and go to strictly commercial men for medical advice?

12. Is it befitting a respected medical journal and teacher to give such advice as you have here given?

The Foot-ball Disgrace grows, naturally enough and fast enough. During the past weeks our postman has brought us from many correspondents and from all over the land an amazing mass of news of deaths, broken bones, wrenches, concussions, dislocations, gambling, orgies, and drunkenness of the victorious, tears and bellowings of the vanquished, and sluggings, sluggings, sluggings—without end. We could fill a whole issue of The Medical News with the nauseating details, but it would be useless. Further arguments or facts are not needed. "If we win this game it will increase the number of our students several hundred next year"—that's the unanswerable argument of those who cheer on the crazy fury. Decent referees and umpires, however, are refusing to umpire future games, and even the cheap newspapers are thoroughly disgusted and are plainly warning against the inevitable conclusion of the tragic farce. The long-suffering of parents and guardians, and their confidence in their "professors" and "educators" are marvellous phenomena. But the signs are plain now that they are near ending.

As to the revision of the rules lessening the mortality it has been wittily said that, *plus on change, plus c'est la même chose*. Let us hear no more of the cant of revision and reform. As to inter-collegiate games, there is but one change demanded: abolish them absolutely!

The Question of the Need of Negro Physicians Again.—A valued correspondent residing in the South thinks that there is no such need as we have urged for negro physicians in the South, and says that in his own vicinity the negroes receive from himself and his colleagues the same medical attention and kindness as do white people in the same financial conditions. Of this we have no doubt, and are glad to believe, as our correspondent avers, that this is generally the case. That it is *always* so (as he also says) may be doubted, and the doubt springs from no race-prejudice, indeed, has nothing whatever to do with it. The North is, perhaps, fully as guilty of race-prejudice as the South. We cannot allow any further space to this discussion, and in closing we shall allude to the annual report of the Mayor of Chattanooga which brings definite figures concerning the shocking difference in the death-rate between the white and negro population, showing that that of the negro is nearly three times as great as that of the white. The actual figures are 9.55 per cent. for the white race and 26.15 per cent. for the colored.

Another correspondent calls attention to the fact that Shaw University, Raleigh, N. C., has a medical department exclusively for negroes.

Teratologia, a journal originated and edited by Dr. J. W. Ballantyne, of Edinburgh, and the first volume of which has just been completed, appears to be already established upon a permanent basis. It was primarily intended to be a channel of publication for cases of teratologic interest coming under the observation of the editor; but the offers of assistance from pathologists and teratologists, both at home and abroad, made it possible to include within the scope of the new venture all matters relating to antenatal disease and deformity and certain closely associated neonatal morbid states. The last part of the first volume contains an article on maternal erysipelas, with streptococcus-endocarditis in the fetus, in Italian, and it is proposed, as circumstances may demand, to publish other articles in French and German. Dr. Ballantyne certainly deserves support and encouragement in his worthy enterprise and congratulation on the success that he has already attained in his efforts.

Paskola.—In the current number of *The Dietetic and Hygienic Gazette*, Dr. Henry Leffmann gives the results of some laboratory digestion-experiments with this much-advertised article, Paskola. Paskola is very similar in composition to commercial glucose-syrup to which a little hydrochloric and sulphurous acid have been added. The circular issued by the manufacturer claims not only direct nourishing qualities, but also high digestive power. Experiment, however, failed to demonstrate any activity as a digestive agent. Starch was not converted to an appreciable extent, even after many hours' contact, and neither uncoagulated nor coagulated white-of-egg was converted into albumose or peptone. Control-experiments with commercial pancreatic extracts showed that these were very active.

SPECIAL ARTICLE.

REPORT OF THE MEDICAL NEWS.

A CLINICAL REPORT OF FIVE CASES OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

By WILLIAM M. WELCH, M.D.,
PHYSICIAN IN CHARGE OF THE MUNICIPAL HOSPITAL, PHILADELPHIA.

(Continued from page 559.)

Case II.—On November 15th the exudate had disappeared from both the fauces and the nares. The temperature had dropped to normal, and convalescence from diphtheria and scarlatina had begun. On November 19th the child was playful, ate well and was anxious to sit up. An examination showed that the fauces and nares were quite normal in appearance. There was no albumin in the urine, and unless serious sequelæ should occur, recovery seemed assured.

On November 23d the child was still doing well; had no albuminuria; had a good appetite, and was convalescing rapidly.

Case III.—On November 13th the exudate had entirely disappeared from the fauces, but the uvula remained somewhat pale. The temperature and pulse were about normal. On November 15th the fauces were normal, with the exception of being preternaturally red; the end of the uvula, however, remained pale. The patient sat up on this day for the first time. On November 19th the improvement continued; the patient had been sitting up every day since the 15th, and had a good

appetite. The fauces were still red, though normal in other respects. The urine passed on this date showed about 10 per cent. of albumin by bulk.

On November 23d the fauces were normal, with the exception of the redness, which still continued. About 10 per cent of the bulk of the urine was albumin. There were no symptoms of paralysis. The appetite was good and the strength improving.

Case IV.—On November 15th no exudate could be seen in the fauces, but the nares had not quite assumed their normal appearance. The temperature and pulse were normal, and the appetite was good. The urine continued free from albumin. On November 19th the patient sat up a short while for the first time; the improvement continued, although the circulation was feeble and the pallor extreme. The fauces, with the exception of marked redness, seemed healthy, but the nares were still somewhat abnormal. The appetite continued good, and the patient had apparently gained in weight. In this, as well as in the preceding cases, tincture of ferric chlorid was continued three times daily, together with a nutritious diet.

On November 20th the child was somewhat indisposed, and the temperature was found to be 101°. During the two preceding days the patient had been sitting up.

On November 21st a rubelloid rash covering the trunk and extremities appeared. The temperature fell to normal, or nearly so, and the appetite was as usual. There were no catarrhal symptoms.

On November 23d the temperature continued normal, and the rash had entirely disappeared, without leaving the mottled condition of the skin peculiar to measles; hence the diagnosis of that disease must be excluded. There was no albumin in the urine, but there was slight evidence of paralysis.

Erratum.—In the first part of this clinical report, published November 17th, it is stated that Cases I and II were admitted to the hospital October 2d; the date should read November 2d.

On November 23d Dr. Kyle reported that the Klebs-Loeffler bacillus was still present in the throats of the foregoing cases.

Case V.—On November 13th the exudate in the fauces was somewhat thinner, and that in the nares also seemed to be slightly diminished. The temperature ranged between 98.4° and 99.6° F.; the pulse was more feeble but the respirations were unchanged. Nourishment was taken, though somewhat reluctantly, and vomiting occurred once or twice. The heart's action was weak and the extremities were growing cold. Strychnin sulphate was ordered in doses of gr. $\frac{1}{100}$ every four hours, and the whiskey was increased. On November 14th the exudate in the fauces had diminished still further; the pulse ranged from 96 to 104, and was almost imperceptible at the wrist; the respirations ranged from 20 to 30; the temperature ranged from 98° to 98 4°. Albumin was found to be present in the urine (about 2 per cent. by bulk). The extremities were constantly growing colder; vomiting was occurring occasionally. The child took nourishment and medicines more reluctantly; the pallor of the face was increasing, and the patient was rapidly losing strength. Spiritus ammonii aromaticus in f℥ss doses was ordered every half-hour, and strychnin sulphate, gr. $\frac{1}{100}$, hypodermically, every four hours. The exhaustion progressively increased, and death occurred from toxemia at 10 o'clock P.M.

SELECTION.

READING-NOTICES IN MEDICAL JOURNALS.

In these times of intense commercial activity it is not strange that, even the most reputable and high-toned chemists and manufacturers of pharmaceutical preparations should seek every legitimate means of commending their products to the medical profession, who are their chief customers. The time has been, and past, when the leading dailies and monthlies of this country did not hesitate to insert in their papers editorial commendations of articles advertised in their columns. It may probably be said with absolute correctness, that none of these at the present time insert anything of this sort without having appended to it in italics the abbreviation "Adv." It seems to us that it is particularly incumbent upon the editor of a medical journal that he should keep his pages so clear from any suspicion even of anything which would appear to be in the interest of those who advertise in it, that his subscribers may feel the most implicit confidence in his desire to supply them only with that which is distinctly in their interest. It is no doubt a fact that oftentimes preparations advertised by first-class houses are worthy of high commendation, but if once it is found that an advertisement is the means of obtaining directly, or indirectly, editorial notice in any medical journal, the confidence of the patrons of such a journal in its disinterested presentation of scientific facts must surely be more or less weakened. No editor is in a position to speak well of one and not of another. The only safe course, the only possible course, is to adhere to an inflexible rule, to admit no article and to print no editorial which either favors or condemns the wares of any advertiser.

Holding these views as to the proper conduct of a medical journal, we notice with regret that one of our esteemed contemporaries has recently published, not only an article highly commending the product of a house advertising in their pages—with which house or product we have no controversy whatever—but it has also, most strangely, commented favorably in an editorial upon the same article. We have no doubt that this is eminently satisfactory to the advertisers, but cannot believe that it will increase the respect to which the usual conduct of this journal entitles it.

The true value of any journal to an advertiser is not only the extent of its circulation and the character and standing of its subscribers, but equally, if not more so, the estimation in which a journal is held for absolute impartiality and fairness toward all, and its single eye to the interests of its subscribers.—*Medical Record*, Nov. 17, 1894.

Lysidin.—Lysidin is a body said to be identical with ethylene ethenyldiamin, and to which is ascribed extraordinary solvent powers upon uric acid in cases of gout. The remedy has been employed by Grawitz (*Deutsche medicin. Wochenschr.*, 1894, No. 41, p. 786) in doses of from 15 to 75 grains daily in a pint of carbonated water, with encouraging results.

REVIEWS.

Manhattan Eye and Ear Hospital Reports. No. I. New York: 103 Park Avenue. January, 1894.

This is a neatly printed pamphlet of 143 pages, telling the story modestly and profitably of the enormous amount of work done in the four departments of ophthalmology, otology, laryngology and neurology, during the year 1893. In addition to the tables of classified diseases we find collated details of cases illustrative of diseases of which the etiology and treatment form live topics of discussion in medical societies and journals, and the results of the practice pursued in each series of cases opened to the criticism of the profession. Thus the benefit of the abundant material of this hospital is not confined to the members of its staff, but is participated in by every reader of the report. The list of medical officers includes 13 surgeons, 1 physician, 48 assistant surgeons, 2 assistant physicians, 16 clinical assistants, 2 consultants, 2 pathologists, and 3 internes. The total number of diseases of the eye observed was 10,640; of the ear, 2670; of the throat and nose, 3126, and of the nervous system, 423, making a grand total of 16,859.

A Manual of Nursing in Pelvic Surgery. By Lewis S. McMurtry, A.M., M.D., Professor of Gynecology in the Hospital College of Medicine, Louisville, etc. Pp. 92. Louisville: John P. Morton & Co., 1894.

As the writer claims, this is merely an outline and not an exhaustive treatise on gynecologic nursing. The principles advanced are those in general practice; there is nothing new offered. The most valuable portion of the little volume is undoubtedly the chapter upon complications in abdominal surgery; here the nurse may find enumerated the beginning symptoms of peritonitis, intestinal obstruction, hemorrhages, and cystitis, upon an early recognition of which largely depends the patient's chances of recovery. Such a book as this is of service mainly in emphasizing a subject that is frequently more or less overlooked in larger books on abdominal surgery.

Syllabus of the Obstetrical Lectures in the Medical Department of the University of Pennsylvania. By Richard C. Norris, A.M., M.D., Demonstrator of Obstetrics, University of Pennsylvania, etc. Third edition. Philadelphia: W. B. Saunders, 1894.

Dr. Norris' book, which has been especially prepared for the use of the students in the Medical Department of the University, well deserves the cordial reception it has received in the past. It is clear, concise, and comprehensive, and presents the subject-matter in an acceptable and easily accessible form. In the preparation of this third edition the book has undergone a thorough revision, in order that the additions to the lectures made during the past two years might be incorporated in the body of the work. Especially noticeable is the improvement in the subject of puerperal fever, which is now dealt with in a manner worthy of the importance of that grave disorder. As a syllabus the book ranks among the best.

NEWS ITEMS.

A Few Foot-ball "Casualties."—B. Foote, a student at the Fairfield Seminary, near Little Falls, N. Y., became violently insane a week ago because of injuries received in a foot-ball game. He rushed around the dormitory all Sunday night in his foot-ball suit, and was only secured by a ruse at daybreak. He was then taken to the Utica Insane Asylum, where he is now confined.

Daniel McTiernan, fourteen years old, who played at Worcester on Saturday in a school game, was fallen on in a rush, and was so injured that he died during the night.

At Shreve, O., on Saturday afternoon, Walter Blackburn, nineteen years old, received injuries in a foot-ball game which caused his death. While "interfering" with another player Blackburn was thrown heavily to the ground, and five or six other players fell on him. When he was extricated he was paralyzed from the neck down, and a surgical examination disclosed the fact that the spinal column had been fractured.

The Monterey Foot-ball Club, of Harlem, owing to the death of a member, Fred. Opperman, resulting from injuries sustained in a game on election day, has disbanded for the season.

A serious accident occurred in a game between the Louisville Male High School and the Manual Training School last week. One of the players on the former team sustained a fracture of both bones of one of his legs.

Steven Brady, of the high school at Putnam, Conn., was injured in a foot-ball game last week, and is not expected to live. Since Saturday night he has had five hemorrhages.

Harry Rider, the right guard of the Mount Vernon College foot-ball team, was severely injured in a game with the Hiram College eleven at Alliance, O., November 19th, and is in a critical condition. He became delirious. His physician says the kick has caused a clot of blood at the base of his brain.

A correspondent of The Medical News, Dr. John A. Graham, of Lexington, Va., reports from his locality five cases of fracture and one death.

Hall Stockton, of the "Credenda Club," Philadelphia, "was taken from the field unconscious and is not expected to live."

In the first place, we respectfully ask the governing bodies of all colleges what they have to say for a game between youths presumably engaged in the cultivation of the liberal arts, which needs among its preliminaries a supply on the field of litters and surgeons? Such preparations are not only brutal but brutalizing. How any spectator, especially any woman, can witness them without a shudder, so distinctly do they recall the duelling field and the prize-ring, we are unable to understand. But that they are necessary and proper under the circumstances the result showed. There were actually seven casualties among twenty-two men who began the game. This is nearly 33 per cent. of the combatants, a larger proportion than among the Federals at Cold Harbor—the bloodiest battle of modern times—and much larger than at Waterloo or Gravelotte. What has American culture and civilization to say to this mode of training our youth? "Brewer was so badly injured

(broken leg) that he had to be taken off the field crying with mortification." Wrightington fell, and as he lay on the ground, Hinkey, captain of the Yale men, jumped on him with both knees, breaking his collar-bone. Beard was next turned over to the doctors. Hallowell had his nose broken. Murphy was soon badly injured and taken off the field on a stretcher unconscious, with concussion of the brain. Butterworth, who is said to have nearly lost an eye, soon followed. As we have said, there was a great deal of "slugging"—that is, striking with the fist and kicking—which was not perceived and punished by the umpires, though two men were ruled out for it.

The Mitchell District Medical Society will hold its forty-sixth semi-annual meeting at Mitchell, Indiana, December 27 and 28, 1894. The following is the scientific program: The Right Pulmonary Apex, by Theodore Potter, Indianapolis, Ind.; Report of Additional Operations for Extra-uterine Pregnancy, by Rufus B. Hall, Cincinnati, O.; Concretions of the Tonsils and their Influence in Producing Sore-throats, by Lewis C. Cline, Indianapolis, Ind.; The Tonsil as a Site of Infection, by John A. Thompson, Cincinnati, O.; Mistaken Notions about Glasses, by F. C. Heath, Indianapolis, Ind.; Hysterical Joint Affections, by P. S. Conner, Cincinnati, O.; Squint, by Dudley S. Reynolds, Louisville, Ky.; A Review of Ureteral Surgery, by R. Harvey Reed, Columbus, O.; The Ideal Operation for Varicocele, by G. Frank Lydston, Chicago, Ill.; Public and Private Hospital Work, by A. M. Owen, Evansville, Ind.; The Cause and Prevention of Pelvic Inflammation in Women, by L. S. McMurtry, Louisville, Ky.; Some Suggestions in Rectal Practice, by Joseph M. Mathews, Louisville, Ky.; Cancer of the Rectum, by Arch. Dixon, Henderson, Ky.; The Medical Fad of the Nineteenth Century, by Samuel H. Collins, Lawrenceburg, Ind.; A Case of Obscure Fracture Complicating Dislocation of the Elbow-joint—Arthrotomy, by Hugo O. Pantzer, Indianapolis, Ind.; Some Cases of Abdominal Section followed by Slow Heart, by T. A. Reamy, Cincinnati, O.; Paper, by J. C. Culberston, Cincinnati, O.; Paper, by J. W. Marsee, Indianapolis, Ind.; Paper, by I. N. Love, St. Louis, Mo.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery.—The quinquennial prize of one thousand dollars under the will of the late Samuel D. Gross, M.D., will be awarded January 1, 1895.

The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the successful competitor who receives the prize shall publish his essay in book-form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, before January 1, 1895.

Each essay must be distingished by a motto, and accompanied by a sealed envelop bearing the same motto, and containing the name and address of the writer. No envelop will be opened except that which accompanies the successful essay.

The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

Another "Gold-Cure" Victim.—An inquest, resulting in a verdict of "death from alcoholism," was held in Chicago on the 12th ultimo. The victim—a commercial traveler named Dresser—was discharged "cured" from a Keeley institute about three years since, and for a time was one of the "star" cures. This makes the sixth or seventh "post" held in that city within a few months on "graduates of the gold cure." It might be worth while to gather up the statistics of this kind for the country at large.—*Journal American Medical Association.*

BOOKS AND PAMPHLETS RECEIVED.

Précis de Clinique Thérapeutique. Par le Dr. A. F. Plicque. Paris: G. Steinheil, Éditeur, 1894.

The Annual Report of the Department for the Insane of the Pennsylvania Hospital, for the year ending Fourth Month 25th, 1894. By John B. Chapin, M.D., Physician-in-Chief and Superintendent. Philadelphia, 1894.

Remarks on Hog-Cholera and Swine-Plague. By William H. Welch, M.D., and A. W. Clement, V.S. Pamphlet, 1894.

Transactions of the Association of American Physicians. Ninth Session, held at Washington, D. C., May 29, 30, 31, and June 1, 1894. Vol. ix. Philadelphia: Printed for the Association, 1894.

Prospectus of the St. Louis College of Pharmacy. Twenty-ninth Annual Session, from October 8, 1894, to April 8, 1895. St. Louis: College of Pharmacy, 1894.

Sixteenth Annual Announcement of the St. Louis College of Physicians and Surgeons, Session 1894-95.

First Special Report of the Factory Inspectors of Illinois on Smallpox in the Tenement Sweat-Shops of Chicago, July 1, 1894. Springfield, Ill.: H. W. Rokker, State Printer and Binder, 1894.

Announcement of the Gross Medical College, Denver, Colo. Annual Session, 1894-95. Reprinted from the Gross Medical College Bulletin, 1894.

Chromicized Catgut as a Means of Direct Fixation in the Treatment of Fractures and Osteotomies, with a Report of a Case. By F. W. Jay, M.D. Reprinted from the Journal of the American Medical Association, 1894. Eleventh Annual Announcement of the Medical and Dental Departments of the National University, 1894-95. Washington, D. C.

H. Bocquillon-Limousin. Formulaire des Médicaments Nouveaux et des Médications Nouvelles pour 1894. Paris: J. B. Baillière et Fils.

Reports of the Trustees and Superintendent of the Butler Hospital for the Insane. Presented to the Corporation at its Fiftieth Annual Meeting, January 24, 1894.

A Case of Male Hysteria Characterized by Recurrent Attacks of Motor Aphasia and Lethargy; Apparent Cure by Hypnotism and Suggestion. By Theodore Diller, M.D. Reprinted from the International Medical Magazine, 1894.

The Non-Operative Treatment of Brain Tumors. By Theodore Diller, M.D. Reprinted from the University Medical Magazine, 1894.

Sperminum-Poehl in chemischer, physiologischer und therapeutischer Beziehung. Von Dr. Bubis. Separatabdruck aus d. St. Petersburger Medicin. Wochenschrift, 1894.

ORIGINAL ARTICLES.

AN EPIDEMIC OF PARALYSIS IN CHILDREN, WITH A REPORT OF ONE HUNDRED AND TWENTY CASES.[1]

BY ANDREW MACPHAIL, B.A., M.D., M.R.C.S. ENG., L.R.C.P. LOND.,

PROFESSOR OF PATHOLOGY AND DISEASES OF CHILDREN IN THE UNIVERSITY OF BISHOP'S COLLEGE, MONTREAL.

DURING the past two months, through the intervention of Dr. C. S. Caverly, President of the Board of Health, and his colleague, Dr. H. H. Swift, I have been able to make some observations upon an epidemic of "Paralysis in Children" that occurred in the State of Vermont. The epidemic commenced late in June, increased in July, and culminated in August, and, though new cases are cropping up, the malady has now almost abated. I obtained the notes of ninety-one cases out of one hundred and twenty that were affected.

I feel at liberty to call the attention of this Association—a body that concerns itself chiefly with the health of the people—to this malady, wholly unknown in origin, and of uncertain nature. The record is fragmentary and imperfect. But it is by reason of its imperfection that it will mainly interest this meeting. Our aim is not so much to investigate the nature of disease as to examine into the conditions under which it prevails and the means that can be taken to prevent, limit, or even eradicate it. An additional reason is that, after as thorough a search of the literature as I could make, this is the first epidemic of the kind that has occurred in America.

I have not, without thought, decided to speak of these cases as "Paralysis in Children." They might be classed as cases of "poliomyelitis anterior acuta," if this would add in any degree to our knowledge, but such a term demands a consent that, with the imperfection of the material, many will be unwilling to make. Even in undoubted cases the use of such a term is open to objection, as it is merely a pathologic remark that does not entirely meet the case. In the cord of a child dead of this disease the lesion is not confined to the cells of the anterior horn; there may be a general hemorrhagic myelitis and there may be even meningeal involvement. But if we accept the definition of Osler, that this formidable name merely signifies "an affection occurring most commonly within the first three years of life, characterized by loss of power in certain muscles, and rapid atrophy," then we may, for the moment, leave names at one side and refer to some cases. As we all know, the nomenclature of disease requires revision to bring it at all into harmony with the amount of definite information, however small, that we really do possess.

At first, the belief was held that the outbreak was one of cerebro-spinal meningitis, and there were several cases presenting the characteristics of this disease. Besides, it is well known that this is an infectious disease that occurs not uncommonly in epidemic form. But from the cases that I shall submit, it must, I think, be clear that the malady is not to be explained by this method of reasoning. It will be noted in most of the cases that there were no typical symptoms of this disease; in some there were no symptoms at all, beyond paralysis. There was a general absence of marked retraction of the head and of opisthotonos; the sensory symptoms were not prominent; the headache was chiefly frontal; and, beyond some slight delirium of the ordinary febrile type, there were no psychic manifestations. The cutaneous symptoms were unimportant. While, in many cases, there were indefinite rashes, in only one were there petechiæ; in none, herpes labialis, mottling or purple spots, or the other undoubted cutaneous manifestations of "spotted fever."

Again, the sequelæ and complications were different. There is no account of pleurisy or pericarditis, and in only one case pneumonia. In only two cases was arthritis a factor, and in no case was there any persistent paralysis of any of the cranial nerves.

There was no impairment of hearing. The eye-symptoms were wholly of central origin. There was no ophthalmia, no conjunctivitis, no keratitis, or any other ocular inflammation; nor did any impairment of vision follow the attack. In these respects the malady departs from the type of cerebro-spinal meningitis, in which disease the eye-symptoms are marked and usually constant. Of thirty-two cases examined by Dr. Randolph these symptoms were present in twenty-eight, and on the authority of Wilson, Niemeyer, Knapp, and Kreitmair, it may be accepted that ocular symptoms predominate in all epidemics of cerebro-spinal

[1] Read before the American Public Health Association, September 28, 1894.

meningitis. Indeed, Hirsch affirms that "conjunctivitis is almost a constant condition."

The earliest case of which I could procure any record occurred on the 17th day of June, 1894, and I have taken the following note.

S. C., a boy five years old, complained on the 17th of June of headache, chiefly frontal, with nausea and vomiting; his temperature was 102°, the pulse 115. This condition continued for twenty-two hours, and was succeeded by soreness in the arms and legs, loss of reflexes, with gradually increasing paralysis, culminating after twenty-four hours in a completely powerless condition of both upper and lower extremities.

I will place by the side of this a later case:

A. B., a delicate girl of twelve years, with a slight left lateral spinal curvature, fell sick of an attack resembling indigestion, with coated tongue and marked constipation. Gradually, without any alarming symptoms, paralysis supervened, and in two days all the four limbs were rendered useless. After five weeks there was no sign of improvement in either arms or legs.

In general features the following cases are much alike:

Mildred T., a strong child of two years of age, on the 28th of August had an accession of fever, with a temperature of 103° and a pulse of 115, a coated tongue, constipation, and headache. These conditions persisted for four days, when it was observed that the right leg was completely paralyzed. It still remains in that condition.

Walter F., a well-grown lad, aged eight, was seen on the 21st of July, with a pulse of 140, a temperature of 105°, with nausea, vomiting, and diarrhea, and in a condition of extreme nervous tension, bordering upon delirium. Under acetanilid the temperature was reduced to 102°, but during the night two convulsions occurred, the temperature rose again to 105, and there was marked and noisy delirium. In the morning the condition was improved, and in four days the temperature was normal. There was now pain in the left arm, and with this exception, convalescence was well established, but the arm was completely paralyzed and hyperesthetic. Atrophy proceeded rapidly, and the limb became flaccid, soft, and flabby. The reaction of degeneration was soon manifest; then the nerves entirely lost their irritability and did not react at all to the interrupted current. The paralysis remained stationary for two weeks, and now shows some small improvement.

C. D., seven years old, was affected on the 18th of July, and for two weeks was in a general febrile condition, with delirium; there was general hyperesthesia and occasional convulsions. Gradually a paralytic condition of the upper and lower extremities supervened, which in a few days was confined to the left arm, and is now passing away after persisting for a month. For two weeks the patient was affected also with loss of speech.

In the following cases there were pronounced joint-symptoms:

The patient was a boy, seven years of age, who from the 4th of July had a temperature of 103.5° and a pulse of 120, lasting three weeks. The temperature now dropped to 97° and the pulse to 50. All this time there was obstinate constipation and general hyperesthesia. The knee-joints were painfully swollen, as well as the elbow-joints and shoulder-joints. Paralysis of the left upper and left lower extremities followed, and still persists.

Arthur A., aged four years, had been ailing for two weeks, and on the 22d of July was seriously ill. After three days there was fever and pronounced delirium; the head was thrown well back, and the muscles of the neck and back were painful and rigid. At the end of a week the temperature was normal, but both legs were drawn up, and the left knee was swollen and tender. For six days this condition persisted, but was gradually relieved. Paralysis with entire loss of usefulness followed, but after a month the limbs, though atrophied, appeared to be regaining their function.

Gowers holds that the pain is only "supposed to be in the joints, because it is produced by moving them, when it is really in the nerves, which are mechanically disturbed by the movement of the joints." In these cases the lesions appeared identical with those of acute rheumatism.

In the following cases the onset was peculiar:

Alice B., aged eleven years, a sturdy girl, on the 18th of July was affected, as a preliminary symptom, with double vision. For the following three days she was slightly unwell, and the next morning was unable to get out of bed. The left leg was completely paralyzed, the left arm slightly so. Fever with delirium followed for four days, when the symptoms abated, and finally all the conditions were relieved, and now the limbs show some improvement. It is to be noted that in the case of this girl the menstrual function was established during the progress of the disease. It is well known that the uterine function has a direct influence upon the cord, and *vice versa*.

Annie H., eleven years old, on the 15th of August was observed to have a coated tongue and symptoms of "biliousness," without fever or any other special symptoms. This continued as a slight indisposition for three days, when the child began to stumble, and on the 18th there was a complete paralysis of the left leg. This remained for ten days, when signs of improvement were noticed, which still continue.

In certain cases, as the following, there was no premonition of the attack:

An infant girl, suddenly and without symptoms, developed paralysis of both lower extremities. The condition persisted for two weeks, and went from improvement to complete recovery.

In view of the fact that in many cases of cerebro-spinal meningitis the lance-shaped coccus, similar

in all respects to the pneumococcus, has been found, and which Cornil and Babes regard as the cause of both diseases, it is worth remarking that pneumonia was present in only one case :

E. F., a boy aged four years, was affected on the 6th of August, after a slight preliminary illness, with paralysis of both legs, and two days later developed pneumonia. Both conditions subsided, and now the child is in a fair way of recovery.

In a few cases the onset was accompanied by symptoms of transient spinal meningitis. Gowers believes that each condition must be regarded as a coincident effect of a common cause.

In the following cases the symptoms of spinal meningitis were well marked :

Cortice C., aged twelve years, on the 8th of August had an attack resembling acute indigestion, and two days later both lower extremities became partially paralyzed. The child was away from home, and was now removed a distance of eighteen miles. The same night the temperature rose to 104.5°, the pulse to 130, and two convulsions occurred. There was undoubted retraction of the head and painful stiffness of the neck. The child was irritable and restless, with photophobia and undue sensitiveness to noises. The pupils were unequal, and there were well pronounced motor symptoms. There was tremor of the muscles, with clonic spasms of the legs and arms. The next morning the child was paralyzed in both legs. This acute stage passed off by the 15th of August, when the tongue was clean, the temperature normal, and the child was eating well, though there was some inabiiity to swallow, due to paralysis of the throat-muscles The paralysis, however, persisted, and on the 17th the child suddenly collapsed, with sordes on the teeth, the pulse imperceptible, the extremities cold, and with all the signs of impending death. Under heat and stimulants the child recovered in three days. Throughout the whole course there was an erythematous eruption which would vanish and then reappear. By the 28th of August one leg had improved, but the other remained much atrophied, and the signs of returning usefulness are indefinite.

In the following cases the issue was fatal :

Hilding A., a Swedish child, twenty months old, on the 31st of August was stricken with fever of 103° and a pulse of 120. The restlessness was extreme, the child moaning and tossing its limbs, but quite conscious. The head was firmly fixed, slightly retracted, and the pupils contracted. The next day the general symptoms were improved, but the child continued restless and in a highly excitable condition. On the 2d of September the fever had disappeared, and the restlessness increased, with clonic spasm, strong grinding of the teeth, and paralysis of the left leg. The next day the temperature rose to 104°, the spasm increased, and general paralysis supervened. The child died in the afternoon.

S. O., an Italian boy, four years old, on the 21st of July became sleepy and complained of headache. He was found to have no fever, but with a pulse of 45, slow, hobbling in character, and intermitting every fifth beat. This continued for four days, when a slight improvement was noticed. Strabismus occurred, but the child made a complete recovery, so far as symptoms were concerned, on the seventh day. He was then allowed to play in the hot sun with a goat, when all of the original symptoms returned—the headache, squint, halting pulse, and drowsiness. This was the last of August ; by the 1st of September he was worse than at any previous time, but yet had no fever. The next day the knee-jerk was absent, but the plantar and the cremasteric reflexes were retained. The legs now became paralyzed, and by the 3d of September the paralysis was general, the eyes half closed, the pupils dilated and unequal, and a temperature of 105°. The child died at three o'clock the same afternoon.

Fannie H., aged six, had been ailing for a week, and on the 25th of July was noticed to be very ill, with a temperature of 104°, a pulse of 120, with pain in the head, back, and legs. The next day all these symptoms were increased in severity. Petechial spots appeared on the legs, and on the third day the paralysis of these limbs was complete. The next day the delirium was excessive, noisy, and continuous. The head was retracted, the pupils unequal, and the child was unable to swallow. The conditions grew worse, the paralysis became general, and the child died July 31st.

An infant boy who had been ailing for five days, with no special symptoms, on the 24th of July had a series of rapid convulsions, and in three hours died.

I was also able to see fifteen cases of children with slight digestive disturbance, but in all there were clearly marked nervous symptoms, but with no sequelæ. In others there was paralysis.

A. B., a Swedish child, four months old, was suddenly affected with indigestion and diarrhea, accompanied by a fever that continued for five days. The nervous tension was marked, and the child was fretful and restless. Suddenly paralysis developed in the right leg and continued for ten days, when complete recovery took place.

A. B., a boy, two years old, had an attack of acute indigestion, with marked nervous tension and general spasms. Under treatment with purgatives and sedatives the symptoms subsided ; in four days the child was well.

I will now set forth the cases of six adults, the ages being respectively nineteen, twenty-four, twenty-seven, thirty-five, thirty-six, and seventy years ; of these three died. In two the paralysis persists, and the man of seventy made a complete recovery.

G. E., thirty-six years of age, had for three weeks complained of lassitude, headache, loss of appetite, and nausea. On July 6th the headache was very pronounced and the prostration general ; there was a coated tongue, but no fever and no acceleration of pulse. On July 11th the pulse was normal as to

rate and quality, but there was a temperature of 101°; the patient kept about his ordinary employment, that of an undertaker, until July 15th, when he was confined to bed. Pain in the back was the predominant symptom, but it subsided under dry-cupping and suppositories of morphin. On July 10th the pain was relieved, but during the day paralysis of the lower extremities supervened, with an erythematous eruption. In the afternoon the fever rose to 103°, and the pulse to 85. Next day at 4 o'clock in the morning the lungs filled up, the temperature became normal, the pulse 130, and eleven hours later, with progressive heart-failure, the patient died.

B. J., a male, nineteen years old, complained of pain in the head and back, with a pulse of 100 and a temperature of 102°. The fever subsided on the fourth day, the pulse fell to 56, and all pain had disappeared. The right arm became paralyzed, and by the next morning the pulse was 38, the temperature 97°, and the extremities cold. Complete paralysis developed during the day, and in the afternoon the lad died.

A. E., aged thirty-five years, on July 28th developed the characteristic symptoms of cerebro-spinal meningitis, with headache, chill, nausea, vomiting, a temperature of 102°, and a full, strong pulse. The muscles of the neck became painfully stiff, with retraction of the head, and flexing of the trunk backward, with rigidity of the muscles. This condition remained for a week, when a convulsive storm passed over the patient, and in two hours she was dead.

A. H., an adult male, aged twenty-four years, was affected on the 12th of July, the temperature being 100°, the pulse 65. In forty hours these symptoms subsided; then there was retention of urine for thirty-six hours, followed by complete paralysis of both legs, which still continues.

A. F., aged seventy, on the 4th of August was affected with severe pain in the lumbar region, high fever, nausea, and vomiting. This condition prevailed for thirty hours, then the temperature fell to normal, and the pulse to 58, accompanied by partial paralysis in the legs, which passed off in a week.

E. G., a female, twenty-seven years old, on July 8th complained of intense frontal headache, with painful neck and back. The temperature was 100°, the pulse 58, and without further symptoms the arms became paralyzed, but gradually recovered.

On the 10th of July a son of this woman was affected with pains in the head and back, a temperature of 104°, and a pulse of 130. After twenty-four hours the legs became paralyzed as well as the left arm, but they were restored to their normal condition in three days.

Notes upon a group of five cases follow:

1. A French boy, on June 26th was seized with slight fever, delirium, and constipation lasting for three days; then paralysis of the left arm and left leg ensued, lasting twenty days, followed by recovery.

2. An Irish girl, on June 26th had general symptoms as in the preceding case, with paralysis of the left lower extremity, which still continues.

3. An American girl, had on July 4th a fever of 105°, lasting for ten days, followed by paralysis of the lower extremities lasting two weeks, and ending in recovery.

4. An American girl, on July 5th had the initial symptom of double vision and loss of accommodation, with nausea and vomiting, but no fever. Paralysis of the left arm and left leg still persists.

5. A French boy, had fever for six days, and paralysis of the lower extremities, which still persists.

I now present notes upon three cases:

1. The patient was five years of age, and had fever, nausea, vomiting, but no eruption and no affection of the special senses; paralysis of the upper part of the right thigh still persists.

2. A child of one year, had on July 28th the first symptom, hyperesthesia, lasting for forty-eight hours; then nausea, vomiting, fever, paralysis of the right leg and right arm, which still persists, though somewhat improved.

3. On August 4th a child one year of age had the same general symptoms, with paralysis of the right arm, which remains permanent.

I add notes upon four more cases:

1. On August 1st a child was seized with fever, nausea, and vomiting, lasting for three days, when the temperature became normal and the pulse 60. Paralysis of the right leg and right arm ensued, persisting for two weeks, and then clearing up.

2. On August 3d an adult male, aged thirty-six, had pain in the back, a pulse of 110, a temperature of 102°, with paralysis of the left arm; recovery was complete in two weeks.

3. On July 13th a brother and sister had fever, pain in the head and back, lasting three days, with paralysis of the right arm lasting ten days, followed by recovery.

In four cases, all of which occurred in July, the ages being one, six, thirteen, and fourteen, the paralysis was in the lower extremities; retention of urine occurred in two cases, and paralysis still persists.

In two cases occurring on June 20th and July 3d the children were one year and nine months and two years and seven months old respectively. The general symptoms were fever, nausea, vomiting, diarrhea for four days, with slight skin-symptoms. In one case the right arm was rendered wholly useless, and the left arm and left leg partially so; in the other case the paralysis affected both legs. In the latter case the condition persisted for five weeks, but in the former it is permanent in the right arm and shoulder and in the left shoulder and upper left arm.

In nine cases that occurred between July 15th and August 15th the ages of the children were be-

tween one and five years. In all there were eruptions on the skin and a temperature ranging from 101° to 104°, and lasting from two to five days. In only two cases was the eruption extensive, and in no case was there desquamation. The paralysis was confined to the lower extremities, and involved chiefly the extensors and abductors, but was never complete; hyperesthesia was present invariably. In six cases recovery took place, and in the other three improvement was noticed.

In ten cases occurring between July 5th and July 18th the ages ranged from eighteen months to four years; there was fever, but no convulsions and no affections of the special senses. The lower extremities in all cases were affected, and in three the condition is permanent, while some made a recovery more or less complete. In one case there was retention of urine.

In seven cases occurring during the month of June the ages ranged from a few months to nine years. The fever was slight, the temperature averaging 100°. In three cases there was a papular eruption, spasm of the facial muscles, and in all these were pains in the legs. The general eruptions persisted for a week, and were followed by paralysis of the lower extremities. None of the cases was fatal, and in all there are signs of improvement.

In eight cases occurring between the middle of July and the middle of August the ages varied between ten and thirty-five years. In two the paralysis was general, and the result was fatal. In two there were erythematous eruptions, in one convulsions, and all had fever.

I have given notes of ninety-one cases. By the most careful estimate I could make there had been in all one hundred and twenty persons affected.

The following table shows the results reduced to percentages:

Fatal cases	13
Recovered	25
Improved	30
Unimproved	32

The muscles in every marked case showed that the degenerative reaction to the constant current was increased. The muscles were variously affected. In some cases the whole arm was paralyzed, in some only the intrinsic muscles of the palm. But the combinations of the different groups affected were endless. After an exhaustive tabulation of groups I was unable to discover any combination that might be looked upon as the natural order of the paralysis. The deltoid was usually affected, but with it, or alone, were the supra-spinatus, infra-spinatus, triceps and biceps, the supinators and pronators, in endless combinations. In one case all the muscles of respiration were paralyzed and the breathing was abdominal. In the legs the extensor group was most frequently affected, and sometimes there was functional association. When the paralysis was partial the muscles below the knee suffered most, and when the condition of foot-drop was pronounced the muscles of the thigh would be found in good condition. The paralysis in every case was motor, and the only disturbance of sensation was hyperesthesia.

The distribution of the paralysis was as follows:

Left arm alone	2
Right arm alone	4
Both arms alone	2
Right leg alone	7
Left leg alone	20
Both legs alone	45
Left leg and left arm	8
Right leg and right arm	3
Both legs and left arm	2
Both legs and both arms	4
Right thigh alone	2

It would be hard to discover a region in which a disorder had less license to become epidemic. The whole district in which these cases occurred lies upon a series of terraces, and increased safety did not come with elevation. Indeed, four cases occurred on the very ridge of the Green Mountains at an elevation of 1500 feet. The line of dwellings in which these patients lived extended over half a mile, and the water-supply was different in each of the four cases, namely, from springs out of the mountains.

The infection during my inquiry was confined to a definite area of fifteen miles in length and twelve in breadth. The eastern limit was the range of the Green Mountains, but on the other three sides there was no natural boundary. The city of Rutland is in the center of the area.

I am convinced that the geologic formation of a district has much to do with the dissemination of disease. Country districts only remain healthy when the territory is enormously large for the number of habitations. When we approach the conditions of village-life we have as a rule the condition most suitable for the propagation of disease. The natural drainage of the soil is of the highest quality but of the most limited capacity, and when once there is an infected focus the very excellence of the drainage increases the danger. It is in the country, for example, that we have the most virulent types of diphtheria, scarlet fever, and typhoid. In the present case, though, I am unable to mark out any definite line upon which the epidemic has marched, I made a careful examination of the geologic conditions, which I wish to record for future reference should similar outbreaks occur in other localities. The region has great geologic interest on account of the faults and dislocations in the earth's crust and the profound breaks in the strata of the whole

district. The great St. Lawrence and Champlain fault, or the Great Appalachian, as it is sometimes called, culminates in this district. It extends all the way from Gaspe to Quebec City, and crosses the boundary at High Gate Springs, proceeding through Vermont to Alabama, where it appears to die out. This great fault, accompanied by numberless smaller ones, must form gaps and reservoirs into which contaminated waters can fall and become breeding-places and again burst forth in the most unexpected spots. It is not the surface-water alone that carries infection, as we know that spores are independent of sunlight and warmth. The whole region is full of springs, as most faulty districts are, and the gaps that yield water may just as likely receive it after it has drained through the surface-soil. Again, the ridge of the Green Mountains marks the eastern boundary of the infected area, and the further slope remains entirely free from disease and free from geologic faults. Again, this region has undergone in the past great metamorphoses, and as the physical agencies are still at work the chemic and physical reactions must affect the soil and water. Further than this one cannot go.

The data from which my conclusions as to the influence of climate are drawn are obtained from Mr. William Line, the observer at Northfield Station of the Bureau of Vermont, and from Mr. Mark Harrington, Chief of the Weather Bureau at Washington. The total rainfall for the months of June, July, and August amounted to only 6.58 inches, the amount for the same period of the preceding years being 11.95, 15.04, and 10.02 inches, or an average of 11.2 for the last forty-seven years.

The average temperature for the same period in 1894 was, 64.3°; 1893, 64.4°; 1892, 65.2°; 1891, 62.9°, or an average of 65.4° for the last forty-seven years, and the relative humidity was for 1894, 79.9; for 1893, 78.6; for 1891, 80.

The summer was dry and hot, the springs were scanty, and the surface water low. The observations in detail are:

Month.	Average temperature.	Relative humidity.	Rainfall.
June, 1891	61.4°	79	2.04
July, "	63.0	78	3.20
August, "	64.0	83	4.78
June, 1892	64.9	75	5.66
July, "	66 0	75	2 88
August, "	64.8	86	6.50
June, 1893	65.0	75	2 07
July, "	63.8	77	3.74
August, "	64.6	83	6.14
June, 1894	64.5	80.1	1.71
July, "	67.2	77.4	1.64
August, "	61.2	82.4	3.23

Neither overcrowding of habitation nor any of the evils usually accompanying or flowing from this condition were factors in the present case, as only in four families was more than one member affected. It was quite usual for children to sleep with those who were affected and themselves remain entirely free from the disease. No isolation was practised, nor would such precautions appear to be of the slightest value. Any statistics of the nationality of those affected would be useless, as the occurrence of cases was entirely independent of place of birth, and the population is intimately mixed. In one locality there are nearly a thousand men employed in marble quarries, many of them Italians, but in this large colony I found only two cases. Indeed, the brunt of the disease appears to have fallen on the purely rural portion of the community. Amongst the cases were found American, Swedish, Italian, French, Irish, and Jewish children.

Nor was anything discoverable in the domestic and personal hygiene of those attacked. The houses are all detached, and in many cases there was nothing in the nature of privy or cesspool found; neither had penury any part in the epidemic. The district is one of the most thriving in the United States, and has been settled for a century and a half. The food-supply and the milk-supply are above reproach, being drawn from the neighboring farms or from the farms on which the patients lived. The veterinary surgeons have remarked nothing unusual in the condition of the cattle; but twelve horses died of a malady about which the veterinary surgeon to whom I applied was unable to give any information. It was called cerebro-spinal meningitis. It is easy to reproach one with lack of zeal and scientific enthusiasm on account of scarcity of pathologic data, but in every case of death up to the present autopsies were refused, even though the most urgent efforts were made. The friends of the patients refused to have their objections overcome by persuasion, by appeals to their reason, or by love of gain, even by pressure and intimidation. But a malady extensive and fatal in its nature should not go unstudied, nor should its lessons be buried with the dead. One private person cannot accomplish much because of want of authority and want of facilities. Besides, no one person combines sufficient clinical skill and experience with bacteriologic knowledge and pathologic technique to deal adequately wilh a matter of soserious a nature. Instruments get out of adjustment, batteries fail, and sterile refinements are hard to preserve in a country district.

But the greatest difficulty of all is lack of authority. In the Province of Quebec, though we are an anomaly to the rest of the continent, we do much better. Before the recent session of the Legislature commenced the Board of Health took counsel as to what changes in law were necessary, but they found that the authority as existing was absolute. The

board may examine under oath and compel witnesses to appear in the manner required by the Code of Civil Procedure, and perform autopsies when desired. In the State of Vermont there is an efficient Board of Health constituted under the act of 1886, but it had little more than advisory powers till 1892. Since then the board has power to promulgate more stringent rules and the authority to enforce them. The defect consists in this: there is no adequately equipped laboratory and no organized system of investigating such an epidemic as that in question. There is no authority that can supply the demand for autopsies, and without the information to be gained in this way, one is working largely in the dark.

In every State and Province there should be a complete equipment in staff and appliances for the investigation of disease, and one of the main purposes of this paper is to emphasize the necessity of such an institution, as well as to call attention to an epidemic so unusual in its occurrence, that, as I have said, it has not been noted before in this country.

I have confined myself to a statement of facts, and have purposely refrained from giving expression to any theories; that can be done more adequately in another place when the work in hand is at an end and the positive or negative value of the pathologic and bacteriologic results is obtained.

THE ATTENUATED BACILLUS TUBERCULOSIS: ITS USE IN PRODUCING IMMUNITY TO TUBERCULOSIS IN GUINEA-PIGS.

BY E. A. DE SCHWEINITZ, PH.D.,
BIOCHEMIC LABORATORY, BUREAU OF ANIMAL INDUSTRY, DEPARTMENT OF AGRICULTURE, WASHINGTON, D.C.

APPARENT IMMUNITY TO TUBERCULOSIS IN GUINEA-PIGS.

IT is well known that a number of the pathogenic bacteria decrease very greatly in virulence when cultivated for a long time outside of the animal body. This fact has also been noticed in the case of the bacillus tuberculosis, and the literature is full of references to the decrease in virulence of the tubercle bacillus and the way of securing this, but some facts have been developed in this connection in my work on tuberculin, in a new direction, which should be recorded.

Cultures with which I started several years ago were obtained through the kindness of Dr. Trudeau, of Saranac Lake, N. Y., and were the second generation on blood serum from a rabbit. After growing for several generations upon glycerin-agar, about two months to each generation, the culture was transferred to glycerin beef-broth, which was to be used as a source for tuberculin. After the fourteenth generation I noticed that the guinea-pigs that were always kept inoculated with tuberculosis, to test the tuberculin, did not succumb nearly as readily, and in the case of the fourteenth generation it required six months before the disease developed. I, consequently, inoculated a number of guinea-pigs with the seventeenth, eighteenth, nineteenth, and twentieth generations of this germ, which was alive and would grow very readily on the liquid media. Some of these pigs inoculated had previously been treated by an injection of tuberculin; the others had never been used. After some months those that had been inoculated with the attenuated germ remained quite well, and one was chloroformed, and the autopsy showed that it was free from disease.

In order to see if this might be accidental I then had nine pigs inoculated, four checks, four pigs previously inoculated with the attenuated germ, and one pig that had received tuberculin by feeding. These were all inoculated in the side with the material from the gland of a tuberculous cow that had just been killed. After seven weeks the checks were all found dead from tuberculosis. The other animals appeared perfectly well. One was accordingly chloroformed, and although very careful examinations were made no disease could be detected. Even the local lesion that was produced where the material had been injected had entirely healed. The animals were apparently immune.

Some experiments that had been made earlier with tuberculin prepared from a younger growth did not show that this material had a positive value in preventing disease, although it retarded it. As the preparation of tuberculin, however, continued, I noticed that the tuberculin was much more constant in reaction and that a larger amount of the active principle was yielded by cultures of the older germ.

At this time I had at the Experiment-station of the Bureau the calf of a tuberculous cow, which, however, although the mother was badly diseased, did not respond to an injection with the tuberculin. The calf was then drenched with 100 c.c. of a growing active liquid culture of this attenuated germ, the twentieth generation. After three months the calf was again injected with tuberculin, and, failing to respond, was killed. The autopsy showed the animal to be perfectly healthy.

Another healthy Southern cow received into a vein an injection of the same generation from this liquid culture, in July. On November 20th this animal, which was rather thin and had an initial temperature of 103° F., was injected with tuberculin, but did not show any reaction. Another animal known to be tuberculous, injected at the same time, with the same-sized dose of tuberculin, showed a good reaction. The cow which had received the

injection of attenuated culture had a small lump, the size of an egg, on the side of the neck, where inoculated. The diagnosis of no tuberculosis, as based upon failure of reaction to tuberculin, will be confirmed or disproved by an autopsy later. These experiments were kindly made for me by Dr. Schroeder.

So far as I have been able to find, the first note of successful cultivation of the tubercle-bacillus upon liquids free from albuminoid matter was made by myself in the *New York Medical Journal* of March, 1893. Since then Uchinsky, Proskauer, and others have used similar media. None has, however, reported a better growth than that obtained by a slightly modified form of the original culture-medium. It required some time until I could persuade the germ to grow in this liquid, but after considerable coaxing it will now multiply as well here as on glycerin-peptonized beef-broth, the fourth generation having become accustomed to the change of food.

The formula that I have found eminently adapted and used may be repeated here:

Water	1000 cc.
Glycerin	70 grams
Acid pot. phos.	1 gram
Ammonium phos.	10 grams
Sodium chlorid	10 "
Asparagin	3 "
Magnesium Sulphate	0.2 gram

After a certain amount of growth has appeared in a definite volume of media the growth will entirely cease. The germ has exhausted the supply of nutritive material or eliminated enough poison to check its own development, and, although the germs may still float on the surface of the liquid, after from three to four months there is practically no growth in the liquid. Further, there is a distinct and peculiar odor generated in the culture-media. This is due to a fatty acid which is difficultly volatile with steam. The reaction of the media when inoculated is slightly alkaline. As the growth increases it becomes less so, and finally it is acid in reaction.

In order to see if the apparent loss of virulence of the germ might be due to some of its products contained in the body of the germ, two guinea-pigs were inoculated with the twenty-third generation of the germ, after the germs had been carefully and thoroughly washed with sterile water to remove all products. These pigs, after two months, are still well. The bacillus grown on purely artificial media might naturally be supposed to be still more attenuated than that grown on the ordinary culture-liquid. To test this, some of these germs were used to inoculate guinea pigs, with the same results as those already noted.

In the case of a disease like tuberculosis, in which the incubation-period is often an exceedingly long one, there is a possibility that what now appear immune animals may in time succumb. In view of the fact, however, that all of the checks died so promptly, so long a time has elapsed since, and that all the other animals remained well, it is fair to presume that we have here a true immunity secured by an attenuated germ.

The following notes give the experiments in detail, and in the table they can be noted in a comprehensive form.

The autopsies are not given in full, as they appeared superfluous.

January 18, 1894. Guinea-pigs, Nos. 27, 28, 29, and 30, about three-quarters pound weight each, were inoculated with an emulsion of an agar-culture of tuberculosis, receiving 0.25 c.c. each, in the thigh. This was the eighteenth generation of the particular germ. On February 13, 1894, No. 27 was used to test some tuberculin, and gave a good reaction, although apparently in good health. February 15, 1894, No. 28 was found dead, but the autopsy did not reveal any signs of tuberculosis. No. 27 was found dead on March 19th, two days after it had been fed a large amount of tuberculin. The autopsy did not reveal the presence of any tuberculous lesions. Nos. 29 and 30 were subsequently, within six months, chloroformed and examined, but no signs of tuberculosis were apparent.

February 16, 1894. Healthy guinea-pigs, Nos. 115, 113, 128, and 127, were fed varying doses of tuberculin, from 3 c.c. to 12 c.c. Nos. 127 and 128 succumbed to the feeding, but this proved to be due to the glycerin with which the tuberculin had been mixed.

On March 30, 1894, Nos. 114, 115, 113, 109, and 112 were inoculated with 0.1 c.c. of tuberculosis emulsion from the seventeenth generation of a liquid culture. June 5, 1894, No. 115 was chloroformed, but the autopsy did not reveal any signs of the disease. October 1, 1894, No. 114 was found dead outside of the cage; it had been killed by the rats and the head was badly eaten. The animal was in good condition and fat, and the autopsy did not reveal any signs of tuberculosis. There was a little thickening of the skin and a small non-tuberculous lump at the point of inoculation.

During April and May, Nos. 113 and 112 were fed on three different dates with small doses of tuberculin, but did not show any reaction. Both of these pigs are apparently in good health and entirely well at the present writing, eight months after inoculation. During this time guinea-pig No. 109 had been chloroformed, September 29, 1894, and examined without any signs of disease being apparent. The seventeenth generation of this germ was evidently too attenuated to cause death.

April 4, 1894. Guinea-pig No. 110 was fed with 9 c.c. tuberculin, diluted with sterile water without ill effect.

February 19, 1894, pig No. 122 was inoculated with 0.25 c.c. of tuberculosis culture, the seventeenth generation, and on April 4, 1894, was fed with 25 c.c. tuberculin. The pig was rather thin;

there was a lesion the size of a pea at the point of inoculation, but the temperature was normal. April 9, 1894, this pig, No. 122, was found dead. The organs were apparently normal, except that the bloodvessels of the stomach and intestines were much congested. The pig had evidently been poisoned with the tuberculin; the contents of the intestines were thick and mucus-like.

February 19, 1894. Guinea-pig No. 121, weight 13 ounces, was inoculated with 0.25 c.c. tubercle culture. May 16th it was well and was reinoculated with 0.25 c.c. tubercle culture.

February 19, 1894. Guinea-pig No. 118 was inoculated with 0.25 c.c. of tubercle culture, the seventeenth generation. March 19th, this pig was found dead, but the autopsy did not reveal any signs of tuberculosis.

February 19, 1894. Guinea-pig No. 119, weight 14 ounces, received an injection of 0.2 c.c. tubercle culture, and on March 24, 1894, an injection of 0.5 c.c. of tuberculin. The temperature-reaction was very slight.

February 19, 1894. Guinea-pig No. 120, weight 14 ounces, was inoculated with 0.2 c.c. tubercle culture On April 4, 1894, it was fed 3 c c. of tuberculin. At this time it appeared to be ill, but did not show any reaction to the tuberculin, and the next day was quite well.

February 19, 1894. Guinea-pig No. 125 was inoculated with 0.25 c.c. tubercle culture. March 24th it received an injection of a small quantity of tuberculin, which caused a characteristic reaction.

March 8, 1894. Guinea-pig No. 141, three-quarters of a pound in weight, was given 18 c.c. of dilute tuberculin.

March 8, 1894. Guinea-pig No. 142, healthy, was fed 27 c.c. of tuberculin, but did not show any reaction. April 11, 1894, this pig was dead; the lungs were hemorrhagic, and the bloodvessels of the stomach and intestines much congested from tuberculin-poisoning.

March 12, 1894. Guinea-pig No. 136, healthy, was fed 12 c.c. of tuberculin.

May 16, 1894. Guinea-pig No. 135, weight one pound; guinea-pig No. 141, weight one pound; and guinea-pig No. 136, weight one pound, all received 0.25 c.c. tubercle culture, the twentieth generation. Guinea-pig No. 137, weight one pound, received 0.5 c.c. of the twentieth generation of tubercle culture. Nos. 141 and 136 had both been fed tuberculin once, the others had never been used.

July 27, 1894. Guinea-pigs Nos. 210 and 211, weight one pound each, received 0 5 c.c. of attenuated culture of tuberculosis, the twenty-second generation. At the present writing neither of these animals shows the least signs of tuberculosis.

July 29, 1894. Pigs Nos. 135, 136, 120, 110, 141, 125, and checks, healthy pigs, Nos. 213, 214, 215, and 133, were all inoculated for me at my request by Dr. V. A. Moore, with the material from the tuberculous gland of a badly-diseased cow, No. 286. The inoculations were made beneath the skin of the side. On September 11th checks Nos. 214 and 215 were both found dead, and the autopsy revealed extensive tuberculosis in lungs, liver, and spleen. September 21st, check No. 213 was found dead, the autopsy showing advanced tuberculosis. September 17th, guinea-pig No. 133 was chloroformed for examination, which revealed extensive tuberculosis.

October 13, 1894. Guinea-pig No. 136, one that had been inoculated in May with the attenuated culture, and subsequently inoculated with a tuberculous gland, was chloroformed for examination. Not a sign of disease could be detected and the local lesion from the inoculation had almost healed.

October 29, 1894. Guinea-pig No. 110 was found dead. This was a pig that had been fed upon tuberculin on April 4, 1894, and inoculated with the gland July 29, 1894. The autopsy showed advanced tuberculosis. The other pigs that had been inoculated with the attenuated culture and then the active virus, Nos. 135, 120, 141, and 125, are, at the present writing, quite well, and show no signs of disease. I may find that some of the animals that are now considered immune will eventually succumb to the disease. This, however, does not appear probable, as pig No. 136, examined after the death of all the checks, did not show any signs of disease.

Further, animals No. 137, inoculated with the twentieth generation May 16th, and No. 112, inoculated March 30th; Nos. 120 and 119, inoculated February 19th; No. 113, March 30th; and No. 121 on February 19th, and again on May 16th, are, at this writing, to all appearances perfectly well, having lived from six to nine months after the inoculation.

February 23d, rabbit No. 141 was inoculated with 0.25 c.c. of tubercle culture of the seventeenth generation. July 27th, this same rabbit was reinoculated with the twentieth generation of a tubercle culture, 0.25 c.c. being used. Still the animal is apparently well.

These experiments which, of course, in connection with so important and troublesome a disease, can be regarded as preliminary only, and must be confirmed by a large number of similar ones, serve to show that by the use of attenuated tubercle-bacilli and their products we may be able to control pulmonary tuberculosis. If the twenty-second generation has shown such attenuation and produced so much resistance, then the thirtieth generation, or later, should give still more satisfactory results.

An examination of the table and accompanying notes will also show that tuberculin, when fed in very large doses to supposedly diseased or to healthy pigs, may cause the death of these animals by poisoning. The amount necessary varies from twelve to twenty times the quantity that would give a reaction in a tuberculous cow.

The digestion-experiments referred to in my report, in *Bulletin No. 7, Bureau of Animal Industry, Department of Agriculture,* have shown that the action of tuberculin upon diseased animals is not affected after twenty-four hours in a hydrochloric-acid pepsin-solution, nor by warming with acetic acid. On the other hand, in two cases noted, feeding the tuberculin in small doses, while it did not

prevent the disease, apparently retarded it. Possibly a combined feeding of tuberculin and the inoculation with the attenuated germ may be found more useful than either alone.

The fact must not be lost sight of that the number of bacilli injected into an animal may cause great differences in the length of time of the development of the disease. There could be no error of this sort, however, in the experiments recorded, as the emulsion of virulent and attenuated cultures used for inoculation were prepared in the same way, and a larger quantity of the attenuated culture was used than is necessary in case of a more virulent one to produce death, in five to six weeks.

What conclusions may be drawn from these experiments? We have guinea-pigs made apparently distinctly immune to an active tuberculous virus by the use of an attenuated germ. We have guinea-pigs in which a single injection of a small quantity of tuberculin increased, perhaps, the subsequent immunity secured by injection with the attenuated culture. We have other pigs the immunity of which has not been tested, it is true, by an active virus, but which were inoculated with the attenuated culture many months ago, and are still well, and in which an autopsy of other animals treated in exactly the same way and at the same time showed no signs of disease.

Recently Viquerat claims to have been able by means of subcutaneous injections of the serum of the ass, an animal naturally immune to tuberculosis, to effect cures and improvement in the disease in man. Our attenuated germ may possibly prove very valuable in checking or controlling tuberculosis in animals, especially cattle.

ZINC STEARATE IN THE TREATMENT OF ATROPHIC RHINITIS.[1]

BY JOSEPH S. GIBB, M.D.,
AURAL AND LARYNGEAL SURGEON TO THE EPISCOPAL HOSPITAL; INSTRUCTOR IN LARYNGOLOGY IN THE PHILADELPHIA POLYCLINIC.

CONSIDERATION of a disease so prevalent, so disgusting and so rebellious to treatment as atrophic rhinitis appeals at once to both the general practitioner and the specialist. Perhaps from a feeling of incapacity or of indifference these cases are often dismissed with general directions and a solution to use in an atomizer or as a douche. In consequence they migrate from one physician to another, often ultimately to fall into the hands of some one of the numerous charlatans that flock to our large cities. But with some little care and perseverance much can be done. It is with the view of recording my experience with a comparatively new drug that this paper has been prepared. The plan of treatment outlined commends itself because of its exceeding simplicity, and it is within the power of every one to apply. If, as seems probable, it merely arrests the destructive process and renders the patient comfortable and unobjectionable to his friends, it will have served us well. I have taken the liberty of prefacing my remarks with a few words on the nature and general management of the disease, feeling that by so doing the subject would be better elucidated.

The name atrophic rhinitis would imply an inflammatory condition with an atrophic element. When the cases come under our observation, usually there is rarely much of an inflammatory condition present, but there can be no doubt that the early history of these cases is one of inflammation. Bosworth[1] has clearly demonstrated, and I believe his views are accepted by a large number of rhinologists, certainly in the United States, that the disease is the successor of that affection in children in which there is a purulent or muco-purulent discharge from the nose, and named for this reason purulent rhinitis.

The atrophic element in a case is at once noticeable. Dilating the alae of the nose, we observe a roomy nasal chamber, the turbinates shrunken often to obliteration of the lower turbinate, and contracting the middle so as to give an unobstructed view through the nasal chambers to the posterior wall of the pharynx, a state incompatible with healthy function of the nasal chambers. We also observe these turbinate bodies, and especially the middle, covered by thickened crusts, which, upon removal leave a reddened surface and rarely an ulcerated spot on the mucous membrane. Before our investigation has reached this stage we are conscious of an all-pervading, disgusting odor emanating from the nose, which is likely to be increased on detaching the crusts. This has given rise to the name "ozena," a term which, while highly descriptive of one symptom, *i. e.*, stench, cannot be used as a synonym. Ozena simply represents a condition present in many cases of the disease, but not in all. The same condition is present in syphilitic and in carious disease, both of which are entirely distinct and will not receive consideration in the present article.

These two symptoms, the crusts and the ozena, give the keynote to the management of this intractable disease. When we obtain a clear conception of their production and can apply means for their permanent eradication we have solved the difficulty. In making this assertion I have not lost sight of the fact that several important physiologic purposes of the nasal chambers have been abrogated when this disease is well marked. Though a firm

[1] Read at the eleventh annual meeting of the New York State Medical Association, held in New York, October 10, 1894.

[1] Bosworth: Diseases of the Nose and Throat: the Nose and Naso-pharynx, p. 162.

believer in the rôle of the turbinate bodies in adding to the moisture of the respired air, so ably enunciated by Bosworth, and in their salutary office in filtering deleterious matters in the inspired air, and also cognizant of the important office of the nasal mucous membrane in secreting mucus, yet I cannot but believe that these offices can, in a measure, be compensated for, and indeed, as we shall see later, in studying the pathology of the formation of crusts, this must be accomplished if we are to meet with success in getting rid of the obnoxious symptoms.

To meet with success in the management of a disease we must have clear ideas of its pathology.

What is the pathology of the formation of crusts and its accompanying ozena? The limits of this paper forbid anything like a full consideration of this subject, and I will advert to points just sufficient to give us a firm basis on which to found our therapeutic measures. I have already stated that the primary stage of atrophic rhinitis is one of inflammation. This inflammation is of sufficient intensity to be attended with suppuration; succeeding it we have sclerosis or atrophy of the mucous membrane. The cavernous tissue of the turbinates and the glandular tissue are all involved in this process, so that ultimately there is little left covering the bones but the connective tissue, with a few glands whose function has become perverted from the contraction to which they have been subjected.

What is the effect of this sclerotic process on the physiologic purposes of the nasal chambers? The venous channels within the cavernous bodies, whose function it is to add moisture and heat to the respired air, are destroyed, and hence the air passes through the nasal chambers poorly prepared for its ultimate purposes. The large number of mucous glands contained in this membrane are also destroyed or perverted in their secretion to such a degree as to be totally inefficient for the purpose for which they are designed.

With this knowledge of the pathology, we are able to give the most plausible explanation of the crusts and the ozena. The glandular secretion being denied, the large admixture of water which is normally present contains a large proportion of solid matter, which collects on the turbinates and undergoes decomposition or fermentation, and hence the odor.

With this view of the causation of the two essential elements of atrophic rhinitis before us we should strive to adopt measures of treatment looking to the restoration of these functions. The first step should be the entire removal of all crusts from the mucous membrane. Unless we are faithful and persistent in our efforts in this direction we cannot hope to meet with success. This is but a necessary prelude to the important step of bringing into contact with the diseased mucous surface medicaments of a stimulating nature, which will excite the perverted glands to secretion and perhaps aid in the regeneration of the mucous membrane. The method of accomplishing this object will vary with the operator; that is immaterial; the object is absolute cleanliness. The plan pursued at the Episcopal Hospital, Philadelphia, is about as follows:

The nasal chambers are sprayed thoroughly with an antiseptic detergent solution, after which all rebellious or adherent crusts are removed with a small probe, the extremity of which is wrapped with a pledget of cotton; as this process is likely to be painful, it is well to first prepare the sensitive mucous membrane by a preliminary spraying of a 4 per cent. solution of cocain. By this means also the cleansing is done more effectively. Should the crusts prove unusually tenacious in their attachment, or should a layer of muco-pus cover the turbinates, the cotton-tipped probe is dipped in a solution of hydrogen dioxid and the crusts or pus is dissolved away. This latter is succeeded by another spraying with the antiseptic fluid, to remove the dissolved and frothy mucus or pus. While this procedure will doubtless cleanse the anterior nares, there still remains a large surface uncleansed, viz.: the posterior surface of the turbinate bodies and the vault of the pharynx—the latter especially being liable to be the seat of inspissated mucus.

The post-nasal surfaces are probably better and more easily cleansed with the post-nasal syringe or by atomization. However, even in this locality the crusts are frequently so tenacious as to defy the usual methods with syringe or spray. In such cases they must be removed by means of a cotton-tipped probe bent at such an angle as to pass readily behind the soft palate and up to the vault of the pharynx. To effect this satisfactorily, and to avoid wounding the sensitive tissues of the upper pharynx and vault, and even the pharyngeal orifice of the Eustachian tube, full illumination with the aid of a rhinoscopic mirror should be employed.

I have dwelt thus on the details of cleansing, doubtless familiar to all present, to emphasize the fact that without it all subsequent treatment will be futile. Assured that our cleansing has been effective, we are ready to apply to the mucous surface our medications.

Compounds of zinc stearate have for their base zinc stearate, to which may be added any drug that the operator deems necessary for the case. They are dispensed as an amorphous powder, which has a saponaceous or oily feel when handled, and has a peculiarly strong adhesiveness to mucous surfaces. Drugs in powder-form have for many years been used in the treatment of atrophic rhinitis, but within

a few years past there has been a tendency on the part of rhinologists to discard them from their armamentarium. I think the reason for this has been the exceedingly limited time a drug in powder-form could be depended upon to adhere to the mucous surfaces, and hence the utter uncertainty as to the beneficial effect accruing therefrom. It has occurred to me that possibly whatever merit the compounds of zinc stearate possess is due to the tenacity with which they adhere to the mucous surfaces, and thereby exert an influence for a prolonged period.

The indications for treatment, as already stated, are that we shall have some drug of a stimulating nature for the purpose of exciting the perverted mucous glands to increased activity, and, if possible, aid in the regeneration of the destroyed tissue. Europhen[1] was the stimulant selected for incorporation with zinc stearate. After the cleansing process, a powder of zinc stearate, with europhen, 25 per cent., was blown into the nasal chambers with the insufflator, so that a thin layer of the powder was apparent over the middle and lower turbinates and the septum.

The observations in the use of this drug have extended over a period of a year-and-a-half at the clinic of the Episcopal Hospital, and they include fifty-four carefully selected cases, *i. e.*, those in which crusts were invariably present, and in the majority accompanied by ozena. All cases presenting simply an atrophic or rather sclerotic condition of the turbinates, unaccompanied by crusts or ozena, have been rigidly excluded, for the reason that they admitted of a doubt as to the diagnosis between the secondary sclerotic change of hypertrophic rhinitis and the disease in question. All of these cases were seen in dispensary service, a source admittedly difficult and unsatisfactory in making deductions or drawing conclusions.

As a matter of convenience and in order the better to study the results, these fifty-four cases have been divided into three classes: (1) Those that were persistent in treatment and faithful in attendance; of this class there were twelve. (2) Those that presented themselves at the clinic at irregular intervals, though seen at times over nearly the whole period of these observations, namely, eighteen months; this class numbered twenty. (3) Those that presented themselves but once or twice after the first treatment; these, numbering twenty-two, have been excluded from all deductions; therefore the observations may the more properly be said to cover thirty-two cases.

The treatment was employed twice weekly; in the interim of the visits, the patient was directed to use a hand-atomizer containing a solution of Seiler's tablets.

[1] Europhen: U. S. Dispensatory, 1894, p. 1628.

After the first cleansing and subsequent insufflation there was in all cases an entire absence of odor, and in the larger number this was persistent, no odor being perceptible upon any of the subsequent visits. It is quite evident to all rhinologists that simple cleansing is not sufficient to effect this result. In five of the most pronounced cases an odor was still perceptible at three, or at the most four, visits subsequent to the first cleansing and treatment, after which it entirely disappeared in the three that belonged to the first class; whilst in the two that fell in the second class, the odor, after the fourth or fifth visit, though still present, was markedly diminished, leaving me to infer that had the treatment been faithfully continued the result would have been the same as in the first class.

As to the crusts, in the large majority of cases no crusts formed after the first treatment; the appearance presented at the subsequent visits was that of a thin layer of muco-purulent secretion covering the turbinates, which became smaller and smaller in quantity at each subsequent visit until finally it disappeared, leaving the turbinates moist and free from the familiar dull, glazed appearance.

Whilst this was the general result, in the five cases noted as persisting in odor of an unusually rebellious nature the crusts adhered tenaciously; but even in these, after three or four insufflations, the three cases belonging to the first class showed a marked improvement. In two of the three the crusts, and finally the muco-purulent secretion, entirely disappeared, leaving the mucous membrane as already described. In the remaining one this thin muco-purulent secretion still persists, notwithstanding an amelioration of all other symptoms both subjective and objective.

In one of the two cases of the second class, or that of indifferent attendance, after an interval of nearly two months, in which time even the cleansing at home was continued in a very irregular manner, there was a reappearance of the crusts, but in no such number or of as great tenacity as when the treatment was begun; they were easily dislodged by ordinary spraying. In the remaining case of the second class, in which the cleansing at home had been carefully done, though attendance at clinic had been irregular, the crusts disappeared, though there is some muco-purulent discharge. In all the cases, after a few insufflations, the nasal mucous membrane presented an entirely different appearance, the dry, shrunken, lifeless membrane being replaced by a reddened, moist, and actively-secreting surface. In two of the cases in which the improvement was the most marked there seemed to be something like a regeneration of the turbinate tissue, though I am not prepared to admit that this is really the case; whilst there undoubtedly was an increase of tissue over

the shrunken turbinates, this has not assumed the appearance of true cavernous tissue.

To sum up: In a total of thirty-two cases of atrophic rhinitis that have been under observation, the shortest time being two months, the longest eighteen months, there were twenty-seven in which there was a complete disappearance of crusts and odor, and two of these cases promised a restoration of normal functions and structure. In five the results are very doubtful, though the improvement is sufficient to promise more for the future.

What is the rationale of this treatment? The first thorough cleansing enables us to apply a stimulating preparation for a long period of time to the mucous surfaces, thus exciting the remaining mucous glands to increased activity, throwing off larger quantities of water, which, bathing the tissues, prevents the formation of crusts and the consequent odor. It may be said that by thorough cleansing we accomplish all that is claimed for this treatment. I have never seen, even when the utmost care has been observed in cleansing both by the physician and by an intelligent patient, such thoroughly clean nasal chambers as after a few weeks' treatment of combined cleansing and application of compounds of zinc stearate. Again, while it is true that thorough and persistent cleansing removes all odor, and, in a measure, all crusts, there still remains that dry, unhealthy, glazed mucous surface; and here, to me, is the most noticeable beneficial change.

Whilst subjective symptoms play a very unimportant rôle in making up our prognosis in this disease, it has a most important bearing in the mind of the patient. The testimony of those who have pursued this treatment is the same—that it is followed by great relief of the feeling of fulness and dryness and other uncomfortable sensations about the head and throat, and that this persists nearly up to the time for the next treatment. I firmly believe that were there not some relief to the feelings of the patient we would not have had among fifty-four cases even as many as twelve to return each time, and twenty more to return at intervals.

These insufflations have been made twice a week. It has occurred to me that perhaps a more frequent, say daily, use would produce results more promptly and of more lasting character. It could easily be accomplished with intelligent patients by first instructing them as to the method of cleansing by means of the atomizer, to be followed by blowing the powder into the nostrils. The method of Ingalls,[1] of Chicago, commends itself to me to accomplish this latter maneuver.

It cannot be claimed zinc stearate is specific; indeed, it is too early to even assume that it is of real benefit; all that can be said is that the trial justifies a continuance of the plan and a further study as to the permanence of the effects. There may be other methods just as serviceable, but to me this has rendered the best service because of its simplicity of application, its effectiveness in relieving the distressing symptoms, and the comfort that it seems to induce.

CLINICAL MEMORANDA.

A LARGE ROUND-CELL SARCOMA OF THE UTERUS.

BY JOSEPH McFARLAND, M.D.,
DEMONSTRATOR OF PATHOLOGICAL HISTOLOGY AT THE UNIVERSITY OF PENNSYLVANIA, PATHOLOGIST TO THE KENSINGTON HOSPITAL FOR WOMEN.

IN the summer of 1893 I received from Dr. Charles P. Noble, Surgeon-in-Chief to the Kensington Hospital for Women, some fragments of tissue removed with a curet from a case diagnosticated as sarcoma of the uterus, with the request that I would submit them to careful microscopic study, to determine their nature and establish their malignancy. Knowing that sarcoma of the uterus is a much more rare affection than is generally conceded by gynecologists, and hoping to discover an interesting case, I imbedded, cut, and carefully examined, several of the largest fragments. Disappointment followed, for the tissues were found to be fibrous instead of cellular, and were in a state of universal myxomatous degeneration. With the exception of an occasional leukocyte, small hemorrhagic areas with well-preserved erythrocytes and a few muscle-cells, the entire structure of the tissue-constituents was destroyed. There was no clinical question of doubt as to the existence of a tumor of the uterus, but of its nature nothing could be determined from an examination of the removed masses. Satisfied that there was nothing malignant in what had been sent to me, and recognizing the condition as one quite common in sub-mucous fibroids of the uterus, I rendered my opinion that *there was no malignancy in the case, but that the patient in all probability suffered from a sub-mucous fibroid which was ulcerated and degenerated.*

This opinion made very little difference in the treatment, for, when after appropriate topical measures, the condition was found to grow worse rather than better, Dr. Noble removed the whole uterus.

When I opened the uterus by an anterior incision extending from the cervix to the fundus, a large, ragged, ulcerated tumor—unquestionably a fibroid—was found projecting from the superior posterior surface into the cavity of the organ. It was circumscribed everywhere except at its broad pedicle, which was very intimately attached to, indeed almost continuous with, the uterine wall.

[1] . . . "By means of a glass tube, about four inches in length, with a caliber of about one-eighth of an inch, which is attached to a rubber tube, through which the patient blows the powder into his nose. The glass tube is disconnected from the rubber; its round end moved about in the powder until it is filled up about one-quarter of an inch; the same end is then reintroduced into the rubber tube, and the flattened end of the glass tube introduced into the nostril. The patient then places the other end of the rubber tube between his lips and gives a quick, strong puff, which forces the powder into the naris."—*Journal of the American Medical Association*, Sept. 15, 1894, p. 424.

After careful macroscopic examination I reported that the examination of the gross specimen confirmed the microscopic diagnosis and that the specimen was one of fibroid tumor.

The later history of the case is best described in the following letter:

PHILADELPHIA, December 21, 1893.

DEAR DOCTOR MCFARLAND:

Perhaps you will recall a specimen from a case of sarcoma of the uterus which I sent you last summer. You reported to me that the patient had a myxomatous degeneration of a fibroid tumor, and that it was a perfectly benign growth.

I removed the entire uterus upon the diagnosis of sarcoma, and will herewith give you the history of the patient since the operation. She promptly recovered, and remained well until about six weeks ago, when pain developed in her right chest. Consulting her family physician, she was told that she had water in her chest. Shortly after this she was obliged to go to bed. Her respiration was profoundly embarrassed. The chest was aspirated, but only about a pint of blood-stained serum could be removed, and apparently there was no more fluid in the chest. She was very slightly relieved by the operation. At this time several small tumors, one under the skin of the breast, another under the skin of the loin, and a third under the skin of the thigh, appeared.

About two weeks ago I saw her after she had been ill for some five weeks. She was breathing eighty times per minute, and her pulse was so rapid that one could scarcely count it. There was absence of respiratory sounds from over the front of the chest, and evidence of consolidation of the lung over the back of the chest, on the right side. She refused further interference and died about a week later. No post-mortem examination could be obtained.

Kindly let me have your opinion of the case. Was it carcinoma or sarcoma? The evidences of malignancy seem clear to me, as at no time was there any rise of temperature to account for the fluid in the chest upon the supposition of an ordinary pleurisy or of a tuberculous pleurisy. The fluid cannot be accounted for either on the ground of disease of the heart or kidneys, as these viscera were healthy. The appearance of the small tumors in the fatty connective tissue under the thigh and the solid enlargement in the right chest, all point to malignancy. Truly the problems confronting the surgeon are difficult of correct solution in every case, and it is very interesting to have the pathologists with whom to compare notes. I think that after a time each will have a greater respect for the difficulties presented to the other in his work. . . . .

Very sincerely yours,

CHARLES P. NOBLE.

The unexpected course and termination of this case suggested to me that the malignant disease was situated elsewhere than in the uterus. As no autopsy was allowed, the only organ which was at hand for examination was the uterus; and though satisfied that the tumor which it contained was a fibroid, I decided to make a careful study of it. A vertical section was made through the entire tumor, a thin slice removed, and after imbedding in celloidin, large topographical sections (1 x 1½ inches in size) were cut, stained with Delafield's hematoxylon and subjected to careful microscopic study. The appearances were as follows: The edge of the section representing the surface that had projected into the cavity of the uterus was found to be denuded of epithelium, to contain no endometrial glands, but to be incrusted with a mass of coagulated blood and degenerated tissue which had been the source of the fragments first sent for examination and study. Here and there this surface-coating was interrupted by a fissure of considerable size which ascended for some distance into the tumor, and terminated in the lymph-spaces. These fissures were the separations between the tissue-bundles making up the tumor. The tumor-substance was of unstriated muscle-tissue mixed with considerable fibrous connective tissue (myofibroma), and was perfectly typical near its attachment, though inclined to be hemorrhagic and myxomatous at the exposed surface. Whether the exposure of the surface was due to the ulceration of the tumor through the endometrium, or to the damage done by the curet, was not possible of determination. As far as has been described, the tumor was an ordinary fibroid. If one began to study the lymph-spaces of this tumor at one of the fissures upon the surface, and gradually ascended into its substance, a rather remarkable series of cellular constituents became visible. As the description of the changes will follow more naturally in a description beginning above and gradually descending, I shall follow that order.

Scattered through the substance of the tumor there were occasional patches, at first sight suggesting small inflammatory areas, consisting of very uniform, small round cells, not arranged with any regularity, but extending indefinitely into the surrounding lymph-channels, only moderately infiltrating the tissue. Where the larger lymph-spaces began to enter the sinuses extending from the surface of the tumor into its substance, it could be determined that these round cells bore a definite relation to these sinuses, in some places accumulating so as to blockade them, in others forming thick marginal linings; in still other places the cells did not appear to occupy the spaces; but formed masses in their close proximity. As the lymph-spaces and channels were followed through the tumor to the sinuses upon its surface, it was evident that this cellular development was a change common to most of them, and extending over a considerable part of their length. While the small cells near the interior of the tumor were about the size of leukocytes and much like them in appearance, their size and appearance changed so that they became larger, and they occasionally presented two, three, or four, or even five nuclei, and in many instances assumed much the appearance of epithelial cells. Between the small round cells and the large multinuclear cells a great variety of transition-stages could be traced. In certain areas in which these large cells were subjected to lateral pressure the appearance of columnar epithelia was suggested. It is not possible, however, that the cells could have had such a parentage.

As the cells were carefully observed in descending from the interior to the surface of the tumor, a peculiar degeneration of the protoplasm of the cells was evident. This caused a greater bulk of protoplasm, an abnormal transparency and a viscidity which allowed the coalescence of neighboring cells and the formation of giant-cells, and even at the lowest points of protoplasmic nucleated masses such as were described by the older pathologists as "nucleated protoplasm." This degenerated protoplasm tinged well with eosin and was quite characteristic of that called *hyaline*. At the very surface of the tumor the destruction of the cells was so great that their

detritus, together with the myxomatous degenerated fibers of the tumor and the extravasations of blood, formed a common coagulation-necrotic mass.

The examination of the cervix and walls of the uterus showed no important changes. Many of the cellular extensions passed from the tumor into the fundus of the uterus, but high up the changes were inconspicuous and the number of cells small.

The peculiarities of the case were marked. The inference, which seems justifiable from the careful research to which the specimens were subjected, seems to point to a primary change in the lymph-channels with the hyperplasia of the endothelia and connective-tissue cells associated with them, and the production of a tumor at least similar to that variety of sarcoma called *endothelioma*. Added to this there were degeneration and the production of monstrous cells. The gaping sinuses and large lymph-spaces connected with them suggest the easy passage of these cells through the lymph-circulation of the uterus, their entrance into the general circulation and the consequent production of the metastatic tumors which caused the death of the patient.

It should also be observed that the amount of sarcomatous tissue in the tumor was small, so that the metastasis originated in all probability from what would have been regarded as an almost insignificant lesion had not such disastrous consequences followed its development. The case also illustrated the changes, so little understood, by which a perfectly benign tumor may change to a malignant one.

DYSPNEA AFTER EXCISION OF THE TONSILS.

BY GEORGE WALKER, M.D.,
OF YORKVILLE, S. C.

EXCISION of the tonsils when properly performed is generally considered an easy operation and devoid of danger. I have lately had a case that deviated somewhat from the general rule.

The patient was a stout, well-developed female, twenty-two years of age, who had every appearance of being in perfect health. She was only slightly nervous at the beginning of the operation.

The tonsils were considerably enlarged from repeated inflammations. The throat was sprayed with a 4 per cent. solution of cocain. The left tonsil was then excised by a good tonsillotome; the operation was easily performed, and with very little pain. In a few minutes the patient said she felt sick and very faint, but these symptoms passed off in a little while. The other tonsil was then cut away in the same manner without difficulty, and without much pain. The whole of both tonsils was taken out. The woman again complained of faintness and sickness, but there was no vomiting. As these symptoms did not pass off as before, she arose, walked to the bed, and lay down. Shortly after this I noticed that her respirations were difficult, and she said that she was choking. On close examination the trouble seemed to be due to spasm of the respiratory muscles; her arms and hands began to cramp, the fingers assuming a claw-shape. The breathing became still more difficult. She rolled from side to side on the bed, her hands clutching her throat; she gasped for breath, and said in a husky voice, "I am choking—I am choking to death!" The face was very red, the pulse somewhat quickened, but regular and strong.

The symptoms increased in gravity; the respiration got still more difficult, shallow, and jerky, and finally ceased entirely. The head was lowered and artificial breathing was begun. In a short time the respiration came back, but it was of the same hard, difficult nature; it continued thus for about forty minutes, and in spite of all efforts ceased again; it was an entire stop, and I was certain that she was dead. We again commenced artificial respiration vigorously, and after prolonged efforts she gave a jerky breath; I stopped a moment and told her to breathe. She did so, then ceased. I told her again, and she did so. By continuing the artificial respiration and telling her in a loud voice to breathe, breathing was finally established, though still somewhat hard. It gradually got easier, and remained so. She came to herself, asking her whereabouts and what had happened, seeming to have no recollection of anything except her throat being sprayed the first time. I think the trouble was caused either by irritation of the respiratory nerves or by toxic action of cocain, most probably the latter. As stated, only a 4 per cent. solution was applied by means of an atomizer. None was injected, and the woman was directed to swallow none. I have knowledge of a case occurring in the practice of a medical friend in which similar symptoms were produced by hypodermics of a 10 per cent. solution of cocain preparatory to the removal of a lipoma.

MEDICAL PROGRESS.

Sub-diaphragmatic Abscess Communicating with the Right Pleura Successfully Treated by Costal Resection and Drainage.—At a recent meeting of the Clinical Society of London, MACKENZIE and ABBOTT (*Medical Press and Circular*, No. 2895, p. 453) reported the case of a boy who came under observation in the fourth week of an illness of sudden onset and characterized by severe pain in the epigastrium and right hypochondrium, together with vomiting. A week after the onset a swelling was noticed in the epigastrium. The right side of the chest yielded the physical signs of a pyo-pneumothorax. The swelling in the epigastrium became more prominent when the patient sat up or coughed, and gave distinct evidence of fluctuation. It was concluded that there existed a sub-diaphragmatic abscess communicating with the right pleural cavity, and it was decided to drain both by an opening in the pleura. Accordingly the sixth rib was resected just behind the mid-axillary line, and thirty ounces of exceedingly offensive, thin, watery pus, containing some flakes, were evacuated. On exploration with the finger the upper surface of the liver was felt through an opening in the forepart of the diaphragm. The whole cavity was well irrigated with a warm boric-acid solution, and a double drainage-tube was inserted. The cavity was irrigated daily, but the discharge continued to be offensive for several days. On the thirty-fifth day after the operation the wound was almost healed and there was no discharge. The patient was dismissed on the forty-seventh day. The lung expanded well, and the only sign to be detected six months later was a slight relative dulness at the base of the right side of the chest. The presence of air as well

as fluid, together with the fetor of the abscess, pointed to the perforation of an air-containing viscus, most probably as a result of gastric or duodenal ulceration.

Femoral Epiplocele in a Woman; Radical Operation.—At a recent meeting of the Section on Surgery of the Philadelphia College of Physicians, Dr. W. J. Taylor reported the case of a woman, forty-six years old, who for twelve years had a lump in the right groin which gave no trouble until about four or five months before coming under observation, when it enlarged and became very painful. She was in the country at the time, and went to bed and applied poultices to the swelling. In a few days she was much improved, the pain and swelling relieved, but the mass did not disappear entirely. There was a good deal of swelling above Poupart's ligament and in the inguinal canal on the right side. There was some doubt as to whether it was a new growth or a hernia. With rest in bed and care the amount of inflammatory thickening was very much reduced An incision over the tumor, exposed a very hard tense sac, which was easily dissected away, and an omental hernia was found just above the internal inguinal ring. The sac was then opened and the omentum drawn out until a healthy portion was reached, around which a ligature was passed and the mass removed. The sac was dissected free from adhesions and ligated with silk. The whole mass showed evidence of long-standing inflammation. On closing the abdominal ring the mass was discovered to be a femoral hernia. The edges of the canal were approximated with two sutures, without injury to the artery; during the operation only one small vessel required ligation.

Perforation of a Typhoid Ulcer in a Young Child.—Schofield (*British Medical Journal*, No. 1763, p. 809) has reported the case of a boy one-and-three-quarters years old who presented failure of appetite, with vomiting, loss of flesh, abdominal distention, considerable diarrhea, and slight cough. These symptoms gradually increased in severity and led to a fatal issue. Upon post-mortem examination a few flakes of lymph were found between the coils of the intestine and about the liver and spleen. One of the lower coils of the small intestine was adherent to the front of the cecum, and between the two was a small cavity whose walls were completed by lymph. This cavity contained some fecal matter, and on further examination was found to open into the ileum about ten inches from its lower end, by a clean-cut perforation one-third of an inch in diameter, in a Peyer's patch. In the same patch was seen another small ulcer, and below this there were a dozen similar ulcers extending as low as the cecum, in which two ulcers were found. All of the ulcers were more or less circular, with sharp edges and smooth floors. There was no noticeable enlargement of the mesenteric glands. The spleen was soft and slightly enlarged.

Neuritis Simulating Progressive Muscular Atrophy, Associated with Nystagmus and Increase of Knee-jerks.—Moyer (*Journal of the American Medical Association*, vol. xxiii, 1894, No. 17, p. 647) has reported the case of a woman twenty-one years old who complained of progressive loss of strength and wasting of the hands and arms, of four years' duration, without previous injury or serious illness. At first there was much pain in the hands, which would dart up the forearm, together with numbness and tingling, but subsequently sensation became impaired. The hands were held in a claw-like, semi-flexed position, but there was no contraction of the flexor tendons. Fibrillar tremors were occasionally to be seen in the wasted muscles, which manifested the reaction of degeneration. Nystagmus was present, but the eye-grounds displayed no lesion. The patellar tendon-reflex was exaggerated on both sides, with prolonged ankle-clonus. The girl, who was a servant, was compelled to have her hands in cold water a good deal, and the wasting and weakness, as well as the sensory changes, were ascribed to a peripheral neuritis dependent upon this exposure. The nystagmus and exaggerated reflexes were attributed to associated disseminated sclerosis.

Myxedema Due to Actinomycosis.—Köhler (*Berliner klinische Wochenschr.*, No. 41, p. 27) has reported a case of myxedema in a woman forty-eight years old, who for eight months presented a swelling of the anterior aspect of the throat, at the outset attended with redness. It was stated that the swelling had been treated with poultices, in the sequence of which a discharge of blood and pus took place. Several surgical operations had been performed, but a slight suppurative discharge persisted. The ulcerated surface was curetted and the case appeared to progress favorably, but subsequently incision became necessary, and resulted in the evacuation of pus containing granulations characteristic of actinomycosis, and which upon microscopic examination disclosed the presence of this fungus. A free excision was made, exposing the partially destroyed thyroid gland. The wound was thoroughly curetted, and finally treated with the thermo-cautery. Granulations soon formed, and closure of the wound was expedited by skin-grafting. With the improvement in the local condition the symptoms of myxedema likewise receded. The portal of infection could not be learned. Reference is made to another case in which symptoms of myxedema were dissipated by anti-syphilitic treatment.

Myxedema in Children.—Northrup (*Archives of Pediatrics*, vol. ii, No. 11, p. 793) has reported two cases of myxedema in children, one in a girl nine years old, and the other in a boy twelve years old. In the first the symptoms appeared at the age of nine months, and from this period the child had scarcely developed, not only mentally but physically as well. Both were treated with a glycerin extract of sheep's thyroid, of which one dram represented one gland from a young animal. One minim of this was administered three times a day, the dose being increased one minim every second day until the temperature rose, the attempt being made to keep the temperature at a point just below 100°. In the first case the treatment was continued for eighty days, and was attended with diminution in the size of the tongue, improved expression of the countenance, ability to take more and varied food, and the acquisition of two teeth. In the second case the treatment was pursued for seventy-six days, and the improvement was more noteworthy.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—KÖRTE (*Berliner klinische Wochenschrift*, 1894, 46, p. 1039) reports the results obtained in the treatment of 121 cases of diphtheria with the antitoxin. He divided the cases into three groups: (*a*) severe cases; (*b*) cases of moderate severity; (*c*) mild cases. Of the whole number recovery ensued in 81 (66.9 per cent.), and death in 40 (33.1 per cent.); while from June, 1890, to December 31, 1893, among 1160 cases of diphtheria the proportion of recoveries was 54.9 per cent., and that of deaths 45.1 per cent. In the intervals between the periods of treatment with the antitoxin, at a time when none of the remedy was to be had, among 106 cases there occurred 49 recoveries (46.2 per cent.), and 57 deaths (53.8 per cent.) Considering 121 cases treated with antitoxin according to their severity, there occurred among (*a*) 43 severe cases, 41.8 per cent. of recoveries and 58.2 per cent. of deaths; among (*b*) 47 cases of moderate severity, 70. 2 per cent. of recoveries, and 29.8 per cent. of deaths; and among (*c*) 31 mild cases, 96.7 per cent. of recoveries and 3.3 per cent. of deaths. Fifteen of the cases occurred in children under 2 years of age, with 8 recoveries and 7 deaths. Tracheotomy became necessary in 42 cases on account of threatening dyspnea; of this number 20 (47.6 per cent.) recovered, and 22 (52.4 per cent.) died, as compared with 22.5 per cent. of recoveries, and 77.5 per cent. of deaths in previous years. Of 108 children under 2 years of age in whom tracheotomy became necessary between June, 1890, and March 31, 1893, 10 (9.2 per cent.) recovered; while of 8 within the same age-limits treated with the antitoxin, 3 (57.5 per cent.) recovered. Fourteen severe cases came under treatment within the first three days of the disease. Of these 11 recovered, while 3 died. In 29 others the treatment could not be instituted earlier than on the fourth day. Of these but 7 recovered, while 22 died. Twenty-three cases of moderate severity came under treatment within the first three days of the attack. Of these 18 recovered and 5 died. Twenty-two others did not come under observation until after the fourth day. Of these 14 recovered and 8 died. In the one mild case that terminated fatally diphtheria-bacilli were not found in the exudate. It appeared that in some cases general intoxication took place so rapidly as to render useless the employment of the antitoxin when the cases came under observation. It also appeared as if the results were better when the initial small dose (200 immunity-units) was increased. In the fatal cases death was due to causes over which antitoxin was capable of exerting no influence. Nephritis was the most common complication. It was not observed that the treatment had any influence upon the temperature or upon the local condition, although the injections were soon followed by distinct improvement in the general condition.

Secondary Effects of the Antitoxin of Diphtheria.—LUBLINSKI (*Deutsche medicinische Wochenschrift*, 1894, No. 45, p. 857) has reported a case of nasal and pharyngeal diphtheria, in a girl eight years old, in which treatment with the antitoxin was followed by the development of erythema exsudativum multiforme. Ten c.c. of Behring's serum (representing 600 immunity-units) were injected on the third day of the attack, and again twice on the fourth day. The local and general conditions underwent decided improvement, although sensitive areas of redness formed at the sites of injection. On the thirteenth day both ankle-joints became reddened and swollen, and in the course of the night a small, measly-like eruption appeared, extending in the course of the following day upon the extensor surfaces of both lower extremities, and subsequently appearing upon the extensor surfaces of the upper extremities. There were also pains in the knee-joints, elbow-joints, and ankle-joints. For several days matters continued thus, the exanthem extending and the pains persisting, but finally both began to subside, and at the end of a week the child was quite well.

Thyroid Gland for Exophthalmic Goiter.—At a recent meeting of the Société Médicale des Hôpitaux, VOISIN (*Gazette Médicale de Paris*, 1894, No. 43, p. 513) reported the case of a woman, thirty-two years old, affected with exophthalmic goiter, to whom he administered twice daily, before meals, from one-and-a half to two drams of thyroid gland from the sheep. After two weeks of this treatment the patient was materially improved. The heart-beat was more regular, and had fallen from 150 to 100 in a minute. The edema of the lower extremities had disappeared, while the thyroid was diminished in size and the exophthalmos had receded. The treatment was thus continued with advantge, being suspended for ten or twelve days every three weeks.

The Treatment of Goiter with Thyroid Gland.—BRUNS (*Deutsche medicin. Wochenschr.*, 1894, No. 41, p. 785) has reported twelve cases of goiter treated by means of the administration of thyroid gland, cases of the parenchymatous variety being selected. Of this number nine were cured or improved, while three proved refractory. Fresh uncooked glands obtained from sheep and cows were employed, and administered in doses of from 75 to 150 grains in cachets or upon buttered bread, at first every two or three days, but subsequently once a week.

Thyroid Extract in Insanity, with Goiter.—MCCLAUGHRY (*Journal of Mental Science*, October, 1894, p. 635) has reported two cases of insanity associated with goiter, in which thyroid extract was administered with highly encouraging results. Five grains were given at each meal in the form of tabloids.

In the Treatment of Dry Pleurisy, CÉRENVILLE (*Semaine Médicale*, No. 60, 1894, p. 477) recommends intrapleural injections of sterilized olive-oil, in the sequence of which the pleural friction and pain soon disappear and the remaining symptoms speedily subside.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SATURDAY, DECEMBER 8, 1894.

THE NERVOUS SYMPTOMS OF CIRRHOSIS OF THE LIVER.

ONE of the oldest chapters in medical science is that which is devoted to the psychology of the liver. "Melancholia," the *black bile*, is the enduring symbol of visceral insanity; it is one of those monumental terms that sum up the history of a science at the same time that they embody an error. It stands for a disease that never had an existence, but which has handed down to present times its ancient terminology, and fastened its name upon one of the most common affections in modern life.

The ghost of this ancient pathology still lingers in our modern text-books. Even now it will not down. A wide domain is preserved for it: the fertile field of the so-called "sympathetic" insanities. VAN HELMONT, we are told, revived the ancient opinions respecting the sympathetic action of diseased viscera upon one another, and especially upon the brain. With him began the era of "visceral irradiation;" he made a sort of recension of that fable of ÆSOP, in which the belly was at war with the members.

The symmetric outlines of this pathology were perfect; all proper analogies were observed in it, as is always the case in good dialectics. Thus, if the peccant viscus was inflamed, the consequent mania by metastasis had all the violence of the inflammatory diathesis; and, on the other hand, if the organs suffered the invasion of some mephitic humor, the consequent psychosis was as black as night. But the blackest of them all was from the liver; *similia ex similibus fiunt.*

There is no organ, says an old authority, with the morbid actions of which the functions of the brain so frequently sympathize as with the liver; and, still more significant, he says, that diseases of the hepatic system will even originate delirium and furious mania, as well as the classic melancholia and suicide. TODD, CHEYNE, and BURROUGHS, all claimed many years ago that they had even found in the liver traces of the morbid anatomy of insanity. Latest of all, RÉGIS, whose work has just been translated, devotes a whole section to "hepatic insanity," and thus completes the ever-revolving cycle of pathology. This brings us to our text.

We maintain that organic disease of the liver is sometimes the cause of grave mental changes; not in the sense of the ancient sympathetic doctrine, although there is some truth in that, too. That doctrine can rest at least upon a broad foundation of gall-stones. We are far from assailing it; in fact, from our own clinical data, we might add a stone or two to its tumulus. We speak in an entirely different sense. We refer to the liver as an *infective* agent in mental disease. We are about to deal here with a form of toxic insanity. And yet, let us note, in passing, our own tendency to revert to ancient methods; what we have seen and what we write here lead us once more to the humoral pathology. By a benign, not vicious, cycle we are led to bear tribute from out of the fulness of our modern science, and lay it at the foot of the altar where worshipped some old Asclepiad. How often is this so!

In cirrhosis of the liver there is observed sometimes a mental affection which is both conspicuous and significant. It is a true toxic delirium, that is to say, it shows the peculiar mental phenomena that characterize, almost without exception, the deliria caused by poisoning of brain tissue. So characteristic are these phenomena that the etiologic factor, *i. e.*, some form of blood-intoxicant, can, we had almost said, be predicated of this class as an essential prerequisite. The mental affection is one of confusion with hallucination. It is a

delirium, in the ordinary English acceptation of that term; not a mania or a melancholia. It is almost identical in form with the delirium, or confusional insanity, that follows prolonged fevers, or the puerperium; or that sometimes explodes as a delirium *grave;* or is seen in the more familiar delirium tremens, minus the tremor. The Germans have the term *Wahnsinn*, which connotes this state.

This *Wahnsinn*, or confusional insanity, whether seen in conjunction with cirrhosis of the liver or any other state, is not, properly speaking, a pure psychosis any more than is the delirium of typhoid fever. It is primarily an affair of the liver when it occurs in cirrhosis, and only secondarily a state of the brain. Purge the obnoxious liver of its humors, and the brain will not be ill. In this sense TUKE, in a recent brochure, emphasizes the fact that the psycho-neuroses are diseases of the body rather than of the "mind." Hence this most instructive, but rather rare, confusional delirium in cirrhosis is an object-lesson of great worth. We see in it, as it were, the brain poisoned, the mind overwhelmed by the infectious materials of the body's own making. We are at the threshold of modern pathology. We are face to face with auto-infection.

It is a curious fact that little note is taken in the text-books of this most important rôle of cirrhosis of the liver. The cause, probably, is the fact that this delirium is rather rare, except toward the very end of the disease. FRERICHS, however, in his great monograph, distinctly notes this complication. He says that delirium occurs in rare cases in cirrhosis, and seems to think that it is due to acholia, as in acute atrophy of the liver. He mentions in the same clause convulsions and coma (seen also in uremia and acetonemia), and seems to imply that the duration of all these crises is brief.

That this latter inference is erroneous, however, our own clinical experience has amply demonstrated. We have seen, in a recent case, a wandering delirium, of mild grade, with hallucinations, and confusion of the identity of persons and places, without convulsions or coma, and, with fair digestion and nutrition, extend over a period of four months, without intermission. During this period there was neither albuminuria nor glycosuria. The ascitic fluid was withdrawn, and reaccumulated four times. Epistaxis was copious at times, but there was neither gastric nor intestinal hemorrhage. The autopsy revealed a hob nailed liver, extraordinarily hard and contracted.

We may note, finally, that in this solitary case an expert analysis of the urine, secured in the hope that it would give evidence of toxemia, revealed nothing but a doubtful trace of acetone. Thus we return to the point whence we started, for we seem to have advanced only by a trace of acetone beyond the humoral pathology and the hepatic psychiatry of the ancients.

THE INJUSTICE OF COMPETITIVE CHARITY.

HAS the medical staff nothing to say as to unlimited endowing of free beds in enterprising hospitals, and the free treatment of anybody and everybody, upon payment of nothing, or of some hypocritically small fee? Is this simply and solely a matter within the control of lay-boards of trustees and of professional philanthropists? These questions are suggested by a widely-distributed circular issued by a large hospital in a city of the eastern United States, which reads as follows:

The Board of Trustees of the —— Hospital of the City of —— strongly recommend the following advantages offered to the public.

Mill and factory owners, lodges, and beneficial associations can secure a bed at the —— Hospital for 365 days by paying $200, and upon averaging the days may have several patients in the hospital at the same time.

Subscription books can be obtained by working people of both sexes up to the age of fifty, subject to the regulations of the hospital, whereby, on paying an initiation fee of one dollar and monthly installments of fifty cents, each subscriber may be treated in case of sickness entirely free of further charge. Heads of families and owners of factories should particularly recommend to their servants and employés to avail themselves of this excellent facility.

Of course, if the medical officers of this hospital have assented to this plan, nothing more in criticism can be said except to ask them:

1. Have you any right to assent to it for *other* physicians who in the course of human events may take your places by and by?

2. If all hospital staffs assent to it, have the non-hospital physicians no criticism to offer and no rights to be upheld?

3. Has the medical profession nothing to suggest as to the encouragement of pauperism and the just claim of members of the profession to some compensation for medical services from those able to pay? Has the public no duties to the medical pro-

fession in this debauching competition in "offering advantages to the public?"

4. By what principle of common justice and decency can it be claimed that well-to do "workmen, lodges, and beneficial associations" are unable to pay medical men something for their services, and that the professionally benevolent should dispose of medical service by virtue of being trustees of hospitals?

In England the impudence of these trustees and dictators of medical men has become a public calamity, and the same trend is more than evident here. Have medical societies and associations, colleges and academies of physicians, no word to utter as to the huge and growing abuse? Instead of permitting or encouraging, they should warn the endowers, supporters, and trustees of hospitals, and the easily deceived public, that the blind sentimentalism of charity almost inevitably ends in wrong and ruin, and that whatever injures the medical profession in the long run injures the health and well-being of the general public.

Not a dollar should be given to any hospital that is not accompanied by an express stipulation on the part of the giver, and by a promise as explicit on the part of trustees and officers, that no person (except in emergency cases, etc.), shall receive medical aid in the institution except it have been systematically and clearly made evident that such person is unable to pay anything for the service. Medical men are already overburdened with necessary or inevitable charity-work in private, hospital, and dispensary practice, but they display a criminal negligence as regards the increase of this evil of charity-abuse, and either supinely submit to the dictatorship of mechanic routine or of trustees, and even go so far as enthusiasm in professional hari-kari. It is high time the brakes were applied.

EDITORIAL COMMENTS.

The Health of the Army.—From the report of the Surgeon-General we learn that the health of the United States Army during the fiscal year ended June 30th differed but little from that shown by the best of army medical records. The admission-rate per thousand of strength present was 1289.04, as compared with 1270.42 for the previous year, a great improvement on the average annual rate of the previous decade (1424.20) and slightly greater than the lowest rate (1247 in 1887) ever furnished by the United States troops. The number of sick daily was 40.15 per thousand of strength, as compared with 39.60 during the preceding year. The number of days lost by sickness equaled 14.7 for each member of the strength of the army, as compared with 14.5 days during the preceding year, and with 15.8 days for the average annual number of the previous decade. The rate of discharge for disability reached its lowest point, 14.93 per thousand of strength, as contrasted with 18.35 during the preceding year and with 28.82 during the years of the previous decade. This result is ascribed to the greater care taken in the selection of men for enlistment. The deaths from all causes equaled 6.91 per thousand living, as compared with 6.44 for the previous year and with 8.51 for the years of the previous decade. Accidents and injuries accounted for 2.90 of the death-rate.

Injuries, as usual, played the most important part in the causation of the admissions to sick report, being the responsible factor in 243.29 of the 1289.04 admissions per thousand of strength during the year. Specific febrile diseases take second place, with a rate of 171.19, mostly due to influenza; diseases of the respiratory and the digestive system take third and fourth place, respectively, with 141.06 and 113.77 cases per thousand men; diarrheal diseases stand fifth, with a rate of 98.47, and malarial affections sixth, with 93.64.

Injuries were responsible also for 7.92 of the 40.15 constantly disabled in every thousand men. Venereal diseases, as in former years, take second place as a disabling cause, having kept 5.41 men unfit for duty among every thousand. Third place was taken by specific febrile diseases, 4.50, the chief factors being influenza and typhoid fever, from the number and duration, respectively, of their cases. Then follow in order of prominence diseases of the respiratory system, 3.45; malarial diseases, 2.45; diseases of the digestive system, 2.09, and of the locomotor system, 2.02, the last mostly cases of muscular rheumatism,

The absolute number of discharges for disability was 413. Seventy-one of these were occasioned by accidents and injuries, including 21 cases of hernia, 53 by venereal diseases; 48 by insanity, epilepsy, and other affections of the nervous system; 44 by pulmonary tuberculosis; 36 by diseases of the locomotor system; 32 by heart-disease, and 24 by affections of the eyes.

The absolute number of deaths was 191. Eighty of these were due to violence or accident, including 25 from gunshot wounds, and 21 by drowning. Pneumonia caused 18; pulmonary tuberculosis, 17; typhoid fever, 16; kidney-disease, 11; alcoholism, 10; heart-disease, 6, and erysipelas 5.

The mean strength of the army during the year was, according to the medical reports, 25,287 men: White, 22,429; negroes, 2,143, and Indians, 715. Both the admission-rate and the rate of non-efficiency of the white troops were larger than the corresponding rates of other races, but the death-rate of the negroes and the death-rate and discharge-rate of the Indians were considerably higher than those of the white troops.

The Indians appear to have suffered more than the whites from mumps, erysipelas, venereal diseases, conjunctivitis, and other diseases of the eye, tuberculosis, pneumonia, and glandular swellings; less than the whites from muscular rheumatism and hernia. The negroes suffered more than the whites from mumps, erysipelas, muscular rheumatism, and frostbite; less than the whites from venereal diseases. The whites suffered more than the other races from malarial and diarrheal diseases

and alcoholism. The high death-rate of the Indian was due to tuberculosis and pneumonia, and his high rate of discharge to the effects of these diseases and of syphilis.

Every Physician to Have His Own Medical Journal.—Our readers will remember our long-time interest in the increase of the number of American medical journals. It has sometimes seemed that the only logical outcome of the present tendency is that every physician, in order to keep abreast of the times, should edit and own a distinct journal of his own. This opera-bouffe crazy-thought, however, has been more than suggested; it is proposed as a business enterprise in downright seriousness and literalness. Can any reader imagine how it is to be done?

The "hustler" who proposes the plan bases his scheme upon what he considers an axiom, viz.: that the present editors of all thriving medical journals are "to-day winning financial success, etc., aided by the journals which they own, edit, etc." Then follows a long list of these remarkable editors—like sample bricks of the Irishman's house—in proof of the astonishing and ingenious discovery.

We have before us a long type-written private letter from "the ——— Medical Journal Company," setting forth the method to a correspondent, whereby the correspondent may secure such a journal for his own private use and behoof, and how the said, the ——— Medical Journal Company, can conform itself to the plan, the entire modus operandi, etc. It will be recognized as an adaptation of the old newspaper dodge of "patent outsides." We can only quote a part of this truly exquisite bit of impudence. In the slang of the day, and in a double sense, "Here's richness," indeed!

First, we will get out a journal in every way as good as the one you have in hand each month, in size, quality, etc. We will allow you one page to be filled with your own items of interest relating to your own doings, those of your patients, friends, and institution, or whatever you may choose. We will carefully eliminate the word ——— from the journal. Instead of it being called the ——— *Medical Journal*, as now, you may give it any name you choose, as the *Grand View Sanitarian*, or *The Lewiston Medical Reporter*, or whatever seems appropriate to you for your location and institution. In the space now used for our motto, "A magazine for the doctor and his family," we will print your name as local editor, publisher, or whatever you wish.

We shall be glad to have at any time short articles of practical value and general interest from yourself or colleagues for publication in the body of the journal, which we will insert as we find opportunity.

In return it is hoped you will take at least one hundred copies of the journal each month at $6 a hundred, additional copies to be furnished you at the rate of 5 cents each. In no case can less than 100 copies be sent. The pay in each instance must accompany the order, and also copy for your local news page, and be received at the home office by the 15th of each month. The price we have made you is cost. (No publishing house in the country could get you up exclusively too such journals as ours for less than $225.) We are able to make this price to you only on account of the great number we issue. Our pay comes through our advertising columns, which are valuable and appreciated.

The gain to be derived by you taking hold of this enterprise is great, we believe, beyond all proportion of the cost. In the first place, it binds you to nothing. You are at liberty to stop whenever you choose. You may secure subscribers to your journal in your own town and county. It will be worth more than the regular price and make it pay for itself in dollars and cents. You can send other copies to desirable parties with your compliments and attention which will win and hold their regard. Other copies left with your druggist for judicious distribution will be like bread cast upon the waters. But undoubtedly the greatest benefit of all will be the prestige that your connection with such a journal will give you and your institution wherever it goes.

In short, there is no end to the usefulness to which doctors may and do put their journals. Please give this matter the careful attention its importance merits.

Very truly yours,

THE ——— MEDICAL JOURNAL CO.,

——— *Manager.*

P. S.—In case you do not care to furnish copy for local page at any time, a notice with cut of your institution can occupy the space very effectively.

The Index Medicus, as we accidentally learn, is about to be discontinued. To publish it without a loss would require about 800 paying subscribers, and the work has been carried on, of course at a heavy loss to the publisher, with less than 300.

The disappearance of this highly valuable publication would be a great misfortune, as everyone will admit who knows or cares anything about the literary aspect of medicine. What few recognize, however, is that it would be a misfortune not to the literary physician alone, but every practising physician would directly or indirectly find himself the worse off, and his patients likewise. In placing at the command of the therapeutist the digested and classified index of all chronicled medical labor, every future patient in one way or another must feel the good and be helped by so much. We cannot practice medicine to the best advantage without in some way or other knowing what our fellows have done and are doing in the same fields of labor.

Now this periodical must not be discontinued! We have a suggestion to offer: In an accurate sense the *Index Medicus* is truly the continuation of the great *Index-Catalogue of the Surgeon-General's Library*, so indispensible to the American medical profession, and such an honor to it and to its authors. Why should not the publication of the *Index Medicus* be continued by the United States Government? If the august legislators will save the money wasted every year on pocket-books and pen-knives for their pages it would probably be amply sufficient to publish the *Index*. At all events, the work is distinctly for the public benefit and use, and the expense of its publication should be borne by the public. Why should it not appear as a part of the work of the office of the Surgeon-General? The library belongs to that department, and its publication of the *Index Medicus* would be both proper and right.

Why will not the College of Physicians of Philadelphia, the Academy of Medicine of New York, and any or all other medical societies pass resolutions or take steps to insure the continued publication of the *Index*.

Mistakes in the Execution of Food Adulteration Laws.—Those who are responsible for the desirable prosecution of offenders against the laws as to the adulteration of foods should be extremely cautious not to make mis-

takes in selecting the articles against which to proceed. Against proprietary preparations, as such, owned or manufactured by non-medical men, there can be no criticism; indeed, medicine is indebted to non-medical chemists and honorable manufacturers for many preparations that have been of great service in therapeutics. It would be a pity if the justifiable intolerance of the nostrum-traffic should proceed to such lengths as to include useful non-secret preparations made by respectable manufacturers. To make a mistake in choosing articles against which to proceed (as, for example, the Ohio Pure Food Commission did in the case of "Vin Mariani," etc.), weakens the power of the prosecutors and creates a prejudice against their judgment. There are plenty of certainly and really adulterated articles, there are plenty of secret preparations and nostrums against which action can be taken with benefit to public health.

The Oyster as a Medium of Transmitting Typhoid Fever.—If current reports can be relied upon, an epidemic of typhoid fever among the students of a New England university has been traced to the ingestion of raw oysters taken from an infected stream. All of the victims had partaken of raw oysters supplied by an oysterman who was in the habit, after taking the oysters from the deep waters, of placing them for some twenty-four hours in the shallows of a river passing near his house. On investigation it was learned that the oysterman's wife had died of typhoid fever at about the time of the epidemic among the students, and that a daughter was also ill with the disease. The drain of the house emptied into the river at a point near where the oysters were placed temporarily. In addition to the students, a number of visitors were also attacked. If the statements cited can be verified, they will have a good deal of significance, and will exert a profound influence on an important industry. On the other hand, it is but right that they should be corrected if they prove false.

The Library of the Office of the Surgeon-General of the United States Army.—During the fiscal year ended June 30, 1894, there were added to the Library of the Surgeon-General's office 1082 medical journals, 214 volumes of *Transactions*, 346 bound pamphlets, 2272 medical books of other kinds, 2258 medical theses and 9053 medical pamphlets. At the close of the year the library was in possession of 33,297 medical journals, 4913 volumes of *Transactions*, 1663 bound theses, 2604 bound pamphlets, 72,090 medical books of other kinds, 52,218 medical theses, and 127,560 pamphlets, a grand total of 183,778. The profession is justly proud of this great library, and will resent any attempt to lessen its usefulness by curtailing its appropriation on the assumed ground of economy. The Librarian, Dr. John S. Billings, and his assistants deserve great credit for their conduct of the library.

The Army Medical Museum at Washington, on June 30th, contained 10,656 specimens in its pathologic section, in its anatomic section 3569, in the section of comparative anatomy 1717, in the microscopic section 12,033, in the miscellaneous section 1894, in the provisional pathologic section 1893, and in the provisional anatomic section 807, a total of 32,269. During the year the Museum was visited by 50,675 persons.

SELECTION.

THE BACTERIO-PATHOLOGY OF THE HUMAN MOUTH AND ITS SIGNIFICANCE IN RELATION TO SYSTEMIC DISEASES.[1]

By PROFESSOR W. D. MILLER,
of the University of Berlin.

I have occupied myself now some fifteen years with the study of the microörganisms of the human mouth, with particular reference to the disturbances that they produce in the mouth and neighboring parts, as well as to their relation to diseases of the more remote parts of the body.

The results of my investigations have been made known from time to time through various publications, and are no doubt familiar to many of the practitioners and students of dentistry here present. I am convinced, however, that this is a subject of quite as much importance to the medical practitioner as it is to the dentist, and I am glad of the opportunity to present a few facts relating to it before an audience composed chiefly of practitioners of medicine, although in the short time at my disposal I shall not be able to present more than a mere outline.

The knowledge that human saliva often contains something which exerts a toxic effect upon the animal as well as the human body is by no means of recent origin.

Many of the ancient writers call attention to this fact, among others the celebrated Galen, who himself was an eye-witness to the operation of killing a scorpion by the action of human saliva, "without the aid of magic." And, further, Aristotle was acquainted with a girl whose bite was as poisonous as that of the most venomous snake. An arrow dipped in her saliva invariably killed any animal that was wounded by it. We can readily understand this now, as we know that the bite of a human being is a very serious matter, and I, personally, would prefer at any time to be bitten by a dog (unless it was suffering from hydrophobia) rather than by a human being. Even the scratch of an instrument infected by usage in an unclean mouth has been known to be fatal, and the case reported by Aristotle can be believed most readily.

Pliny relates, also, that the human saliva is poisonous, and that a snake will flee from human saliva as from boiling water, and that saliva dropped into the mouth of a snake will kill it. In all these years since Pliny no one has taken the trouble to test the accuracy of the statement, although it would be a comparatively simple matter to do so.

In recent times (1834), Eberle refers to the fact that the human saliva contains poisonous elements, and, according to his ideas, its toxic properties depend on the state of the mind at the time being. He found his own saliva to be more poisonous when he was enraged or suffering pain than at other times. He would subject himself to irritating influences in order to become enraged artificially, and noticed that the toxic action was

[1] Read before the Wistar Biological Association of Philadelphia, October 2, 1894.

From advance-sheets kindly furnished by the Dental Cosmos.

increased thereby. Later on many observations were reported, all tending to definitely establish the fact that when smaller animals, as rabbits and mice, are vaccinated with saliva, they almost invariably die within twenty-four or thirty-six hours.

It was believed for a time that the toxic agent was potassium sulphocyanid. However, it was shown by others that the amount of this salt in the saliva is too small to have any influence on the human being; while, in 1881, Pasteur and a score of other observers established the fact that the poisonous character of the saliva is due to the presence of a group of microörganisms, which have been designated as the micrococci of sputum-septicemia.

Since 1881 a great many have occupied themselves with investigations relating to this subject, and have met with no less than thirty-two different species of microörganisms of a pathogenic character in the human mouth, some of them having most virulent properties, besides a large number of organisms which are not pathogenic.

One of the most common results of bacterial action in the human mouth is caries of the teeth. We have not time to enter into a discussion of this process; photomicrographs that I shall demonstrate can scarcely leave any question as to the nature of the process.

A second result is the inflammation of the pulp of the tooth (pulpitis), one of the most common causes of toothache. It is a great mistake to look upon pulpitis as a disease of very trivial nature, because apart from the intense suffering caused by it, and apart from the possible, or often probable, loss of the tooth, it not infrequently incapacitates the patient for the time being for any kind of labor, and when it occurs, as is too often the case, in connection with other disturbances—during gravidity, confinement, or protracted illness—it becomes a disturbing factor of no mean order.

The inflammation of the dental pulp, if left to itself, will almost invariably be followed by suppuration, and eventually by the death of the organ. Putrefaction then sets in, and the pulp soon becomes converted into a putrid, stinking mass, which contains substances (ptomaïns) of an exceedingly toxic nature.

If but a minute portion of such a pulp is forced through the apical foramen it almost invariably gives rise to intense inflammation of the pericementum or lining membrane of the root. The tooth becomes intensely sore; considerable edema sets in; swelling of the cheek and lips, and frequently general symptoms, such as fever and chills, are present, which indicate that a certain amount of the poisonous product has been taken into the system. Usually the inflammation ends in the formation of an abscess, and the pus escapes through the external lamella of the alveolar process into the mouth. Occasionally it finds its way into the antrum or nasal cavity, or escapes externally at the angle of the jaw, under the chin, on the breast, in the arm-pit, etc. After discharge of the pus the process usually assumes a chronic character, and may give rise to no marked symptoms for years, more or less pus, however, escaping constantly or at intervals through the fistulous opening.

These alveolar abscesses are by no means infrequently the cause of secondary complications of a most serious nature; periostitis, osteomyelitis, caries, and necrosis of the bones being some of the most common results of infections orginating in gangrenous or putrid tooth-pulps. Koehler, director of the Charité Hospital in Berlin, observed no less than forty-four cases of this nature in two years. Many cases have been reported in which these processes have terminated fatally through the intervention of septicemia or meningitis, less frequently through edema of the glottis, pneumonia, etc.

A few cases may serve to give an idea of the varied course which the process may take.

Case I.—A child, four-and-a-half years old, with carious teeth in the lower jaw and suppuration in the inferior dental canal, periostitis and ostitis of the vault of the skull, developed general pyemia, death taking place in nine days.

Case II.—In a workman, thirty-six years old, abscesses of some of the teeth of the lower jaw were followed by osteomyelitis, phlegmon, periostitis purulenta, mediastinitis, pleuritis, and pericarditis, death taking place twenty-four hours after the appearance of the phlegmon.

Case III.—A boy, eight years old, had an abscess of the right inferior first molar tooth, followed by suppuration, edema, necrosis, gangrene, sepsis, and death in twelve days.

Case IV.—A boy, nine years old, had abscessed teeth in the right lower jaw, followed by periostitis purulenta, necrosis of the entire side of the jaw, sepsis, and death.

Case V.—A man, forty-eight years old, had abscessed incisors in the lower jaw, followed by osteomyelitis, necrosis, laryngitis, and death.

Case VI.—A woman, twenty-six years old, had an abscess of the right inferior first molar, followed by osteomyelitis and necrosis of the condyloid process.

Case VII.—A girl, fifteen years old, had an abscess of the right inferior first molar, followed by ostitis and periostitis mandibulæ dextræ, endocarditis, pleuritis, nephritis, broncho-pneumonia, and death in four-and-a-half months.

Case VIII.—A diseased tooth in the upper jaw led to inflammation of the antrum, caries of the ethmoid, abscess of the orbit, arachnitis, encephalitis, and death.

The foregoing cases are sufficient to show *some* of the complications arising from diseased teeth. A long list of such cases will be found in the second German edition of my work on *Mikroorganismen der Mundhöhle*, as well as in the *Dental Cosmos* for 1891, p. 706.

A further complication of abscessed teeth that gives much food for thought is illustrated by the following case: A sickly boy, nine years of age, suffering from an large abscess of the right inferior molar, accompanied by periostitis, on attempting to get up, fell from his bed, slightly bruising his thigh. The bruise became the seat of a secondary abscess, the pus of which had the same character and contained the same microörganisms as that discharged by the abscess of the tooth. A large number of similar cases have been reported—cases of acute or chronic pyemia in which abscesses in various parts of the body have been caused by diseased teeth. Baker relates a case in which an abscess on the big toe was cured by the treatment of a suppurating molar. These cases are easily accounted for. From the abscess of the tooth not only are toxic substances constantly

being absorbed, but also pathogenic bacteria from time to time find their way into the circulation, to be redeposited again, and to proliferate anew wherever, at the time being, they may find a *locus minoris resistentiæ*. While, therefore, a focus of chronic suppuration in the jaw may apparently produce no evil beyond the local symptoms, we can never tell but that it may be preparing or keeping up some process in some remote part of the body. Fürbringer puts it very well when he makes the assertion that many of these obscure cases that we are obliged to record as "unknown mycoses" will undoubtedly be traced to their origin when we come to properly appreciate the importance of a thorough understanding of the human mouth as a focus of infection.

Let me call your attention, in the next place, to a condition very commonly met with among the lower classes, and indeed often enough among well-to-do-people, which might be designated as total decay of the teeth. We find nearly every tooth in the mouth more or less decayed, many of them completely broken down, with exposed pulps or abscessed roots, and swollen, suppurating gums. Mastication of food is entirely out of the question, while quantities of pus and bacteria are swallowed with every meal, a condition of affairs to which an attack of measles or scarlet fever were, in my opinion, decidedly preferable. The recent examinations of the teeth of schoolchildren have made some startling revelations in this line. Then, again, we often have in the mouths of uncleanly persons a condition brought about by the action of fermenting and putrefying matter upon the mucous membrane which I have likened to a "spoiled stomach," and designate as spoiled mouth. As early as 1656 Pfaff called attention to the fact that loss of appetite, nausea, etc., are often erroneously attributed to the innocent stomach, when the cause was to be found in the filthy condition of the mouth. Von Kaczorowski has furnished us with very interesting data in support of this view.

The causal relation of diseased teeth, particularly of teeth with putrescent pulps, to chronic swelling of the lymphatic glands in the region of the lower law and neck has been clearly established by Odenthal, who found glandular swellings in ninety-nine per cent. of all children who suffered from badly decayed teeth, and only in forty-nine per cent. of those with sound teeth.

A further condition in which bacterial processes are involved is that known as pyorrhœa alveolaris, in which more or less profuse suppuration takes place about the necks or roots of the tooth, involving the bony socket. The teeth gradually loosen and eventually fall out. Apart from the loss of the teeth, the constant swallowing of pus from such teeth is not to be regarded as a matter of indifference. On n'absorbe pas impunément pendant des mois et des années, des sécrétions purulentes, contenant des agents aussi infectieux que ceux de la pyorrhée alvéolaire. (Gallipe.)

The question of pyorrhœa aveolaris has excited unusual interest recently on account of its supposed connection with the uric-acid diathesis. It remains for the future to definitely determine in how far this affection actually depends upon the uric diathesis for its origin.

The tonsils have already received a great deal of attention as harbingers of pathogenic germs. It is a fact generally recognized that various pathogenic germs, among others even the bacillus of diphtheria and the ray-fungus (actinomyces), may vegetate in the lacunæ of the tonsils without producing any serious symptoms as long as the general health of the person is good, and no lesion or other point of diminished resistance is formed in the tonsils or mucous membrane of the throat. Otherwise an infection is liable to occur at any time.

The literature of this subject is already very extensive and exceedingly instructive, but we have not the time to enter into a further discussion of it.

Another disease of the mouth of parasitic origin is *thrush*. You are all acquainted with its nature and treatment. I will merely state that this is the only disease of the mouth, and in fact of the human body, which is caused by a yeast-fungus. The view formerly held, and still commonly met with in medical journals, that we have here to do with a mold-fungus, has been shown to be untenable.

It is well known that the prolonged administration of mercury or its compounds brings about an affection known as stomatitis mercurialis, the symptoms of which are familiar to you all. Very careful and reliable observations by Gallipe, which have been confirmed by Ritter, leave little doubt that these symptoms are in a great measure due to the action of bacteria upon tissues that had been rendered more susceptible to their action by the influence of the mercury. If the mouth is put in a perfect hygienic condition, as it always should be before the mercurial treatment is begun, much of the trouble arising from this source will be avoided.

Actinomycosis is still another bacterial affection, very often terminating fatally, in which the point of entrance is usually to be found in the mouth.

Of two-hundred-and-twenty-five cases, one-hundred-and-twenty-eight were found to have originated in the jaws, defective teeth most commonly furnishing the *locus minoris resistentiæ*. Of the remaining one-hundred cases many were primary infections of the lungs and alimentary tract, in which, again, the germs entered the body through the mouth.

The relation of mouth-germs to affections of the middle ear (otitis media) merits particular attention. Fifty-four cases have been reported by Maggiore and Gradenigo in which they found the micrococcus of sputum-septicemia twenty-eight times, staphylococcus pyogenes albus eight times, staphylococcus pyogenes flavus five times, and streptococcus pyogenes eight times; all of these being microörganisms very commonly met with in the mouth. They found, moreover, in eighty per cent. of these cases examined, the same germs in the secretions of the mouth and nose as in those of the middle ear. According to Zaufal the microörganisms find their way into the middle ear through the tuba Eustachii. Inflammation of the salivary glands has been shown by various observers to be frequently brought about in a similar manner, bacteria penetrating from the mouth through the ducts of those glands.

It has been established beyond all doubt that the specific cause of croupous pneumonia lies in a microorganism or group of microörganisms that can readily be found in the mouths of the majority of all persons. It is the same group that was referred to in the beginning of these remarks as the chief cause of the toxic action of human saliva, variously designated as micro-

coccus of sputum-septicemia, pneumococcus, meningococcus (from its frequent causal connection with meningitis), etc. Many experiments and observations have been reported which render it highly probable that the infection in case of pneumonia does not take place directly from the air, because the specific microörganisms soon loose their virulence or even vitality in the air. Furthermore, it has been pretty well established that in the breathing of air that contains moderate numbers of microörganisms, the latter lodge in the mouth, nose, and throat, and do not reach the lungs in sufficient number to be able to bring about an infection. It is much more probable that the infection takes place directly from the mouth by particles of saliva or mucus loaded with germs being carried into the lungs in forced inspiration, as in coughing. Whether this act would be followed by the development of croupous pneumonia or not would, of course, depend upon the susceptibility of the lungs or any part of them at the time being. This same group of microörganisms has furthermore been met with in parotiditis, multiple subcutaneous abscesses, tonsillitis, otitis media, pleuritis, endometritis, peritonitis, pericarditis and endocarditis, abscesses of the mastoid process, and retro-pharyngeal abscesses, meningitis, etc.

I find that I have already overrun the time set apart for these few introductory remarks; I shall, therefore, only mention some of the other affections that demand consideration in this connection, such as stomatitis gangrænosa and aphthosa, stomatomycosis, foot-and-mouth-disease, and, particularly, those general diseases that originate in the mouth, or, at least, produce marked local manifestations there, such as syphilis, tuberculosis, diphtheria, influenza, etc., in all of which the thorough and intelligent care of the mouth is imperative in the highest degree.

The foregoing, which is only a mere outline of the subject, may suffice to show what an extensive influence the condition of the mouth exerts in determining the general state of health of the whole body, and how imperative it is that every one practising medicine or any branch of it should be thoroughly informed in regard to this question. It furthermore, in my opinion, justifies the statement that stomatology, or that branch of medical science which has to do with the diseases of the human mouth and their treatment, is perfectly entitled to stand on an equal level with the other specialties of medicine: otology, ophthalmology, etc.

A demonstration was then made by means of photo-micrographs projected upon the screen by the lantern, showing in detail the morphology of the several groups of pathogenic bacteria that inhabit the human mouth.

A full set of slides, illustrative of the author's investigations upon the etiology of dental caries, was exhibited, showing bacteria *in situ* in normal caries and also in that artificially produced by subjecting sound dentin to the action of pure cultures of the specific microörganisms concerned in the production of the disease.

A most interesting slide was one taken from a section of the kidney of a mouse that had been inoculated with the thrush-fungus. The section showed the bacterium *in situ* with inflammatory reaction set up by its presence, thus demonstrating conclusively the power possessed by the thrush-fungus of inducing metastatic inflammatory processes.

The remainder of the demonstration consisted of an exhibit of mouth-bacteria that have been described in detail by the author in several contributions to the *Dental Cosmos* and are embodied in his work, *Die Microörganismen der Mundhöhle*.

CORRESPONDENCE.

THE TREATMENT OF APPENDICITIS.

To the Editor of The Medical News,

Dear Sir: In the clear and emphatic article of Dr. John B. Deaver, entitled, "Further Observations upon the Etiology, Diagnosis, and Treatment of Acute and Chronic Appendicitis," etc., he says (p. 592), the diagnosis having been made, "I at once administer a purgative, preferably castor-oil or salts. If this is not retained I give calomel. If, after the purgative has operated satisfactorily, the symptoms continue along with an increase of intensity of the localized tenderness, I at once operate."

The doctrine maintained is, therefore, this: the diagnosis established, purgation; no amelioration—operation. From this I dissent. A limited experience in private practice has led to the conclusion that medicinal purgation in appendicitis is harmful; that thereby the symptoms are surely aggravated; that the patient always grows worse after taking a purgative, which he is very likely to do on his own responsibility in the outset of the attack.

The formula for medical treatment should be rest, topical applications, rectal enemata. Rectal enemata may be repeated every hour or two until the bowels act freely, if necessary, to the number of twenty.

Finally, the selection of proper surgical cases of appendicitis is a subject for the display of the finest judgment and reasoning. A death without operation is lamentable; complete recovery, patient declining operation, mortifying to its advocate.

Louis Kolipinski.

Washington, D. C.

TESTIMONIAL TO SIR JOSEPH LISTER.

To the Editor of The Medical News,

Sir: Sir Joseph Lister having recently retired from active hospital and teaching work, the occasion has been thought appropriate for presenting him with a testimonial of the esteem in which he is held by his former colleagues and pupils, and committees have, therefore, been formed in Glasgow, Edinburgh, and London for the purpose of raising the necessary funds.

It is proposed that the testimonial shall take the form of a portrait. Subscriptions have been limited to two guineas (about $10.23), and it is hoped that sufficient funds will be collected to permit of some memento of the occasion being presented to each subscriber of that amount.

As there are probably many surgeons in the United States who may wish to join in the movement, but whose names and exact addresses it has been difficult to ascertain, I should be glad if you would permit me to state that subscriptions may be sent to me at 29 Weymouth

Steeet, Portland Place, London W., England, or to one or other of the following gentlemen, who have kindly consented to act as treasurers, viz.: Dr. James Finlayson, 4 Woodside Place, Glasgow, Scotland; Prof. Chiene, 26 Charlotte Square, Edinburgh, Scotland; Prof. William Rose, 17 Barley Street, London, W., England; Dr. Malloch, 124 James Street, South, Hamilton, Ont., or J. Stewart, M.B., 37 South Street, Halifax, Nova Scotia.

I have the honor to remain, sir,

Yours faithfully,

J. Frederick W. Silk,

Honorary Secretary.

NEWS ITEMS.

Foot-ball Incidents.—The events of the past week have most thoroughly discredited the game of foot-ball as at present played. The contest at Springfield between the Yale and Harvard teams was one of the most unwholesome performances that ever masqueraded under the name of amateur sport. Players slugged into unconsciousness, eyes nearly gouged out, brains concussed, disabling sprains and bruises constantly interrupted the progress of the game, which even an ex-ball-player and friend of the sport declares to have been characterized by "sickening brutality." Besides this we hear of a student made insane through injuries received in playing, and two fatal accidents are reported. The number of young men who are permanently injured and who go through life more or less crippled in consequence of foot-ball playing can never be known. We should be sorry to see foot-ball abolished altogether from our colleges. There is no game that equals it in many ways when played as a manly sport and not for gate receipts. But the new rules are plainly ineffective, and unless some change can be made, the game really deserves to be placed under the supervision of boards of health working in coöperation with an efficient police.—*Medical Record.*

In a saloon in San Francisco in a quarrel over a foot-ball game, a foot-ball player was shot, perhaps fatally. The saloon in which the affray occurred was crowded with college students feverishly discussing the game. Loughborough, who is a law student, has University of California affiliations, and after some offensive remarks by Whitehouse, the men attacked one another. Glasses were smashed and chairs were used as weapons before they could be separated. Loughborough's nose was bleeding, and he drew his revolver, firing three shots at Whitehouse, one bullet lodging in his abdomen.

"This talk of stopping the game if it gets rough," said an old Yale player, "is the veriest rot. Superintendent Brynes would have to summon his whole force, and the Governor would be compelled to call out the militia to stop this game. Foot-ball players are not easily bluffed."

A letter protesting against the disorderly conduct of the students after the foot-ball match Thanksgiving Day in San Francisco has been forwarded to the presidents of the University of California and the Stanford University by the saloon-keepers of that city. The students overran the city, breaking chairs and glasses in beer-halls and saloons and terrorizing saloon-men. The police were unable to control them.

Three Yale and Princeton students were arrested after the game in New York, December 1, for drunkenness.

Charles Jones, the youth who sustained a fracture of the skull on Thursday, while playing foot-ball at Camden, N J., was still unconscious last night. It is thought that he will die.

A foot-ball game between a team of college men and the town men of Kirkwood, Mo., Thursday, resulted in the serious and possibly fatal injury of Philip Gauss, quarter-back of the college men's team. He was the under man in a scrimmage, and his physician reports him badly injured internally.

The condition of Bahen, the captain of the Georgetown College foot-ball eleven, who was so seriously hurt in the game with the Columbia Athletic Club on Thanksgiving Day, remains about the same. His spine is fractured, and the pressure on the spinal cord has produced paralysis from the chest down. He will be moved from the College Dispensary to-morrow and be taken to a hospital, where an effort will be made to remove the fractured pieces of bone. The operation is to be made as a last resort, and his recovery is doubtful.

The expenses of one foot-ball team (Yale) for one year (1892) were $15,284.62 and the gross receipts $31,300.71, leaving the net receipts $16,016.09. The net receipts last year were for the same team, $22,914. In 1892 the team paid for drugs, surgical supplies, medical services, and rubbers, $857.89.

Prize of the American Neurological Association.—The American Neurological Association offers a prize of $200 for the best essay on any subject connected with neurological science.

This competition is open to *physicians* who are legal residents of States in North and South America.

Essays must be sent to the Secretary of the Association, Dr. Græme M. Hammond, 58 West Forty-fifth Street, New York City, on or before the tenth day of May, 1895.

Each essay shall be accompanied by a sealed envelop containing the name and address of the author, and bearing on the outside a motto, which shall also be inscribed upon the essay.

Essays shall be type-written, in either the English or French language, and with the pages securely fastened.

The Council of the Association reserves the right to reject any or all essays judged unworthy of the award.

Each essay must exhibit original research, and none will be accepted that has previously been published.

The Antitoxin Treatment of Diphtheria.—A reaction against the unmeasured claims advanced for the curative effects of Professor Behring's diphtheria-serum is setting in rather seriously. The most significant utterance in this respect was made at a meeting on Wednesday, November 28th, at the Berlin Medical Society, when Dr. Hansemann, an assistant in Professor Virchow's Pathological Institute, as the mouthpiece of Professor Virchow himself, sharply criticised in detail Professor Behring's serum-therapeutics. He denied that the serum immunizes human beings, and declared that no sufficient

proof had been produced respecting its curative properties. Furthermore, Dr. Hansemann claimed that the effects of serum-treatment in many cases were dangerous to health and even to life. The statistics thus far obtainable of the results of the serum-treatment, he pronounced to be unreliable and often misleading.—*Newspaper Report.*

Antitoxin for New York.—It is announced that pending action of the New York Board of Estimate and Apportionment upon the application of the Board of Health for an appropriation of $30,000 to enable the Board to prepare the antitoxin of diphtheria, and carry on its scientific work, an anonymous philanthropist has furnished the means for the inoculation of a number of horses, sheep, goats, and dogs with diphtheria for the purpose of obtaining the antitoxin. It is proposed first to supply the Willard Parker and the North Brother Island Hospitals and then the general profession.

French Congress of Surgery.—The next French Congress of Surgery will be held October 21, 1895. The following subjects will be considered: 1. Surgery of the Lung (not including the pleura); 2. Early or Late Operative Intervention for Solutions of Continuity in Bones (not including the skull).

Correction.—Dr. Deaver wishes correction made of a typographic error in the title of his article in THE NEWS of December 1st. Instead of "Professor of Surgical Anatomy, etc.," read "Assistant Professor, etc."

The Colorado Climatologist and Denver Medical News is the name of a new journal published monthly at Denver, Col., and edited by Dr. C. Manly and J. N. Hall, together with a list of collaborators.

An Addendum to the article of Dr. MacPhail in the present number of THE NEWS, received too late for insertion, will appear in the issue of next week.

ORIGINAL ARTICLES.

THE DIURETIC VALUE OF CALOMEL AND UNUSUAL TOLERANCE OF THIS DRUG IN A CASE OF CARDIAC AND RENAL DISEASE.

BY WILLIAM PEPPER, M.D., LL.D.,
OF PHILADELPHIA;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

IN the treatment of chronic diseases nothing is more gratifying than the possession of various remedies or plans of treatment by which one end may be obtained. Not only is this true of the treatment of different patients in whom various individual peculiarities or associated conditions may contra-indicate or render useless one or another remedy, but also and only to a slightly less extent is it true in the treatment of the same individual. There is, perhaps, no remedy that may be continued indefinitely with the same happy effect as attended its first exhibition; and in every chronic case conflicting conditions will from time to time arise that make it undesirable to continue a course of treatment in every way satisfactory so far as the immediate end and aim of that treatment is concerned, but undesirable on account of other effects produced. This is eminently true of the treatment of heart-disease. Valuable as is digitalis, and thoroughly acknowledged as is its preëminence as a cardiac stimulant and tonic, no one would deny the usefulness of other cardiac remedies—of strophanthus, of strychnin, of nitroglycerin and others—in their own proper sphere or in cases in which digitalis has lost its influence or is contra-indicated; and any work devoted to the study of these remedies of lesser value will prove useful in times of greatest need when the potent remedy has failed and other aid is imperatively demanded.

These preliminary remarks are pertinent to the question of the diuretic value of calomel. This drug is certainly of less general value as a diuretic, and more frequently entirely valueless than many others; but there are cases (and the one here to be briefly described proves this) in which the great efficiency of calomel justifies and repays the labor given to the investigation of this subordinate action of the drug in question.

The diuretic action of calomel is not a newly-discovered fact, though only of recent years has it engaged attention prominently. The indications governing its use for this purpose, and the precautions necessary to the fullest success of the treatment, are recent additions to medical knowledge, and are perhaps still but imperfectly established. Before discussing these points, however, it will be well to abstract the notes of a case that strikingly illustrates the salient features of the question.

G. W. H., aged thirty-nine years, had for some years been engaged as a post-trader at one of our frontier stations in Dakota. His family history does not bear on the case. During a number of years he was much exposed to the vicissitudes of a rigorous climate, and had once suffered a sharp attack of rheumatism, from which recovery was apparently perfect. Subsequently, in 1890, he was suddenly seized with great epigastric pain, and became jaundiced. The history of this attack leaves little doubt but that it was one of biliary colic. Under treatment and careful regimen he recovered, and remained well until December, 1892, when he began to suffer with epigastric pain, especially after eating, shortness of breath, and swelling of the feet. These symptoms persisted, and in February, 1893, he came to Philadelphia for treatment. During the journey eastward he was taken very ill at St. Paul, and was confined to bed two weeks with increased edema and a palpitating and severe aching pain in the back. On his entrance to the hospital we found him in the state described, and detected on examination a loud to-and-fro aortic murmur that completely obscured the heart-sounds. The vessels of the neck pulsated violently; the pulse was quick and collapsing. In short, the evidences of extreme aortic regurgitation were unmistakable. The urine was scanty, high-colored and dense; there was considerable albumin and numerous hyaline and slightly granular casts, with some blood-cells.

The man remained in the hospital from February until the middle of June, during which time his condition was much the same, though at times there was great improvement. The urine cleared up to such an extent that albumin disappeared entirely for a time, and casts could not be found. In addition to the general condition described there were frequent attacks of most alarming cardiac asthma and cyanosis, which after great difficulty proved controllable. In June he was so much better that he was enabled to return to his mother's home in Indiana, and during the summer he was quite comfortable. Indiscretions and neglect of treatment led to a relapse of his previous bad state, and he returned to Philadelphia in September. There were now, as before, great dyspnea, dropsy of the legs, palpitation, throbbing of the vessels, and frequent attacks of cardiac asthma and cyanosis. The urine was still

greatly lessened in quantity, and albumin and casts were abundant. No important changes were noted, excepting occasional improvement and subsequent relapses, until September 7, 1894, when he was suddenly taken with a severe chill, which lasted for a half-hour and was followed by copious sweating. No change in the heart-signs was detected on a careful physical examination, and the temperature regained the normal in thirty six hours. Subsequently a number of chills, with sudden elevation of temperature, occurred, and during several of these the patient suffered agonizing abdominal pains. The urine became loaded with albumin, then hematuria set in, the spleen became enlarged and tender, and the patient's general condition left no doubt as to the occurrence of embolism of the kidneys and spleen and of a general septic condition, probably from malignant endocarditis. The heart-signs remained unaltered. Finally wild delirium led on to coma, and the patient died October 25, 1894.

The treatment of this case was most instructive. In spite of the serious nature of the cardiac lesion and of the kidney-complication, the improvements under treatment were at times simply marvellous. During the early part of 1893 his condition was so serious that members of his family were summoned from Indiana, and his death was expected hourly. The urine was reduced to from eleven to fifteen ounces, and was loaded with albumin; the pulse was extremely feeble, and attacks of asthma and cyanosis followed each other in rapid succession; a large part of the time the patient was stuporous; yet, in spite of all this, improvement slowly manifested itself, and he recovered sufficiently to leave the hospital in June.

The most serious condition, the attacks of asthma and cyanosis, persisted in spite of every treatment until morphin and atropin were administered hypodermically. These remedies were at first used with great reluctance, on account of the diminished renal secretion and the albuminuria; but finally were forced upon us by the serious character of the asthmatic attacks. Subsequently morphin was used almost continuously, and often in large quantity. During the period from January 1st to March 14th, 1894, the total quantity of morphin administered hypodermically was 294 grains, or a daily average of about 3.5 grains. During February alone the quantity was 156 grains, or over 5.5 grains per day. The greatest quantity used (during one of the embolic attacks) was 18 grains; the least, 2.5 grains. At no time did the morphin in any way affect the secretion of urine noticeably; on the contrary it seemed that the general relief afforded rather tended to favor renal secretion. Sweating was always copious, but no distinct influence could be traced to the morphin, and with aortic regurgitation the symptom was not unexpected.

The most striking feature in the treatment of this case was the influence of calomel. This drug was used repeatedly with the most decided benefit. Under its influence there was invariably a great increase in the quantity of the urine secreted, and, in consequence of this, relief of dropsy and of the general symptoms. This effect was obtained only when the dose of calomel was a large one, and never lasted more than a week or ten days. Minute doses of calomel, gr. $\frac{1}{40}$, given hourly, failed entirely; larger doses were efficient in proportion to the dose, the greatest daily excretion, 140 fluidounces, occurring under the influence of three-grain doses administered every six hours. Scarcely less notable than the tolerance of the patient for morphin was his tolerance for calomel. During one period of three weeks he was given 210 grains of the drug, or about 10 grains daily, without the slightest indication of mercurialization, in spite of the fact that for weeks before smaller quantities had been administered almost continuously. The diuretic action is, perhaps, best illustrated by the following extracts from the notes:

These tables show graphically the very powerful diuretic influence of the drug in this case, how under large doses the amount of urine increased immemediately, and maintained itself at a high figure for several days, only to fall as rapidly as it rose. It was equally evident that the drug was most active when dropsy was marked and when the bowels were kept in check. Rarely ever in this patient was there the least tendency to purgation. This is partly due to the large quantities of morphin administered; but from the comparative ease with which he could be purged with other remedies, this explanation does not suffice. There was undoubtedly a tendency rather to diuresis than to purgation under the influence of calomel in this patient. Whether the existenee of dropsy plays a part in this modified action is unsettled. Certainly it would appear that calomel increases diuresis in dropsical patients, by causing absorption of serum and rapid elimination by the kidneys. The recent cases of Palma are interesting in this connection. In six cases of cirrhosis of the liver, with ascites, large doses of calomel proved actively diuretic in four, the two negative results being in well-advanced cases. In one case of secondary carcinoma of the liver with ascites the drug acted most powerfully, and the ascites rapidly disappeared. In two cases (hypertrophic cirrhosis and carcinoma of the bile-ducts) without ascites, on the other hand, little or no diuretic influence was noted. The rapid loss of the diuretic power is rather peculiar to this drug, but was so constantly noted in the case reported, and has been so uniformly observed by others, that it seems an established fact. After a few days' interval the calomel acts as effectively as before. The dose should be not less than one grain every three hours, and the bowels should be controlled by opium. Constant use of antiseptic mouth-washes, no doubt, contributed to the avoidance of stomatitis in this case, and should never be neglected.

Other diuretics, such as diuretin, spartein, digitalis (this, however, was used almost continuously) were active to a degree, but far less efficient, and sometimes attended by unpleasant symptoms. Diuretin, in ten-grain doses, was the most active, but caused headache and vomiting and had to be discontinued. The patient died in apparently a septic state and with symptoms of heart-failure. The autopsy showed distorted and agglutinated aortic leaflets, without much thickening or calcification. Recent malignant endocarditis of the mitral and aortic valves was detected. The heart-cavities were filled with somewhat dense thrombi clinging to the trabeculæ and chordæ tendineæ. The kidneys presented the lesions of an old nephritis, together with recent congestion and hemorrhagic infarctions. The spleen was enlarged and contained fresh infarcts. The liver was large and fatty; the lungs congested posteriorly, and the other organs normal.

MYXEDEMA AND ITS DIFFERENTIAL DIAGNOSIS FROM CHRONIC NEPHRITIS.

BY M. ALLEN STARR, M.D., PH.D.,
PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING NEUROLOGIST TO THE PRESBYTERIAN AND ORTHOPEDIC HOSPITALS.

THERE are very few diseases that have excited more interest in the medical world within the past decade than myxedema, and there are very few discoveries in the domain of therapeutics that have been so brilliant as the treatment of this disease by thyroid extract. The history of the discovery of the remedy reads like a novel. The clinical features of the disease were carefully determined by a committee of the Clinical Society of London in 1889, but its origin remained unknown. The observations of surgeons, that a similar affection followed the removal of goiter, gave the first clue to the origin of the clinical symptoms. The brilliant researches of Horsley, by means of physiologic experiment, determined the function of the thyroid gland in maintaining the body-temperature and the nutrition of various parts of the system, and proved that the absence of the gland caused the symptoms of myxedema. Finally, the idea developed of transferring to the human body the thyroid glands of animals, either by direct transplantation (Horsley and Kocher) or by subcutaneous injection (Murray) or by ordinary administration by the mouth (Mackenzie), for the purpose of removing the symptoms of myxedema, which were due to the absence of this substance from the blood. The success of this method completed the history of the affection.

Those who have seen the very distressing physical and mental symptoms occurring in myxedema rapidly and progressively disappear under the administration of thyroid extract, until the patients are restored to perfect health, cannot but be impressed by the wonderful effect that the presence of this active principle in the blood has had. It has been my fortune to watch this transformation from a state of disease to a state of health in fourteen adults. The histories of several of these cases have been already published by myself[1] and by others.[2]

[1] Transactions of the Association of American Physicians, 1893, vol. viii, p. 361, three cases.

[2] Dr. George W. Crary, American Journal of the Medical

My object in reporting another case at this time is to call attention to certain features of myxedema that closely resemble the symptoms of chronic nephritis and to emphasize the importance of the distinction between these two diseases. This can hardly be exaggerated, for many of the cases of myxedema that are now cured had been considered cases of nephritis of an incurable nature, a mistake easily accounted for when we consider that the presence of albumin and of casts in the urine, together with an appearance of general edematous swelling of the body, is uniformly noticed in this disease. After recording the history of the following case an attempt will be made to indicate the chief points of differential diagnosis.

Fig. 1.

Fig. 2.

G. W. H., aged forty-five, had been perfectly well until the early part of 1892, when without any known cause he began to suffer from a gradually increasing swelling of the hands, face, nose, mouth, and tongue, which was accompanied by the appearance of a yellow pigmentation upon the hands and face and a decided thinning of the hair. This condition gradually increased during the summer, and he found that he was unable to perspire, no matter how hot the weather. During the autumn, in addition to the symptoms mentioned, he noticed that his teeth were loose, that the gums were sore, bled quite frequently, and seemed to be soft; that the swelling of the mouth and tongue had become so great as to materially change the character of his voice, making talking monotonous and decidedly slower; and that the swelling also interfered with breathing easily through the nose, so that he kept his mouth open, and at times had some difficulty in swallowing. As winter came on he suffered more from the cold than he had ever done previously. The swelling had by this time gradually extended over the entire body, giving him the appearance of being rather fleshy, so that his tailor had to let out his clothing an inch-and-a-half about the waist. The appearance of his face during this time had progressively altered, and presented certain peculiarities; the hair of the head had become coarse and rather thin; the hair of his moustache was also coarser than formerly and had become bristly, so that it could not be kept smooth as formerly; the skin of the entire face was thickened and pigmented; this was particularly noticeable about the forehead, where deep wrinkles appeared, and around the eyes (which could hardly be opened to their full extent), and about the mouth, where the lips were thick and heavy; there was a peculiar elevation of the external corner of the eyebrows in the effort to open the eyes; and a thickening of the face at the side of the nose was very perceptible. His extremities were also swollen and pigmented; the skin all over the body was dry and scaly. His friends had noticed the slowness of his speech and the peculiar thickness of utterance. Many of these characters are well shown in his photograph (Fig. 1), which was taken in May, 1894.

The diagnosis of myxedema was made by his physician in San Francisco, in September, 1893, and the thyroid treatment had been begun about that time and kept up until May, 1894, when I first saw him. Whether the preparation used had been defective or imperfectly prepared I do not know;

Sciences, April, 1894, two cases: also, Dr. S. J. Meltzer, N. Y. Medicin. Monatschr., April, 1894, one case.

but his improvement had been slow, though perceptible, during the winter. When I saw him in May I observed, in addition to the symptoms and appearance already noticed, very marked supraclavicular swellings, slightly subnormal temperature, a marked slowness mentally, attended by a tendency at times to feelings of depression and the characteristic speech of myxedema. He had not had hallucinations, and the mental hebetude was less than I have seen in other cases. Examination of the urine showed the presence of small amounts of albumin and a few large and small hyaline casts; his pulse was slow—60—and rather hard and irregular. He felt himself unfitted to do business by reason of his condition, and though not suffering any pain, was decidedly uncomfortable and distressed at his state. He was placed immediately upon the 5-grain tabloids of thyroid extract prepared by Burroughs, Welcome & Co., of London, these having proved to be the most active and least disagreeable of all the preparations of thyroid which I have employed. He was given three a day, but this number caused a rise of temperature and a rapid action of the heart, and hence the dose was reduced to two daily. During the following month his progress was very rapid, and the change in his appearance was extraordinary. All the symptoms gradually disappeared, excepting the pigmentation of the face and hands; the swelling subsided everywhere, so that at the end of the month he was wearing a number fifteen collar instead of a seventeen, and all his clothing was too loose; his facial expression had altered greatly for the better, and was almost like that shown in Fig. 2, a photograph taken in September, 1894. This photograph shows the remarkable change in the general appearance. There has been a corresponding change in his general feelings and in his mental capacity; he is now able to do business of an active kind with his usual ability. His voice has become natural, he has no disturbance in swallowing or breathing, and in fact, is in his usual state of health. Within a month of the beginning of treatment the albumin and casts had entirely disappeared from the urine, and there was present no evidence of any disease of the kidneys. The only unfavorable symptom that has been noticed during the course of treatment has been a marked effect of the thyroid extract upon his heart; the pulse has been persistently rapid and irregular, and he has suffered from a sense of weight and distress in the region of the heart and dyspnea on any exertion. This had never been present until the thyroid extract was used. It increased to a point of great distress when the thyroid was increased beyond fifteen grains daily, and it became less when the thyroid was stopped. He finds it necessary to take three grains of the extract, however, as, if he stops for more than two weeks, his symptoms begin to return. The distress did not appear to be very much affected by heart-stimulants and by strychnin, which were administered from time to time with a view of correcting this depressant action of the remedy. It is, of course, necessary for him to continue indefinitely the use of the thyroid extract, as this supplies to his blood an element, the absence of which produces all his symptoms.

The general appearance of patients suffering from myxedema—their cachectic look, yellowish color, and swollen faces and extremities—suggests to the ordinary observer a condition of nephritis. When the history of gastric distress and indigestion, of general malaise and fatigue on slight exertion, of headaches and mental incapacity, of insomnia, and of general edema is heard, the first suspicion is likely to be strengthened. And when the examination of the urine shows albumin and hyaline casts it seems as if the diagnosis of chronic nephritis was perfectly certain. I have made this mistake myself in two cases, and have known it to be made by some of the most accurate diagnosticians in this country before myxedema became as familiar as it is at present. Yet unless a physician has examined and studied patients suffering from myxedema he may be quite liable to this error, and hence I desire to call particular attention to the points of differential diagnosis between myxedema and chronic nephritis.

(To be concluded.)

TREATMENT OF TYPHOID FEVER.[1]

BY CHARLES W. DULLES, M.D.,
OF PHILADELPHIA.

THE recent appearance of articles on the treatment of typhoid fever advocating principles similar to those that have impressed themselves upon me in the course of my practice prompts me to present the views on this subject that I have come to hold after nearly twenty years of observation and experience. Though these impressions differ in some ways from those that are strongly urged by certain writers on typhoid fever, I present them with confidence, because I see in various places that opinions I once held with hesitation, as unorthodox and somewhat hazardous, are held by others, independently drawing conclusions from their own experience.

My experience in the treatment of typhoid fever has ranged from cases so mild as to leave some doubt in regard to the diagnosis to cases so severe as to be marked by hemorrhages from the bowels, kidneys, and lungs, with delirium and collapse; so that I have had sufficient opportunity to test the teachings of others and the deductions from my own observations since my student days.

The principles of the treatment of typhoid fever may be summarized, I think, as consisting in: first, careful maintenance of the natural processes of excretion; second, the judicious administration of food—finding a mean between starvation and overloading the alimentary canal; third, moderate regulation of temperature; and, fourth, medication

[1] Read before the College of Physicians of Philadelphia, November 7, 1894.

reduced to the lowest possible point and shaped to meet definite indications. Nothing in these principles is novel; but I do not think the text-books put them as forcibly as might be done with advantage to students and young practitioners.

In regard to the first matter, I would say that the views in regard to auto-intoxication, expressed by Bouchard at the International Medical Congress held at Geneva, in 1877, impressed me at that time as being of very wide applicability. He applied them especially to typhoid fever, in which disease, if ever, we have an accumulation in the intestinal canal of material which taxes to the utmost the powers of elimination possessed by the patient. Here, if ever, we need to see that no interference with the process of excretion takes place, but that, on the other hand, aid shall be given to the excretory function of the lungs, the skin, the kidneys, and the bowels. For the lungs, we need fresh air, with careful avoidance of undue chilling; for the skin, we need, again, abundance of fresh air, judicious management of bed and body coverings, and the application to the skin of some form of hydrotherapy. To the kidneys unremitting attention should be given in every case of typhoid fever. The urine should be examined often for albumin and for tube-casts; and in every case the quantity of liquid drunk by the patient and the amount of urine passed should be known. I believe that much of the delirium of typhoid fever might be avoided if the kidneys were considered as carefully as the intestines. During the entire progress of a bad case the tendency of the urine to hyperacidity should be combated by the free use of water and dilute alkaline solutions. From my experience I should say that the best form of the latter is the solution of ammonium acetate with the addition of potassium acetate.[1] I have found it desirable, also, in these cases to induce patients to drink water freely, by giving it to them in forms which are agreeable to sick persons as well as to well ones: for example, carbonated waters, or plain water slightly acidulated with lemon-juice, or weak tea, hot or cold, flavored with a little lemon-juice and sugar, in the manner so widely known as "iced tea."

Of the various modes of elimination, I have chosen to refer last to that from the bowels, because it is in some respects the most important and in some respects the most neglected. My own observation leads me to think that too great fear is sometimes felt for the diarrhea of typhoid fever. This diarrhea is the result of Nature's efforts to get rid of material that is injurious to the patient; and I believe, on the one hand, it would be less likely to occur if the physician secured proper evacuations from the bowels before the diarrhea began, and, on the other hand, that lives are sometimes sacrificed in a desire to check it. This endeavor seems to overlook the indications furnished by the natural course of a case of typhoid fever, as well as the principle that the contents of foul cavities in the body—whether these be natural cavities, like the pleural cavity or the peritoneal cavity, or unnatural cavities, like those of abscesses—shall be removed. I think it important at the outset of a case of typhoid fever to secure a thorough clearing out of the entire intestinal canal—not merely a single purging, but several moderate ones, which shall quite empty the whole tract. After this I believe that the bowels should be relieved with mild saline laxatives, like Rochelle salts, or with small and repeated doses of calomel, at least every third day, unless the case is one in which Nature provides this form of relief. As for astringents, I think the occasions for their use are extremely few. This is especially true of astringents administered by the mouth. Astringents administered by rectal intubation, I think, are of little more value than simple lavements of the sort now called "enteroclysis," but which the students of Monti became familiar with some twenty years ago in Vienna, where it was called "irrigation of the colon." This I have practised on suitable occasions for seventeen years. Such irrigations are useful in several ways—for cleansing, for cooling, for assuaging thirst—but at this time I do not care to discuss details. The sum of what I believe in regard to elimination from the bowels is that it should be facilitated, and that, instead of attempting to check it, the object should be to regulate what Nature may be doing in an irritating and irregular fashion.

The second important point in the treatment of typhoid fever is, I think, the judicious administration of food. It goes naturally with what has been said in regard to checking Nature's efforts at elimination, to say that Nature should not be harassed by having burdens laid upon a weakened and irritable intestinal canal. The teachings of physiology and of ordinary common sense are opposed to the introduction into the alimentary canal of a sick person of more food than he can either appropriate or cast out. A healthy person can dispose of a large excess of unneeded ingesta, but a patient with typhoid fever cannot. I am sure I have seen patients killed and others nearly killed by relentless feeding, prac-

[1] To make a preparation of ammonium acetate and potassium acetate that is not very disagreeable, I order a mixture containing one-hundred-and-sixty grains of potassium acetate in three ounces of the solution of ammonium acetate sweetened with one ounce of syrup of lemon. To this I add ten grains of quinin sulphate, and order the mixture to be filtered by the druggist. The dose is a dessertspoonful, taken with a wineglassful of water, about four times a day. The quinin substitutes for the mawkish taste of the potassium a distinctly bitter taste, and that part of it (which is considerable) that is not dissolved in the mixture is filtered out, in order to make a better-looking preparation. To each dose I sometimes recommend the addition of a few drops of lemon-juice.

tised by physicians who have, without judgment, followed the teachings of writers who advocate what is called "regular" feeding, and especially with milk-food, in typhoid fever. Forcing patients to take measured quantities of milk at short intervals sometimes results in a diarrhea which shows that Nature repudiates the imposition—the stools resembling those of sick, milk-fed infants. At other times, when milk is given, the milk-water and salts are absorbed while the casein remains undigested and accumulates in the lower bowel until a condition of coprostasis is set up, in which the patient is subjected to the dangers of total obstruction to elimination from the bowels and to horrible pains and violence when the mass of solid feces is finally expelled by an act of Nature or by the stimulation of cathartics.

An error of another sort is committed when certain extracts of beef are administered with the idea that they are highly nutritious. To support this belief there are, I think, only an untenable theory and deductions which the facts do not warrant. I feel sure that the advantage to patients of preparations such as Valentine's meat-juice is chiefly that they are so costly that not much is likely to be given, and that they contain so little tissue-building material that they do not oppress the digestion or overload the intestinal canal. Such food probably contains, bulk for bulk, less tissue-building material than is found in the white of a chicken's egg, and is equally innocent. Beef-tea is now generally recognized as a substance which is useful for the same reason, namely, that it does not burden the intestinal canal, while it gives both patient and friends a sense of security which is very desirable in all medical cases. This suggests what I believe is one of the most important points in the management of typhoid-fever cases, namely, that they should be given as little food as possible—not as much as can be forced down them.

My own rule—which I have found has been that of others—in almost all cases of sickness, in young and old, is to say that patients may eat when they wish to, and go without eating when they have no desire for food. I let them drink all they want to, and give them food which shall resemble as little as possible those trying things that remind a patient of his sickness. I give a list of permissible foods, and tell the nurse or members of the family to get up a little meal for a patient who is conscious enough to appreciate it. I sanction the use of the albumin-water already referred to (cool water in which the white of an egg has been stirred up, with the addition of some pleasant flavor), and of almost all clear soups as they are prepared for well persons. I give milk, plain or peptonized, or made more palatable and less constipating by the addition to it of some good preparation of cocoa. I allow tea and coffee, with plenty of cream and milk, which often do good, and which I have never known to do harm if used with ordinary judgment. I have no fear of eggs, and give them whenever a patient with typhoid fever or any other fever wishes them, either soft-boiled or shirred.

Besides this, if I have a patient whose bowels are acting nicely I give custards and simple corn-starch preparations. A patient who can digest anything can digest these foods; and a patient who cannot digest anything will not want anything to eat; and, according to my views, he will require nothing but albumin-water and thin soups.

When we recall, on the one hand, the fact that persons making more or less constant exertions have gone for weeks without food and without serious impairment to their health, and, on the other hand, that fevered intestines are in no condition to do much in the way of digestion, and are capable of taking up only foods which contain finely divided or soluble hydrocarbonaceous substances and albuminoids that make their way through the intestinal walls without digestion, we can, I think, understand that not much food is needed to keep fever-patients from starving, and that this food should be of the very simplest character.

Further, when we reflect that perforation of the bowels is most likely to occur when the bowels are obstructed and distended with gas, and that this accident does not result from the unimpeded movement of soft fecal matter, but that the intestines are rather advantaged by the internal drainage which such a process secures, we can understand that, while the bowels are not constipated but moving freely, there is no need to restrict a patient to food like milk, which is almost entirely composed of water, and which has but little residue. Because I think this is true, I believe that typhoid-fever patients who have reached the stage in which they feel an inclination for food may be allowed moderate quantities of any soft food, like thick soups (digestible, of course), good fresh fish, and the soft part of oysters, with occasionally sweet-bread or beef's tongue, with eggs, milk and cream. Of vegetables, I think baked or mashed potatoes may be used, and rice and corn-starch preparations, with thoroughly boiled oatmeal and such things as spinach or well-boiled onions and very moderate quantities of toasted bread thoroughly softened with boiling hot water and seasoned, as well as soft milk-toast. For relishes, cocoa, tea and coffee may be used, and, for desserts, jellies, ice-cream, and orange-juice in moderate quantities.

The third point in regard to the treatment of typhoid fever about which I wish to speak is the regulation of the temperature. Views on this sub-

ject have undergone considerable modifications within the time covered by my own experience. At one time the greatest stress was laid upon lowering the temperature of fever-patients. This plan has given way to a more rational one, that recognizes a principle known as long ago as the time of Asclepiades, two thousand years ago—namely, that fever may of itself be a curative process or the mark of a process which is useful. I think the majority of thoughtful medical men are entirely satisfied if a patient presents the general appearance of doing well, even though the temperature be several degrees above 100° Fahrenheit. If a patient is really suffering from high temperature, I think the first attempt to reduce it should consist in having removed the needless bed-covers with which fever patients are often burdened, as the air constitutes one of the best and safest means of properly reducing the temperature. After this, I have found that sponging with cool water, especially upon the abdomen, is pleasant to the patient, and I think it has a distinctly beneficial influence upon the temperature and the inflammation within the abdominal cavity. In some cases I advise that a few light layers of muslin or gauze such as surgeons use be laid upon the abdomen and moistened at times with ice-water gently squeezed from cotton or a sponge. In a few cases I have found it convenient to have such light cloths "ironed" occasionally with a small piece of ice.

My experience with drugs given to reduce temperature by means of their physiologic action has led me to abandon their use; not because I have ever seen them do harm, but because I do not believe they really do good, and I think it better to let the temperature alone as long as it is in bounds, and, if it requires repressing, to effect this with external applications of cool air and cool water. Since I have adopted this plan I have found it to work according to the expression attributed to Asclepiades, namely, "*cito, tuto et jucunde.*"

This suggests the last of the points which I have mentioned as constituting, in my opinion, those most important in the treatment of typhoid fever, namely, that which concerns medication. I am not peculiar in believing that medication should be reduced to the lowest point and that it should be shaped to meet definite indications. As I have already said, I think the bowels should be well opened at the beginning of a case believed to be one of typhoid fever, and that when the diagnosis is established they should be kept open. I have also suggested the use of mild diuretics, the tendency of which is to reduce the acidity of the urine and to increase the solubility of its solid contents. With these procedures, intended to aid elimination, I think it is useful to administer what are known as intestinal antiseptics. These appear to do something which is not yet explained by any laboratory-observations; and, from the time when turpentine was first used until the present time, when it is the rival of modern chemic inventions, intestinal antiseptics have seemed to be of distinct value in the treatment of typhoid fever; for, in addition to their purifying action in the bowel, they appear to exercise a beneficial influence upon the nervous system. Turpentine and its congeners have tonic and stimulating properties in addition to their antiseptic influence, and drugs like salol probably control pain, not only by acting upon the fluids circulating in the bloodvessels and lymphatics, but also by directly influencing the brain and nervous system. I think turpentine and salol are two valuable drugs, if given in moderate quantities and with care that the turpentine shall not be pushed to the point of producing strangury, and that the salol shall not be pushed to the point of producing carbolic-acid intoxication. In certain conditions I think morphin may be used, and should be used, without hesitation. But these circumstances are rare. The bromids (and I prefer sodium bromid) are useful as occasional remedies. So is sulfonal, and so is trional, to control restlessness and to secure sleep, in the absence of pain, on which they have no effect whatever. Phenacetin is also useful with a view to controlling nervous irritability, bearing in mind its effect in producing perspiration. I believe that at times pepsin-solutions, with dilute hydrochloric acid added, are useful as an aid to digestion and the natural processes in the intestines, and not as medicine.

My view in regard to alcoholic stimulants is that they are seldom required, and never in the large quantities sometimes prescribed. There are times when a dose of a teaspoonful of whiskey in a little hot water, repeated every ten minutes, may tide over a short period of weakness or collapse; but I think the administration of such quantities as eight or sixteen fluidounces of whiskey in twenty-four hours is not good practice; while I believe that hot tea or coffee, without cream or milk, may be used instead of the smaller quantities of alcohol just mentioned.

I have not attempted to describe in detail the mode of treating typhoid fever, but only to state the general principles which impress themselves upon me as correct after a reasonable experience. These are, as stated: 1, careful maintenance of the natural processes of excretion; 2, the judicious administration of food; 3, moderate regulation of temperature; 4, medication reduced to the lowest possible point. My object in discussing the subject at this time is not so much to present my own opinions as to put them in evidence in order to strengthen the hands of those who have recently

contended for what I believe is the rational mode of treating this very serious disease.

THE NATURE AND MANAGEMENT OF FUNCTIONAL GASTRIC DISORDERS.[1]

BY CHARLES G. STOCKTON, M.D.,
PROFESSOR OF MEDICINE, UNIVERSITY OF BUFFALO.

IT is said that things are known when understood and understood when interpreted. Concerning the familiar symptom-complex embraced under the term functional gastric disturbances there is much lack of agreement in interpretation, and, therefore, it is concluded that there exists disagreement as to the nature of the pathology in question.

A recent American writer has arrayed these symptoms to explain them as the result of subacute gastritis. One Continental observer attributes the phenomena to an on-coming gastrectasis, and another easily divides the group into a series of special stomach-diseases in which hyperchlorhydria stands forth prominently. Ewald, Rosenheim, and Boas separate the disturbances into irritative forms and depressive forms, and then assign to each abnormalities in motion, secretion or sensation.

Unquestionably there is functional disturbance of the organ in subacute gastritis, and the same holds true of beginning gastrectasis; also there are types that are sufficiently distinct to admit of their description as varieties, and an analysis of these varieties, after the fashion of Ewald and others, leads to a clearer understanding of the nature of gastric neuroses; and yet it would appear as though the subject were open to still another interpretation of which in part it is the purpose of this brief paper to speak.

In the first place, let it be said that the functional gastric disorder is very rarely a primary trouble. In reviewing the records of a series, including between five hundred and six hundred cases of supposed stomach-disease, in which at least one complete examination of the gastric contents was made, in not one instance can it be said that functional trouble indubitably arose from a disturbance that was primarily gastric.

This is not impeaching the possibility of such occurrence. It can be readily seen how overtaxing the stomach alone might eventually induce exhaustion and a consequent seated neurosis. Indeed, perhaps nothing is more important, as a contributing factor, than gluttony; but in point of fact one rarely finds gluttony the essential cause of the neurosis. Something has gone before, or something accompanies the pernicious habit of over-indulgence, and as a joint result we discover the neurosis. It is remarkable that the stomach will tolerate patiently so many insults of a dietetic character, both in food and in drink. True, a subacute gastritis may result, but under a diminished appetite it soon subsides, and no functional disorder follows.

Of course, this statement may be met by quoting the freely-admitted fact that it is the everyday experience for physicians to have patients complain of persistent gastric symptoms resulting from injudicious eating. Quite true. A failing gastric function is usually first made manifest by the overtaxing of that function; but even if overtaxed, that function rarely, if ever, remains weak and perverted from the effect of the indiscretion alone. On the contrary, a healthy organism, after a short period of reaction, congestion—if you please, of subacute gastritis—resumes its customary pace. (Note Beaumont's oft-mentioned observations on St. Martin.)

What, then, are the influences that invite the appearance of the persistent functional disorders of the stomach? The question is one that should arise in the physician's mind with every case that is presented. This paper is intended as a protest that the question is not more frequently raised.

In ratio to one's ability to hunt down and remove the causal factor will be his success in relieving the neurosis, failure in which has come to be an opprobrium. The stomach, like a mirror, reflects pretty nearly every influence to which the organism is subjected. Irritation of the brain, the cord, the testicle, the uterus, the kidney, or the liver, results in anorexia, or perhaps vomiting. Grief, joy, worry, and pain, lead to similar results. When there is toxemia from constipation, or renal or cutaneous insufficiency, or the infections, it is the stomach that raises the alarm. In the cerebral anemia of naupathia, or of a fainting turn, and in the cerebral congestion of sunstroke, the gastric are in the tumultuous front of the anarchistic functions.

One need not go far for explanation of these phenomena. Perhaps no portion of the organism has so complex a sympathetic nerve-supply as the stomach. Robert Ewald's extraordinary exposition of this truth, in his brother's masterly book on diseases of the stomach, is entitled to mention on all occasions. Just why Nature has provided this curious arrangement it would be interesting, but at this time extraneous, to discuss. Enough to say that it exists. Now, of those suffering from these various irritations, any of which, either through toxemia or reflex disturbances, may lead to the gastric symptoms, and if the stomach-contents were examined there would be found no evidence of subacute gastritis, none of the "ropy mucus" that inexperienced men so much talk and write about, and which those who have largely studied gastric contents usually fail to discover; but there would be found testimony that

[1] Read before the New York Academy of Medicine, May 17, 1894.

there had occurred a serious derangement in gastric innervation, exhibiting itself to some extent as excitement, to some extent as depression, and in some instances it is impracticable to say that either of these states predominates.

An attempt at the segregation or the classification of these gastric phenomena appears to me as usually inexpedient, if not unsuccessful. They are mixed symptoms resulting from remote disturbances. Undoubtedly a stomach having such faulty and spasmodic innervation would now resent bad diet, or perhaps any other kind of diet, and yet the trouble is not one primarily of the stomach. It is not that the face of the mirror is irregular, but it is because of the distorted figures reflected from it that the picture is hideous.

If these statements are facts, and if they be applied as guides in traversing the maze of functional disorders of the stomach, it would seem as though they would help us to rightly understand the real nature of those affections.

Let any case of undoubted functional gastric disease be put under examination. There may be eructations of gas or sour fluid (that means insufficiency of the cardia, as a rule); there may be an excess of free HCl (that means a faulty inhibition of the peptic glands, probably); there may be uneasiness amounting to gastralgia (that means undue irritation or hyperesthia, one or both). Now, instead of resting content with this diagnosis, admirable and advanced though it may be, and making for himself limitation in therapeutics that are directed toward immediate relief and really nothing else, no matter how successfully they are applied, the physician is asked to look further, having before him the conviction that there is operating an unthought-of cause that has diverted nervous energy from its ordinary courses and is the present malefactor.

Where will the trouble be found? In the search it is convenient to examine for the possible presence of: *First*, some centric or eccentric nerve-irritation acting reflexly; and, *second*, some toxemia. The nerve-irritation may prove to be some central structural disease or persistent circulatory disturbance, or it may follow excessive mental strain, as seen in actors, school-teachers, and those suffering constant interruptions, or it may be, and in fact often is, accounted for by defects in the organs of special sense, particularly the eyes.

One cannot be unmindful of the doubts that this last statement may arouse in the minds of listeners who have given the question of eye-strain large attention, for it is well-known that observers differ widely as to the importance of ocular defects in the development of functional disorders. I have no contention to make, but a faithful record of personal experience to report.

To leave for the present the matter of the brain and its nerves, it will be found that irritation of the cord, either directly, as from pressure in lordosis, scoliosis, and other sources, or interference with innervation, as in tabes or focal myelitis, or indirectly, as in irritation from hysterical spine, is a common source of gastric disorder.

Further than this, the mischief may be lurking in the genito-urinary apparatus. Not alone the uterus and ovaries, but the urethra, the meatus, and the prepuce should be critically examined. A frequent and generally overlooked cause of the disturbance exists in ureteritis, to which attention has been especially directed by Dr. Howard Kelly and by Dr. Matthew D. Mann. Wandering and movable kidney and renal irritation from hyperlithuria belong to the list. It is not intended to catalogue all the known reflex causes of functional disturbance, as the subject is too trite, and perhaps the array is already redundant.

There now remains to be considered the influence of toxemia in the production of gastric disturbances. One of the most common and most important forms results from defects of the kidneys, either dependent upon nephritis or upon functional inadequacy of the organs, a subject fully discussed by Sir Andrew Clark, Casper A. Peyer, and others abroad, and by Rochester and Allen Jones in this country. So alcohol, tobacco, coffee, and other substances may induce digestive disturbance indirectly through the blood and nervous system. Malaria, gout, and tuberculosis often offend in the same manner.

Not to be prolix, there is another potent, and, it is believed, hitherto an undescribed cause of functional gastric disorder doubtless operating through the medium of the blood. Reference is had to the very late phases of syphilis. The patients usually give a history of an ancient infection, with presumably the usual routine of medication. In several there is a history of healthy children. As a rule, there is an absence of the ordinary tertiary lesions, although the skin is usually muddy, and in some there exists a moderate anemia. In the series already mentioned, representing over five hundred cases in which the stomach was minutely studied, there were twelve whose gastric symptoms depended upon late syphilitic toxemia. Only one of these, a gentleman residing in this city, improved upon ordinary treatment. Fully one-half failed to improve after such treatment was faithfully tried, but all of them made immediate, prompt, and lasting improvement when given ascending doses of potassium iodid, and with one exception all have been discharged on no other than syphilitic treatment, the other measures having been abandoned. It is interesting to note that in these cases there occurred but little disturbance in secretion. The complaint

was of sensory and motor symptoms—gas-eructations, nausea, distress after eating, and frequently more or less gastralgia. This account has been somewhat amplified, because the conclusions are believed to be new.

In reviewing the multitudinous causes of functional gastric disorders it would be interesting to analyze with a view of determining whether or not given irritations, particular reflexes, and special forms of toxemia produce uniform and distinct varieties of gastric neuroses. So far as this matter has been studied the answer must be in the main no. However, there is ground for believing that in a few instances with a pronounced given reflex irritation there will probably result functional failure along certain lines. An example may be given, but as a preliminary the belief should be stated that long-continued functional perversion leads invariably to structural change.

Now as to the example:

Your distinguished fellow, Dr. Max Einhorn, in 1893 first described, under the title "Achylia Gastrica," a most important condition of the stomach, that was later described by Dr. Allen Jones as "Gastric Anacidity." Now, of the cases reported by the latter, together with several others included in the series already mentioned, the majority have been examined as to the existence of eye-strain. Without a single exception in the cases thus investigated there has been found to exist a definite, and relatively speaking, uniform ocular defect, viz.: unsymmetrical astigmatism of high degree, varying from one to five diopters. It should be noted that there was an absence of the slight astigmatic faults, such as are reported to be responsible for so much headache. Also, that the present ametropia was irregular, such as myopia in one eye and hyperopia in the other, besides a lack of correspondence in the axes of astigmatism. Obviously no claim is made that these ocular defects are generally followed by "Achylia Gastrica;" but it is true that in every case of this form of gastric trouble in which an eye-examination was made ametropia of the forms described was found present.

Letting repose the eye-question and asking a moment's attention to the stomach-disease under consideration, the opinion is ventured that in "Achylia Gastrica" we have to do with an affection that in the beginning is often a mere functional disturbance. The long-continued inhibition of the peptic glands is succeeded by atrophy, and what is at first an amenable condition terminates in structural change and is persistent. The history of the patient is not one of acute or chronic gastritis, but one of long and troublesome functional derangement. These cases have been followed through the very transitional stages and, as it were, taken *in flagrante delicto*. Here seems to be evidence of the truth of the assertion that long-continued functional disturbance leads to change in structure.

The etiology of most cases of gastrectasis is involved in the history of functional insufficiency. Many believe that peptic ulcer has often a neuropathic origin. It is highly probable, then, that sometimes, as a result of functional disturbance, chronic gastritis may be established. The successful management of functional disorders of the stomach, therefore, includes not only an intelligent special treatment of this condition and correction of the diet, as indicated by the precise study of the stomach and its contents, but also the discovery and removal of the cause, and that cause is frequently remote from the organ in question.

To recapitulate it is held that:

1. Functional gastric disorders generally arise from influences outside the stomach.

2. Those causes are usually to be found in some reflex irritation or some toxemia.

3. Amongst the latter syphilis occasionally has a place that apparently has passed unnoticed.

4. Structural changes in the stomach are not so much the causes as they are the results of functional disorders.

5. The successful treatment of these affections must include the removal of the often unsuspected exciting cause.

THE TREATMNT OF TUBERCULOSIS WITH YEAST-NUCLEIN.

By VICTOR C. VAUGHAN, M.D., Ph.D.,
of Ann Arbor, Michigan;
Professor of Hygiene and Dean of the Departments of Medicine and Surgery in Michigan University.

I closed my paper on "The Nucleins and Nuclein-therapy," read before the Michigan State Medical Society last May, with the following paragraph: "I have been using nuclein in the treatment of tuberculosis in man since the 1st of May, 1893. At first I employed only yeast-nuclein, but now now I am using spleen-nuclein in some cases. When sufficient evidence has been obtained, either to reject or to recommend the treatment, the results will be communicated to the profession. I may say, however, that only in initial cases may we expect any benefit, and even in regard to these I must have more abundant material and a longer experience before I can speak with any certainty."

Since the reading of the paper mentioned several articles on nuclein and nucleinic acid have appeared, and Professor Kossel, of the University of Berlin, has applied for and has received in Germany a patent on a process of manufacturing nucleinic acid.

In this paper I shall deal only with my own observations and experiments, and, in order that my statements may be properly connected with those

that I have previously made, I repeat the most important conclusions that I have reached and stated in preceding papers. These are as follows:

1. The nucleins and nucleinic acid are powerful germicides. This was first shown in a paper by McClintock, Novy, and myself, published in THE MEDICAL NEWS of May 20, 1893. Additional facts on this point were given in my address before the Medical Section of the Pan-American Medical Congress and published in THE MEDICAL NEWS of October 7, 1893. This work was confirmed in a paper published by Kossel in February, 1894.

2. The germicidal constituent of the serum of blood is a nuclein. This was shown in a paper by McClintock and myself, read at the Pan-American Congress and published in THE MEDICAL NEWS of December 25, 1893.

3. Rabbits and guinea-pigs may be protected against virulent cultures of the diplococcus of pneumonia by previous treatment with hypodermic injections of a solution of yeast-nuclein.

4. The immunity thus secured is not due to the action of the nuclein as a germicide directly.

5. The process of securing this immunity is an educational one, and most probably depends upon the stimulating effect of the nuclein upon some organ whose function it is to protect the body against bacterial invasion.

6. The longer the nuclein-injections are continued and the more frequently they are administered, the more complete is the immunity secured.

7. In order to obtain this immunity, the inoculation with the germ must follow soon after the last treatment with the nuclein.

8. Attempts to render guinea-pigs immune to tuberculosis by the methods so far employed show that previous treatments with nuclein retard, but in the majority of cases do not prevent, the development of tuberculosis from subsequent inoculations.

9. Attempts to arrest tuberculosis already developed in guinea-pigs, by treatment with solutions of yeast-nuclein, have been followed by varying results, depending upon the virulence of the germs used in inducing the disease, the stage of the disease when the treatment is begun, and the susceptibility of the animal, especially as influenced by age. Upon this point we have bestowed much time and labor, but the results have been so conflicting that I am not yet prepared to formulate any positive conclusions. I have in my note-book details of experiments upon more than one-hundred pigs, and I feel that I am as little able to speak positively on the subject as I was when the experiments were begun.

10. I have used nuclein with benefit in the treatment of indolent ulcer, tonsillitis, and streptococcus diphtheria.

The preceding condensed statements bring us to the publication of my last paper on the nucleins, *i. e.*, the one read before the Michigan State Medical Society and published in the *Transactions* for 1894.

Taking up the work at this point, I wish to detail work done upon two other points before I proceed to discuss the results which I have obtained in the treatment of tuberculosis in man with yeast-nuclein.

IMMUNIZING RABBITS TO TUBERCULOSIS.

On March 19, 1894, I inoculated rabbits 1, 2, 3, 4, 5, 6, *a* and *b*, with a virulent culture of the bacillus. Animals from 1 to 6 inclusive had had previous treatments with a one per cent. solution of yeast nucleinic acid, as follows:

March	9,	10,	13,	14,	15,	16,	17,	19
Amt. of sol. in c.c.	0.3	0.5	0.6	0.7	1	1	1	1

a and *b* had had no nuclein. All of the animals were half-grown, and weighed respectively: No. 1, 714 grams; No. 2, 724; No. 3, 740; No. 4, 729; No. 5, 647; No. 6, 614; *a*, 709; *b*, 705. On July 6, 1894, I killed No. 6, *a* and *b*. No. 6 weighed at this time 1557. I found a nodule the size of a pea at the point of inoculation. In all other respects this animal was normal. I could find no bacilli in the nodule, which was rubbed up with beef-tea and injected into the abdominal cavity of guinea-pig No. 186, weighing 385 grams. On October 10, 1894, I killed this pig, and I found a nodule the size of a pea at the point of inoculation. Three small tubercles were found in the peritoneum; the omentum and liver were filled with tuberculous nodules. One testicle was tuberculous.

This is an interesting case, showing that the germ, which had not spread in the rabbit, had, when transferred to the more susceptible pig, induced a widespread tuberculosis.

Pig *a* weighed 1030, and *b* 1100 grams. In both nodules as large as filberts were found at the point of inoculation, and smaller nodules in the omentum. On October 10th I killed No. 1, weight 2134. This animal was found to be wholly free from tuberculosis. On October 4th I killed No. 2, weight 2150, which was found perfectly normal. No. 3 was found dead October 2. Post-mortem examination showed a pear-shaped tumor in the omentum. This tumor was three inches long and one-and-a-half inches in diameter at the base. It consisted of three cysts, which contained very fetid pus, in which were found a short bacillus and a large micrococcus. There was no evidence of tuberculosis. No. 4 was killed October 10th, weight 1990. I found a small nodule at the point of inoculation. This was not attached to the abdominal wall, but was in the connective tissue, between the skin and the muscle. I could find no germ. In all other respects this rabbit was normal. No. 5 was killed October 10th, weight 2000, and found perfectly normal.

These experiments indicate that rabbits may be rendered immune to tuberculosis by previous treatments with yeast nucleinic acid.

THE TREATMENT OF RABBITS WITH NUCLEIN.

On May 26, 1894, I inoculated rabbits 1, 2, and *a*, intra-abdominally with a pure culture of the bacillus tuberculosis. Their respective weights were 657, 685, and 547 grams. Nos. 1 and 2 had daily, from May 28th to July 3d, 0.5 c.c. of a 1 per cent. solution of yeast-nucleinic acid; *a* had no treatment. No. 1 was killed October 11, 1894, weight 1390, and found normal in every respect. No. 2 was killed October 11th, weight 1530, and was found perfectly normal. Pig *a* was killed October 11th, weight 990 grams. A nodule as large as a filbert was found in the peritoneum at the point of inoculation. There were many millet-seed nodules in the peritoneum and omentum, one in the left kidney, two on the walls of the abdominal aorta opposite the left kidney, several on the peritoneal covering of the greater curvature of the stomach, a tuberculous mass on the smaller curvature of the stomach, and the liver was dotted with pin-point nodules.

June 8, 1894, I inoculated intra-abdominally rabbits 1, 2, 3, 4, 5, 6, 7, and *a* and *b* with a pure culture of the bacillus tuberculosis. These animals were only a few weeks old, and their respective weights were respectively 365, 335, 327, 405, 415, 430, 385, 350 and 375 grams. No. 1 had daily,[1] from June 11th to September 25th, 0.5 c.c. of ½ per cent. of yeast nucleinic acid.

These experiments convince me that when the treatment is begun within three or four days after the inoculation, the development of tuberculosis in rabbits may be prevented by yeast-nucleinic acid. These experiments will be repeated, and the length of time between the inoculation and the beginning of the treatment will be increased.

[1] The statement that these treatments were given daily needs some modification. My assistant, Mr. Perkins, who administered these treatments, gave up his vacation to the work, and, had it not been for his untiring perseverance and sacrifice of time and labor, I could not make this report. But he could not attend to this every day, and during the time mentioned there were eighteen days in which no treatment was given. No. 1, now weighing 1337, was killed October 5. Examination showed no abnormality. Nos. 2, 3, 4, 5, 6 and 7, having had the same treatment as No. 1, were also killed October 4. Their respective weights were 1400, 1410, 1295, 1425, and 1395 grams. No. 2 had coccidia in the liver, but no tuberculosis. No. 3 was normal. No. 4 had a millet-seed tubercle in the right inguinal region. This contained bacilli. No other abnormality could be found. No. 5 had a millet-seed nodule in the omentum, in which no germs could be found. Otherwise it is normal. No. 6 had coccidia in the liver, and one pin-head tubercle in the omentum, in which no germs could be found. Otherwise it was normal. No. 7 was normal in every respect.

Pigs *a* and *b* were killed October 5, their respective weights being 1488 and 1320 grams; *a* had a tuberculous nodule as large as a cherry-seed at the point of inoculation, and numerous smaller ones in both the greater and the smaller omentum. The liver contained several nodules as large as split peas, and a few were found in the diaphragm. The right kidney was tuberculous. *b* showed diffuse tuberculosis in the abdominal walls for one-half inch around the point of inoculation. There were two nodules in the omentum, and the liver was thickly dotted with pin-point tubercles. The other organs were normal.

YEAST NUCLEINIC ACID IN TUBERCULOSIS IN MAN.

In reporting my observations on this point, I am beset with certain difficulties. In the first place, the solutions used during the first six months were by no means free from other proteid material, and the exact amount of nucleinic acid in them was not known. In the second place, I had an idea in the first part of my work that the efficiency of the nucleinic acid would be increased by administering it in a strongly alkaline solution. This idea was founded upon the experiments of Fodor, who has shown that certain animals are rendered partially immune to anthrax by increasing the alkalinity of the blood. However, a condition may be protective to an animal against one disease, and without influence, or even detrimental, in another disease. McClintock has recently made one series of experiments in which a number of tuberculous guinea-pigs were treated with hypodermic injections of a solution of sodium carbonate, while others inoculated at the same time with the same sputum were left without any treatment whatever. The results showed not only that the treated animals died before the untreated ones, but the treated ones showed a much more extensive tuberculosis than we have ever before observed in animals dying from inoculation-tuberculosis. These experiments will be repeated, and should the results be confirmed we must conclude that the administration of an alkali diminished rather than increased the efficiency of the nuclein-treatment.

In the cases most recently treated I have, of course, attended to many details that I have ascertained to be important, and of which I was formerly ignorant. Moreover, I have improved the preparation of the nuclein. I also now refuse to employ the remedy in advanced cases in which I know it can be of no service. By carefully examining the sputum of every person who comes to me with a cough, and by testing every sample of urine that contains any pus or blood for the bacillus, I have detected the presence of the disease in its earlier stages. Consequently, the results obtained during the past twelve months have been more satisfactory than those of the earlier months.

(To be concluded.)

Hypertrophic Cirrhosis of the Liver in a Boy of Fourteen.—MIRINESCU (*Rev. des Maladies de l'Enfance*, October, 1894, p. 560) has reported the case of a boy, fourteen years old, who had drunk considerable quantities of alcohol, and had also been exposed to malarial fever, and who presented enlargement of the liver and of the spleen, with peritoneal effusion, pronounced icterus, and enlargement of the veins of the abdomen. There was an absence of actual symptoms of alcoholism, and the condition was diagnosticated as hypertrophic cirrhosis of the liver, and ascribed to chronic malarial intoxication.

DEPURATION AS A THERAPEUTIC PRINCIPLE IN THE TREATMENT OF NERVOUS AND OTHER AFFECTIONS.

By ROBERTS BARTHOLOW, M.D., LL.D.,
of Philadelphia;
Emeritus Professor of Materia Medica, General Therapeutics, and Hygiene in Jefferson Medical College.

The publication of *Armstrong on Purgatives* early in this century made a deep impression on the medical practice of the time, and its influence may still be traced in such phrases as "unloading the chylopoietic viscera," "changing the secretions," etc. The principle of depuration, as well as of derivation, was then distinctly recognized, but in our day physicians have been so occupied with the results of chemic and biologic research as to be hardly sufficiently mindful of the great truth embodied in this phrase. It is the purpose of this paper to show the importance in therapeutics of this principle.

First, as to the method: It consists in the exhibition of remedies acting on the organs of excretion, to secure elimination of accumulated waste products, and of various poisons, organic and inorganic, produced in or finding admission to the human body. The remedial measures in question are full doses of the iodids carried to the point of saturation, of pilocarpin in sufficient doses to set up its physiologic actions on the glandular apparatus of the whole internal and external integuments, and of purgatives and diuretics according to circumstances. The combined effect of these remedies is to set in motion the organs concerned in elimination and excretion. We know that the iodids form soluble combinations with the metals, which are then reabsorbed into the circulation and eliminated. We know that pilocarpin secures the excretion of waste products through the glands of the skin and mucous membrane. It is within every one's knowledge that suitable purgatives and cholagogues procure the expulsion of the complex products of intestinal fermentations, and also, by means of salines and diuretics, we can increase the functional activity of the kidneys, and thus effect the elimination of the waste materials of tissue-metamorphosis.

Second, as to the conditions requiring the depurative method: It is an indisputable fact that numerous and subtile influences of a pathogenic kind, only in part ascertained or even suspected, affect every individual in these days. Morbid states are produced not only by minute organisms, but many mineral and vegetable poisons are formed by various processes in the arts, and supplied through the agency of the conveniences of life. Metals, especially lead, zinc, copper, tin, etc., are much employed in the conveyance of water and in culinary operations, and, although their grosser effects are recognizable, they sometimes cause remote and unexpected changes that elude our means of investigation. Volatile metals are cast into our atmosphere by manufacturing establishments, and metals are deposited in the tissues in insoluble forms in the course of medical treatment, and the results are equally obscure. Gaseous poisons formed by animal and vegetable decomposition are freely inhaled with the air, and minutely divided solids find access to the system in the same manner.[1] Ptomains are generated in the intestinal canal, and organic poisons, the products of the physiologic activity of pathogenic organisms, are formed there also in quantity. Other sources of possible contamination might be mentioned, but these must serve our purpose, which is merely to indicate the fact that depurative treatment has its reason in some obvious conditions, and in others that are suppositious merely, yet probable.

According to the plan here suggested, we prepar the way for the curative action of our remedies, and sometimes, indeed, obtain immediate curative results. To illustrate the manner in which the method acts, the case of syphiloma of the brain may be cited. The routine treatment of gummata, as all the world knows, consists in the exhibition of massive doses of the iodids and mercurials; but it sometimes happens that the best-directed efforts fail, we may suppose, for lack of preliminary or contemporary depuration. Not long since I saw in consultation a case of gummata at the base, with the well-known signs of interference with the cranial nerves, and epileptiform seizures, in which, notwithstanding the usual remedies had been diligently applied, they did not produce the expected results, but soon yielded when pilocarpin was simultaneously administered. The abundant perspiration diminished the intracranial pressure, and the increased excretion of the organs concerned in this function brought about absorption of the products of the specific inflammation. The action of pilocarpin may be regarded as a substitute for the decoctions and the baths, so long held to be of sovereign efficacy in these affections. By means of it we can readily obtain that eliminant action which was formerly supposed to be excited only by measures of a complicated and troublesome character.

To illustrate the character and success of the depurative method in question, I submit some cases treated in this way.

A gentleman of sixty-four years began to have the evidences of a commencing hemiplegia of the left side, with some sensory disturbance of the right. He is of fine physique, weighs 180 pounds, is active in his habits, and free from the usual vices,

[1] A few years ago there was found in the air of this city dust derived from the destruction of an island in the Pacific by an earthquake.

except that he smokes rather too much. For several months he had felt himself declining in strength, became unable to walk, lost his breath on slight exertion, experienced a good deal of headache, and hebetude and uncertainty of mind.

On objective examination the following symptoms were developed: An evident paresis of the muscles of the left side of the face, the labio-nasal fold being nearly obliterated on that side; the upper and lower extremities of the left side were weak, the reflexes rather heightened, and the senses of touch, pain, and temperature were less active than the normal; on the right side he experienced some sensory disorders; the tongue was protruded to the right, and there was some tingling of the tip of the tongue and of the lips; speech was slow and somewhat thick; the pupils were sluggish; hearing was dull; respiration was labored on even slight exertion; the action of the heart was weak and the sounds reduplicated; appetite was indifferent and digestion labored; he was constipated; the urine contained 0.5 per cent. of albumin, and was rather diminished in amount. The point of chief concern was the condition of his mind. His faculties had become somewhat clouded and he had experienced great difficulty in writing a letter, making wrong use of words and omitting words, so that he had been compelled to give up his correspondence.

In considering the case with a view to a therapeutic diagnosis, the character of the changes in the organic substratum seemed rather obscure. The nature of the etiologic factors was also not readily determined. There had been no rupture of an intracranial vessel and hemorrhage; there were no signs of an embolus, and little evidence of arterial degeneration, although capillary thrombosis from endarteritis might be suspected. There were signs, however, of insufficient excretion, of accumulation of waste products, for, notwithstanding the predominant symptoms were unilateral, there were some bilateral, showing that the causative conditions were general in operation also. The most obvious necessity was to put in action the various organs of elimination. Accordingly I prescribed scruple-doses of sodium iodid four times a day until iodism appeared, and pilocarpin hydrochlorate, ⅛ grain, every night, to be increased if necessary till free diaphoresis occurred. A mercurial purgative began the treatment. But few doses had been taken when the conjunctiva became inflamed and an acute laryngeal catarrh was set up, and all of the usual symptoms of iodism came on energetically. The pilocarpin acted with the same severity. The result was admirable, and a few days disposed of the formidable morbid complex, and full restoration to the normal ensued, and has been since maintained.

To demonstrate the utility of the depurative method in other than nervous maladies, I will cite a case in which the gastro-intestinal mucous membrane, the stomach and liver were affected simultaneously.

A gentleman aged about thirty-five years, employed in a bank and closely confined to business, began to suffer from digestive disorders. He was a small, spare man, weighing in full health not more than 140 pounds, and he progressively declined in flesh and strength, was compelled to quit business, and presently was confined to his bed, being reduced when at the lowest point to 94 pounds. He had severe pain at the cardia and much distress after taking food. Nausea, and vomiting of almost every article swallowed ensued. There was no vomiting of blood; the matters brought up had an acid reaction, and no blood-globules could be found on the most careful examination. He was obstinately constipated. At one time he became jaundiced. The blood became so altered that it flowed from the mucous surfaces, especially from the nasal, and plugging became necessary at last to prevent death from hemorrhage. He was now reduced almost to the lowest point compatible with life. The physician in attendance, a most skilful man, had exhausted every resource in his efforts to stay the progress of the disease. When called in consultation it seemed to me futile to suggest remedies of approved utility in gastro-intestinal disorders, and recognizing the need in this direction, I advised a resort to depuration. The doctor gave ⅛ grain of pilocarpin to begin this plan of medication. The action was striking. Every organ—the skin, the mucous membrane of the gastro-intestinal canal, the salivary glands of the mouth, and we may reasonably conjecture the pancreas, and certainly the liver—took on most abundant activity. The saliva flowed in a stream, he sweated profusely, and the bowels moved copiously, the discharges having the so-called "bilious" character. No depression followed this free elimination; on the contrary, immediate improvement took place, and he had no more hemorrhage. The effects of the pilocarpin were sustained by the exhibition of 15-grain doses of iodid. It might be supposed that in a case characterized by such extreme irritability of the stomach, a remedy of this kind would be badly, or not at all, borne by the stomach. The result, however, demonstrated the utility of the treatment, for the patient made great immediate progress, and although there have been occasional relapses, he has since continued to improve in nutrition, and is now practically well.

Other examples might be brought forward to show the application of the principle to the treatment of diverse affections, and the two already given might have been described in fuller detail; but these must suffice for the present. My purpose is subserved by calling attention to the method, which may profitably become a routine-habit in many cases whose etiologic relations are of a kind to suggest it.

The Value of State Medical Examinations.—From the organization of the Maryland Board of Medical Examiners, in June, 1892, until November, 1894, 130 candidates for license to practice have been examined, of whom 102 were successful upon the first examination and 3 upon a second examination; the remaining 25 that failed to pass the first examination did not apply a second time, and were rejected.

SELF-RETAINING DRAINAGE-TUBE AFTER SUPRAPUBIC CYSTOTOMY FOR CHRONIC CYSTITIS AND PROSTATIC OBSTRUCTION.

BY N. SENN, M.D., PH.D., LL.D.,
OF CHICAGO;
PROFESSOR OF SURGERY IN RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY IN CHICAGO POLYCLINIC; ATTENDING SURGEON PRESBYTERIAN HOSPITAL; SURGEON-IN-CHIEF ST. JOSEPH'S HOSPITAL.

THE formation of a permanent suprapubic fistula in the treatment of hypertrophy of the prostate gland complicated by cystitis has become a recognized surgical procedure. It is an operation which not only affords prompt relief after all other methods of treatment have failed, but is also calculated to prolong life by preventing further extension of the inflammatory process in the direction of the kidneys. Contrary to the experience of other surgeons, notably Dr. Hunter McGuire, I have found it very difficult to keep the suprapubic fistula sufficiently patent for any length of time without a resort to some form of drainage-tube. I have almost invariably observed that as soon as the drainage-tube is dispensed with the fistulous opening contracts rapidly, and in a few days it has to be dilated in order to afford a free outlet for the urine.

Systematic catheterization of the new passage has proved very unsatisfactory in my experience in all cases in which this part of the treatment was intrusted to the patient. I have resorted to the use of various kinds of drainage-tubes devised and described by different surgeons from time to time, with similar unsatisfactory results.

It is difficult to maintain the necessary degree of patency of the new outlet for the bladder with any kind of a soft-rubber tube. The tubes made of metal, or of hard rubber, used for the same purpose, are likely to produce pain and harmful pressure at the neck of the bladder. The neck of the bladder is the most sensitive part of the viscus, particularly when the bladder is in a condition of inflammation in consequence of chronic prostatic obstruction. A drain that has to be employed for a long time, or permanently, should not press against the swollen sensitive prostate or inflamed neck of the bladder. For the purpose of rendering the drain self-retaining, and with a view of preventing painful pressure, I have devised the instrument shown in Fig. 1. The instrument is made of silver; the bulbous end has a large round terminal, with numerous smaller oval, lateral openings, and when in place, corresponds with the long axis of the bladder. The adjoining elbow shows two lateral and one posterior oval opening, which are intended to drain the space above and behind the enlarged prostate. The straight part of the instrument between the two elbows should correspond in length with the thickness of the tissues above the pubes, interposed between the skin and mucous membrane of the bladder. The part below the second elbow terminates in a raised margin over which a piece of rubber tubing is slipped. An ordinary clamp fastened to the end of the rubber tube prevents the constant escape of urine, and is made use of as soon as continuous drainage has became superfluous and the patient is able to leave his bed. The instrument when in place (Fig. 2) drains the bladder perfectly,

FIG. 1.

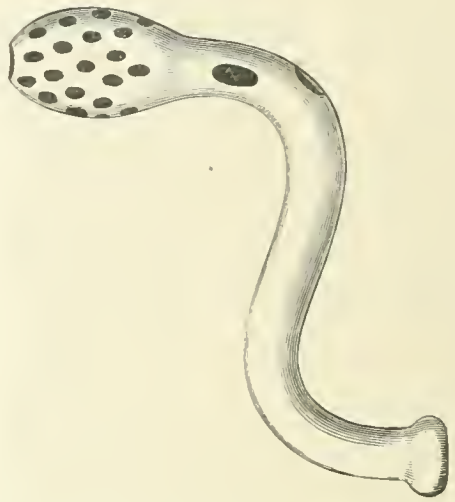

FIG. 2.

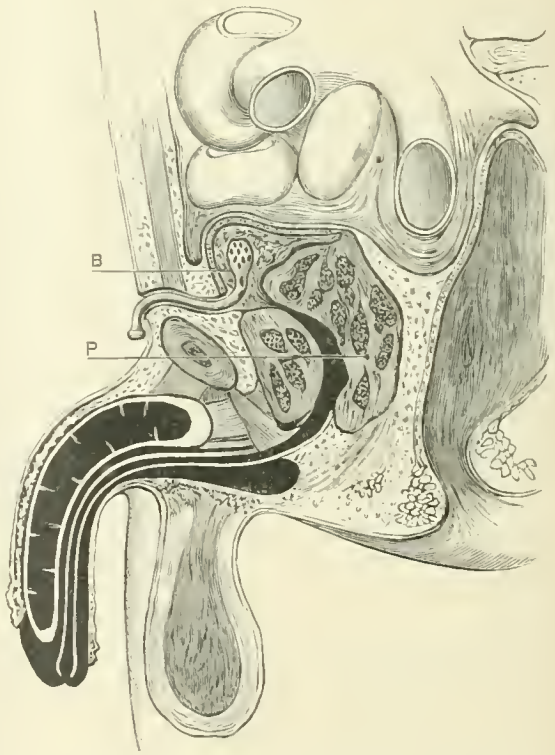

makes no pressure against the prostate or neck of the bladder, and is self-retaining. It can be removed and reinserted with ease. I have recently performed suprapubic cystotomy in three cases of enlarged prostate in men from sixty-five to seventy-two years of age, complicated by chronic cystitis, and in two of the cases by stone in the bladder, and in every instance prompt relief was obtained. All of the patients made the statement that they were never aware of the presence of the tube. The tube should be removed at least once a week, and be thoroughly cleansed of all internal and external incrustations and at once replaced. The bladder can be thoroughly washed out by injections *per urethram*. With a little instruction and practice the patient soon acquires the necessary manual dexterity and skill to remove and reinsert the tube himself. As long as prostatectomy either by the urethral, perineal or vesical route remains such a dangerous and unsatisfactory operation as it is at the present time, any improvement in the formation of a permanent suprapubic fistula will be appreciated by surgeons who are frequently appealed to for relief by a large class of patients whose declining years are clouded and rendered miserable by one of the most distressing of all surgical affections.

ON THE VALUE TO THE SURGEON OF ANTIPYRIN, OF MUSTARD AND SUGAR, AND ON THE PREPARATION OF CERTAIN SURGICAL DRESSINGS.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO; SURGEON TO THE BUFFALO GENERAL HOSPITAL.

DURING the winter of 1885 my attention was called to an article by someone whose name I do not now remember, stating that he had found a solution of antipyrin to be an efficient hemostatic in the treatment of urethral hemorrhage. This statement was made to me by a visitor at one of my clinics at a time when I was in need of something that might act in this way. Accordingly, I at once made a 4 per cent. solution, tested it for this purpose, and found it very satisfactory. This was my first introduction to antipyrin as a hemostatic. Charmed with the result thus produced, I at once began experimenting with it in a variety of surgical cases. Having learned, in one way and another, that it was a most efficient and practically harmless styptic, I desired to ascertain whether it was one that could be safely used inside of the body-cavities, and whether it had any antiseptic properties. I tested it carefully in my own laboratory, and learned, by repeated experiments, that while not a strong antiseptic it, nevertheless, had marked antiseptic properties, holding its own fairly well with many of the other synthetic productions that have of late been so freely placed upon the market for this purpose. It compares, indeed, very favorably in this respect with most of the anilin or coal-tar derivatives that we use in medicine. I then began experimenting upon animals, or, rather, using the drug during various experiments, employing for this purpose a 4 per cent. or 5 per cent. solution in sterilized water. I soon learned that this could be used anywhere upon the peritoneum, upon the bowel, upon the brain-surface, or anywhere else, invariably exhibiting its styptic properties and causing no symptoms that lead me to regret its use. Thus fortified, I began its general use in aseptic surgery. Now I keep a standard solution in my clinic, where I always have fifteen or twenty pounds of air-pressure ready to be used for spraying, and small hand-sprays, which, with this-air pressure, are conveniently at hand for any emergency. I have never hesitated to spray a 5-per cent. solution on an exposed and oozing surface, whether this were on the cortex of the brain, in the nose or mouth, in the peritoneal cavity, upon injured liver or bowel, or anywhere else.

I have found that antipyrin has power not sufficient to contract vessels of any size that spurt, but to almost instantly blanch and check oozing from any surface from which blood is escaping just fast enough to be an annoyance. I have hundreds of times demonstrated this efficiency in my clinic, and at various times, when visiting other operators, have been able to make the same demonstrations for them. As a consequence, a number of my surgical friends are now using this remedy for this purpose. It may be injected into a cavity, as in bone; it may be applied on compresses to the oozing surface, or it may be sprayed as mentioned; but no matter how applied, under circumstances indicated within the limits given, it will seldom, if ever, be found to disappoint.

I think it essential to say that I have thus tested it bacteriologically, because some might otherwise hesitate to use it. My own preference for operating is, whenever possible, by the dry method, and in many cases, unless something is positively indicated, I let nothing come in contact with the fresh wound-surfaces—neither antiseptic solution nor anything save sterilized compresses. Upon such a surface, however, if necessary I would not hesitate to employ a sterilized solution of antipyrin, believing that it is sufficiently antiseptic to be left without feeling that one must remove every particle of the solution. Moreover, it is practically unirritating, since I have never known harm to occur from its entrance into any part of the body where it was not called for. I should have no fear, for instance, if a little of the solution trickled down into the peritoneal cavity after it had been applied to the surface.

Antipyrin has this great advantage over such styptics as the salts of iron, in that it constringes the minute vessels and does not leave any external clot in the way, or that may break down, or that in any sense shall be undesirable, as are the clots, for instance, made by Monsell's solution. In cases of epistaxis, for example, a solution of antipyrin may be sprayed into the nose with the greatest benefit. It will serve a most admirable purpose after intranasal operations, as I have many times convinced myself. In the urethra, as after internal urethrotomy, it will have the same beneficial effect. In certain operations on the mouth I have had patients occasionally gargle a weak solution, or have inserted tampons saturated with a solution of antipyrin to which a little glycerin has been added. Up to the present I never have known any unpleasant result from its use in any part of the body in solutions not exceeding 5 per cent. for the purposes stated. Sometimes, in fact, I have used solutions as strong as 10 per cent.

This leads me to speak of certain other purposes for which a 4 per cent. or a 5 per cent. solution of antipyrin may be locally used. In 1888 I mentioned to my friend Professor Hinkel, of this city, the relief that I had found antipyrin to afford in certain cases of inflammatory occlusion of the nose, as well as its hemostatic virtues. He began using it, was much pleased with its effects, and wrote an elaborate article entitled "Clinical Notes Upon the Use of Antipyrin in the Nasal Passages," which was published in the *New York Medical Journal* for October 28, 1888. I speak of this particularly, because quite recently I have seen an article, emanating from New York, claiming originality for this discovery, the author apparently being quite unmindful of the article published by Dr. Hinkel some years previously.

When antipyrin is to be used for any medicinal purpose necessitated by affections of the head, as, for instance, headache, coryza, etc., there is no way by which its effects are so speedily gained with so little disturbance and so little danger, as by spraying it into the nose. It must be acknowledged that these solutions give rise to some temporary smarting and irritation of the mucous membranes, and my custom is first to spray in a weak solution of cocain and to follow it in a few moments with the antipyrin. At other times the two may be combined. The effect of the cocain is not merely to anesthetize the surface, but to constringe the vessels, this effect, however, quickly passing away. The effect of the antipyrin seems to be to carry out to a much more marked degree the conditions thus produced by the cocain, the constringing of the tissues lasting sometimes for several hours, which would not be the case when cocain alone is used. For "that stuffy feeling" of which many patients speak, complaining of a catarrhal condition of the upper air-passages, accompanied by a certain amount of discomfort or actual pain in the anterior part of the head, there is nothing in my experience that begins to afford so speedy relief. For my own part, if I ever have to resort to antipyrin to gain relief from headache, I should prefer to use it locally rather than to take it internally. The quantity required is much less, which of itself is an important item, while the effect produced is manifested very much more quickly. The same is true also of certain acute affections of the throat; and the discomfort attending an ordinary attack of pharyngitis, with the soreness radiating into the neck and head, can be more quickly relieved by this spray than by any other measure that I know of. Of course, I do not mean to imply that this solution will be all-sufficient. Other and more general measures are called for at the same time; but I maintain from a quite extensive experience with the drug that it will give early relief more satisfactorily than anything else of which I have knowledge.

Undoubtedly, the effects, either styptic or analgesic, that I have eulogized are due to the same constringing effect upon the tissues of the body. Antipyrin in its local effects is generally astringent, but that it has these properties comparatively few are yet aware, and this therapeutic note is written with the view of enabling others to take advantage of a very valuable fact.

(To be concluded.)

CASTRATION FOR THE CURE OF HYPERTROPHIED PROSTATE.

By J. WILLIAM WHITE, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

The reception by the medical profession here and elsewhere of the suggestion made by me in June, 1893, that castration might be an effectual remedy for prostatic hypertrophy has been increasingly favorable. Up to that time no reference existed in surgical literature to the possibility of affecting the overgrowth by the removal of the testes. Since then twelve more or less successful cases have been published. It is not too much to say that, in connection with the further corroborative evidence that has been brought forward, they serve to establish the operation as a rational and justifiable procedure. I have already reviewed in The Medical News (June 2, 1894) the history of eight of these cases (Haynes, 3; Smith, 1; Ramm, 2; Powell, 1; White, 1). The other four may be briefly summarized as follows:

Mayer and Haenel (*Centralblatt für die Krankheiten der Harn- und Sexual-organe*, August 23, 1894) operated May 16, 1894, on a man, about

seventy years of age, with a much enlarged prostate, with cystitis and ammoniacal urine, tenesmus and toxemia, and in whom catheterism was becoming impossible on account of the pain it excited. There were several ounces of residual urine. Some improvement was noted in a few days; after two weeks the tonicity of the bladder began to return; in three weeks the urine was nearly normal; and in six weeks the prostate had shrunk to its proper dimensions, the bladder emptied itself completely, no catheter being required, urination was performed only once in four hours, and the urine was limpid and of acid reaction.

The authors discuss the apparent analogy between the prostatic and the uterine fibro-myomata (which was what led me to the researches that resulted in my suggesting the operation to the profession), mention my confirmatory experiments on dogs (which gave a definite and scientific basis for the suggestion), and after quoting Ramm's cases arrive at conclusions entirely favorable to the method, on account of its comparative safety and the ease of its performance, as contrasted with the other operative measures directed against the hypertrophied prostate.

Moullin (*The Medical Press and Circular*, September 19, 1894) reported the case of a man, about eighty-one years of age, with complete retention due to a prostatic enlargement the size of an orange, with cystitis and failure of general health, and in whom catheterization was impossible, all attempts being followed by hemorrhage. Supra-pubic aspiration was necessary on several occasions.

After the castration the improvement was almost immediate, the prostate was appreciably smaller in ten days, and in three weeks had practically disappeared. An ordinary catheter could be readily passed. The bladder had begun to regain power. The urine was nearly normal.

J. I. Thomas (*The Pittsburg Medical Review*, September, 1894) reports a case in which castration in a patient of sixty-five years, who had had symptoms of prostatic hypertrophy for fifteen years, had caused "considerable improvement." He adds, "urination, which was formerly very frequent, is now necessary but three times a day." This report was made very soon after the operation, and no further details are given.

B. M. Ricketts, of Cincinnati, reports (*Cincinnati Lancet-Clinic*, December 1, 1894) a case in which he did this operation in a patient, about seventy-four years old, who left the hospital at the end of the sixth day. On the second day after the operation the patient could urinate with greater ease, and the pain was so slight that he said he had not had so much comfort for a year; he could sleep four hours at a time during the night, whereas formerly he had been getting up once every hour, and had been urinating thirty times daily. The condition continued to improve. A further report was promised later.

Launois (*Ann. des Mal. des Org. Gen-Urinaires*, October, 1894) publishes an interesting memoir reviewing the whole subject, and bringing forward some collateral evidence, chiefly from the works of Godard, showing that monorchidism is likely to be associated with unilateral atrophy of the prostate, and giving instances of such atrophy after gonorrheal epididymitis, and of complete atrophy in cryptorchids, after syphilitic sarcocle, etc. He too concludes that the operation is of distinct curative value.

What might be called a supplementary indication for the operation will, I think, be found in some cases in which, with the usual urinary symptoms of prostatic overgrowth, there are others referable to the sexual system, and often causing more serious trouble. Every genito-urinary specialist is familiar with instances of "psychopathia sexualis" in old men, but not every one realizes that they often have a physical rather than a psychic basis, and depend on the prostatic congestion and excitation incident to the early stages of hypertrophy. In one of Haynes' cases the relief experienced in this direction was as marked as that derived from the disappearance of obstruction.

The details of several successful operations performed here will shortly be published.

The objections to the operation met with in practice have, in my experience, arisen altogether from the sentimental side of the question. As Launois says, men of advanced age, "aimant à se faire illusion," insist upon retaining their testicles as evidences of a "virilité passée." This applies of course with especial force to the cases in which dysuria is slight or catheterism easy, the general health remaining unaffected. As to the more serious cases, such as those I have noted, we have now reached a point in certainty of knowledge where we can promise results at least equivalent to those obtained by oöphorectomy for uterine fibroids, and I believe that the assertion made in my original paper was correct, and that "there will be no lack of cases willing to submit to an operation almost painless, with a low mortality, and followed by no such unpleasant conditions as accompany persistent fistulous tracts, either supra-pubic or perineal, even although the operation carries with it the certainty of sacrificing whatever sexual power has survived the excessive and often intolerable sufferings of such patients."

All who are interested in anti-football should secure a copy of the *Ithaca* (N. Y.) *Daily Journal*, in which Professor Burt G. Wilder occupies six full columns in a splendid answer to the question, *Is Intercollegiate Football to Continue at Cornell University?* It is a masterly and convincing epitome of the unanswerable arguments against the intercollegiate game.

REMARKS ON THE CONTINUED FEVERS OF LOUISIANA.[1]

BY RUDOLPH MATAS, M.D.,
PROFESSOR OF SURGERY IN TULANE UNIVERSITY, NEW ORLEANS;
PRESIDENT OF LOUISIANA STATE MEDICAL SOCIETY, ETC.

IN the nine years that have elapsed since the reading of my paper before this Society on the "Long-continued Fevers of Louisiana that Resist Quinin" my opportunities for observation have greatly increased, and I feel that I have gathered sufficient evidence to permit me to formulate a few conclusions pointing to the real nature of these fevers. In the paper referred to I insisted upon the distinctive clinical type of our continued fevers, and emphasized its differential characteristics from malarial fevers and from typhoid. I also confirmed the careful observations of Dr. John Guitéras, who had studied this form of fever in Key West, and had described it as an independent morbid entity in a paper published March 10, 1885, in the *Therapeutic Gazette*, under the title "Continued Fever, or so-called Typhoid Fever of the Tropics, or Continued Thermic Fever." I believed with him then that it was neither malarial nor typhoid nor a hybrid combination of both, but the result of some form of exhaustion of the heat-regulating apparatus.

It is now unnecessary to reproduce the clinical picture of the fever in question. We all know it, though we may call it by different names. I simply desire to supplement my paper of 1885 by expressing the opinion that the type of fever in question is not a new or independent morbid entity, but an atypical typhoid fever. This opinion is based upon the following conclusions derived from personal observation and experience and by clinical records which substantiate the facts:

1. The course of the long-continued fevers of Louisiana is not in the least altered or notably influenced by the cinchona alkaloids; ergo, it is not a malarial fever from the therapeutic standpoint.

2. That this fever occurs at all seasons of the year, though it is more prevalent during the summer months; ergo, it is not a "thermic" fever pure and simple.

3. That cases of the fever occur in groups (and probably in districts), several members of a household being attacked simultaneously or in rapid succession; ergo, infection from a common source.

4. That while the true classical and grave typhoid type of fever is exceptional and comparatively rare, it nevertheless exists in our midst in persons who are born in this city and who have never lived elsewhere; ergo, typical typhoid fever exists as an endemic in New Orleans.

5. That in the comparatively rare cases of typical typhoid fever all the essential characteristics of the typhoid state are present, viz.: long-continued fever, varying from four to six weeks, with typical chart; adynamic state, stupor, low muttering delirium, diarrhea, intestinal hemorrhages, perforation of the bowel and fatal peritonitis.

6. That in many other (less rare) cases the febrile movement, though long continued, presents few of the adynamic or ataxic characteristics of the typhoid state; the mental state is good, but diarrhea and intestinal hemorrhage are nevertheless present.

7. That in the majority of the cases the chief and apparently only characteristic of the fever is its persistence; its long duration and rebelliousness to antiperiodic or other medication. The only point of contact between this and the preceding types lies solely in the continued thermic movement.

8. In infected houses, where several cases are under treatment, it is not very rare to observe a fever of a most *typical* and grave typhoid type running through its course by the side of a benign *atypical* fever in which there are no adynamic symptoms, no diarrheas, no hemorrhages, nothing, in fact, but a simple and uncomplicated thermic movement.

I would now also state, as a matter of pure personal impression and belief without a sufficient basis of statistical facts outside of general personal observation, that it is my impression that:

1. The true malarial type of fever—the strictly intermittent—is gradually disappearing from the city limits, and is now almost restricted in its prevalence to the swampy portion of our suburbs.

2. That the continued type of fever is gradually gaining the ascendency, and the true typhoid type is yearly becoming more frequent.

3. That this gradual transition from the intermittent to the plain remittent continued, and, finally, to the continued typhoid type of fever, is a phenomenon that has been observed elsewhere, where the original conditions of nature gradually suffered profound alterations from the presence of a progressively increasing human population; that malarial fevers are the products of the unredeemed, uncultivated swampy lands, while the typhoid type is a product of human aggregation which usually follows in the wake of increased means of communication and other conditions inherent especially to metropolitan life.

4. That this transition in our fever-type is being effected gradually without any perceptible change in our water-supply, milk-supply, or food-supply, or in our sewerage-system or drainage-system, and that the only conditions that have changed have been the notable increase in the facilities for communication between this and other large northern and western metropolitan centers where the typhoid type of

[1] Read before the Louisiana State Medical Society, May, 1894.

fever has long predominated and whence it could be readily imported.

. . . . . .

Finally, a word as to treatment:

The vast majority of our cases are benign in their tendency, and require only symptomatic and hygienic treatment and careful nursing. The chief therapeutic indication is usually to control an excessive or hyperpyretic movement. In sthenic cases the antithermic remedies, especially phenacetin and antifebrin in small doses and in combination with some alcoholic, will meet the indication. My rule has been never to administer an antithermic dose (2 to 3 grs.) unless the temperature rises above 103°, and in the latter stages, when the patient is showing signs of exhaustion, never to give the dose until 104° has been reached.

In the asthenic cases stimulation, with proper nourishment, and the cold bath constitute my chief reliance. The method of Brand is far superior to all forms of antithermic medication, but it is difficult to apply in the homes of the poor, who are without help and unable to pay for the services of a competent nurse.

In the asthenic cases in which the ordinary antithermics are badly tolerated, and in which for fear of hemorrhages or other causes it is impossible to move the patient to the bath, I believe that the epidermic use of guaiacol by Sciolla's method and Da Costa's directions is of service in combating hyperpyrexia. I had a typical case which occurred a few months ago in which guaiacol did good service. As an adjunct of great value in reducing fever and in diminishing the tendency to delirium I always insist upon the use of the ice-bag or ice-pillow as a head-rest. All the other indications for complicating conditions should be met in the manner described in the classics.

CLINICAL MEMORANDA.

OBSTETRIC MEMORANDA.

By B. C. HIRST, M.D.,
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

A PELVIS SPINOSA.

Case I.—A true spinous pelvis is very rare. So far as I know the condition has never been recognized before in America. It was referred to as early as 1697 by Hauder; again by Merz in 1790, and later by Denman, Burns and Duparcque, but was not clearly described until the appearance of Kilian's work, in the middle of the present century. The peculiarity of the spinous pelvis is the development at the ilio-pectineal eminences and along the crests of the horizontal rami of the pubic bones of sharp spicules and ridges of bone. Over the promontory of the sacrum and at the sacro-iliac junctions there may also be exostoses, but these are not shaped like thorns; they are buttons or knobs in form. It is possible to find sharp spinous projections of bone from other portions of the pelvis than the ilio-pectineal eminences and the crests of the pubes. Leopold has published a picture of a pelvis with a large thorn-shaped exostosis springing from the left ilium near the sacro-iliac junction. Kilian claimed that in the four cases he reported the sharp-pointed exostoses perforated the womb in each instance, and this has since been asserted to be almost a necessary consequence of labor in such a pelvis. But it was true of only one of Kilian's cases, and in some others more recently reported the uterine rupture can be demonstrated not to have been due to the exostoses at all. While sharp-pointed exostoses in the pelvis, therefore, can perforate the womb in labor, it is by no means certain that they will do so.

The woman in whom I recently discovered a spinous pelvis gave the following history: Mrs. S., aged twenty-four, married four years, has had two children. The first child died when two months old; the second was born two years ago. The woman has congenital osteomata on the heads of the tibiæ. A brother and a sister also have osteomata on the lower extremities. Her second child is alive and well, with no bony excrescences on its body. After the birth of her first child, three-and-one-half years ago, she first noticed a small, hard tumor over the posterior superior spine of the right ilium, extending down along the sacro-iliac junction. She had always enjoyed perfect health till after the birth of her second child, when she noticed a sudden and decided enlargement of the iliac tumor, which has steadily increased in size, and is now as large as a base-ball. During this period of constant growth there has been an increasing pain in the lumbar region, extending down the right leg to the great toe, evidently due to pressure upon the lumbo-sacral plexus.

Vaginal examination shows a sharp, bony excrescence springing from the left ilio-pectineal eminence, a ridge-shaped exostosis along the crest of the pubis, an outgrowth of bone over the right ilio-pectineal eminence not so pronounced as that upon the left side, and a large osteoma over the right sacro-iliac junction. The woman's history pointed to the possibility of pregnancy of a few weeks' duration. Should that be her condition, and should she return to the dispensary service, where I saw her, and which she has so far failed to do, I should induce labor three or four weeks before term, such a course being perfectly safe for the child and affording the mother all needful protection by securing the passage through her pelvis of a soft, compressible fetal head that will not grind a hole through the uterus between itself and the pelvic exostoses.

DIFFUSE UNLIMITED SUPPURATIVE PERITONITIS IN A PREGNANT WOMAN, ENDING IN RECOVERY.

Case II.—In as thorough a search as it was possible for me to make through medical literature some three years ago, I was unable to find a single case of diffuse suppurative peritonitis during or after the child-bearing process saved by operation. This was in accord with my own experience. I had had a number of successful results in localized intra-peritoneal suppuration, even when one-quarter of the abdominal cavity was involved, but had never saved a case of diffuse suppuration. Five months ago I had my first success with this form of suppurative

peritonitis, and this is the first successful result I have any knowledge of, though it may well be that a few others are by this time on record.

Mrs. ——, a patient of Dr. M. Graham Tull, was seized at nine o'clock one evening last summer with violent abdominal pain. She was at the time four-and-one-half months pregnant. Dr. Tull found her with a distended, exquisitely sensitive abdomen, rapid pulse, and a temperature of 101°. There was no accounting for her seizure. On the following morning she was worse. By the afternoon Dr. Tull saw that an operation was necessary. I was sent for, and operated that evening about eight o'clock. The incision was median. A large quantity of thin pus ran out when the peritoneum was opened. The abdominal cavity and the intestines presented the typical appearance of diffuse suppurative peritonitis. There was no limitation, no demarcation between a diseased and a healthy area. Pushing the pregnant uterus aside, the origin of the trouble was discovered in a diseased appendix. There were also two ulcers on the caput coli excavated down to the mucous coat of the bowel. The appendix was removed, the ulcers oversewed, the abdominal cavity washed out, the walls closed and drainage for a few hours provided for. The woman made an uneventful recovery, and is about to be delivered at term.

The explanation of the recovery in this case is to be found, perhaps, in the lesser virulency of the infecting agent—the bacterium coli commune—compared with the streptococci, commonly the cause of the suppurative peritonitis after childbirth.

A CASE OF ACUTE OSTEOMYELITIS IN AN ADULT, WITH EARLY OPERATION AND COMPLETE RECOVERY.

By BAYARD HOLMES, M.D.,
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

THE diagnosis of acute osteomyelitis presents many practical difficulties, and the rarity of the disease makes it worth while to report every case observed during the first forty-eight hours. Old cases are common enough, and the diagnosis is easy when the pus is pouring out of a sinus or when sequestra are being discharged.

In June, 1893, it was my fortune to be called in the night to see a young man, about twenty-four years old, who was suffering great pain in the right leg. He had a temperature of 102.5° and a pulse of 108. The pain was constant and had been growing in severity during twenty-four hours. A surgeon had been consulted the day before and found no cause for alarm. The tibia was found exquisitely tender on pressure at a single point not more than an inch in diameter. There was no swelling or edema. A history of influenza and a short stay at the Hot Springs, Ark., was given. There were no other significant points in the history. A provisional diagnosis of acute osteomyelitis was made and the prognosis and indications for treatment explained. A hypodermic of morphin was given to relieve pain, and a cathartic was administered. In the morning the temperature was higher and the pulse more rapid. The pain and tenderness had increased. The family called Dr. Edmund Andrews and Dr. Christian Fenger in consultation. They saw the patient at different times of the day and confirmed the diagnosis and the indications for treatment. The temperature at night, eighteen hours after the first observation, was 105° and the pulse 124. The patient was partially delirious. The spot of tenderness over the middle of the tibia had become slightly swollen and edematous. The urine was examined, but no evidence of nephritis was found. Upon the following morning, thirty-six hours after the first observation, the patient was anesthetized and an incision made down to the tibia. The periosteum was distinctly edematous, and a yellowish serum poured out, which disappeared quickly upon sponging. The bone itself, at the point of tenderness, was more than ordinarily vascular, though the change was very slight. After chiseling away the anterior portion of the tibia near the middle of the bone a distinct vascular mass was found, in the center of which was a drop or two of pus. The sharp spoon was used to scrape out the surrounding tissues, and the wound was packed with iodoform-gauze. The upper and lower ends of the wound were brought together and the middle left open to secure drainage. The leg was put in a plaster-of-Paris cast. Upon the morning after the operation the temperature was normal and never rose again. The appetite immediately returned, and the patient felt the restraint which the cast imposed. The second dressing occurred about ten days after the injury, and at that time the tissues showed no sign of infection or inflammation. Upon the fifth dressing the wound had entirely closed, leaving a defect of bone underneath the skin.

Some weeks after the recovery the patient was getting on to a moving train and was thrown upon the ground, sustaining a simple fracture of this tibia at the point of operation. From this recovery is said to have taken place in the usual time.

EYE-STRAIN A CAUSE OF NOCTURNAL ENURESIS.

By GEORGE M. GOULD, A.M., M.D.,
OF PHILADELPHIA.

ON November 12, 1891, a little girl, M. S., nine years of age, a "nervous child," with headache, no appetite for breakfast, etc., was brought to me for treatment. The mother stated that the child slept very poorly, having frequent night-terrors, was somnambulistic, and had "other troubles," the nature of which I did not exactly learn until subsequently. Under a mydriatic I found the following remarkable error of refraction:

R. + sph. 0.75 D. ⊃ + cyl. 5.00 D. ax. 100° = 20/70.
L. + sph. 1.00 D. ⊃ + cyl. 5.00 D. ax. 85° = 20/70.

After wearing the glasses I then prescribed the visual acuteness became in a short time normal in the right eye, but it was a year or more before I succeeded by the "blinder-treatment" in bringing that of the left eye to normality. The headaches soon passed away after getting glasses, likewise the nightmare, and the appetite became good. Within a year the child was as robust and hearty as could be desired. At this time I first learned that for years prior to consulting me the child had been afflicted with nightly enuresis, for which all treatment had been in vain. This had continued up to

the day of instilling the mydriatic and applying glasses, but from that day it has never occurred once since.

The second case was not cured so suddenly, as the circumstances, age of the patient, continuance of the malady, etc., were not by any means so favorable. The boy was fourteen years old, had been afflicted with frontal headache "all his life," and had also had "fainting spells" for a number of years. There had also been a frightful nasal catarrh. Many physicians and surgeons had been consulted for nocturnal enuresis that had persisted from infancy, but all treatment and operations had been without effect. I found a high degree of compound hyperopic astigmatism and hyperphoria. After prescribing glasses the headache disappeared at once, and a partial ptosis of the left lid also disappeared. The wetting of the bed did not stop immediately, but did do so "very soon afterward." The patient disappeared from view, and it is only lately that I have learned that the enuresis stopped soon after getting glasses, and has not appeared since. The parents now ascribe the cure to the glasses, and I agree with them. As general treatment of the boy's health was also instituted by me, a legitimate suggestion might arise that the cure of the enuresis might have been due to that instead of to the stoppage of eye-strain. General treatment, however, had been previously thoroughly tried, but in vain until the ocular treatment was added. Taken in conjunction with other cases, I think that the reflex had its source in the eyes.

Another little girl, G. M., eight years of age, was brought to me December 14, 1889, with a history of headaches and of chorea during the preceding four years. The choreic affection was limited to the face and to the hands and feet. She was a very restless child, the hands and feet jerking and moving all the time, even in sleep, and "she talked in her sleep all night." Nocturnal enuresis had likewise existed for four years, and occurred every night. In this case there was difficulty in getting the child to wear glasses correcting the anisometropia. The chorea and other symptoms gradually ceased during the first month or two, but resumed again with their old intensity when she "lost her glasses" and was without them for two months. In June, six months after the first visit, I again took the case up, and prescribed other glasses, and they were now worn continuously. On October 2, 1892, with great patience, I succeeded in getting a still more accurate correction of the error of refraction (compound hyperopic astigmatism), a task of the utmost difficulty. But long prior to this date the enuresis, chorea, night-terrors, etc., had entirely disappeared. The nervous system had been so profoundly deranged that a sudden cure was not to be expected, but that the eye-strain bore a causal relation to the symptoms of enuresis and chorea, I have no doubt.

On March 12, 1894, a little girl, M. S., six years of age, was brought with a history of great nervousness, kicking about and crying out in her sleep, headaches, painful eyes, etc., and with nightly enuresis. From the day glasses were give her these symptoms disappeared "as if by magic."

On October 13, 1894, Dr. O. P. Rex sent me a child of ten years, H. S., who had headache a great deal, and painful eyes. I did not at this time know that the child had been afflicted with persistent noctural enuresis for years, for which all treatment had been in vain. I found the following vicious error of refraction:

R. and L. + sph. 4.50 D. ⌒ + cyl. 2.00 D. ax. 90°

This gave her only 20/100 visual acuteness, which, however, soon improved by wearing the glasses, until one eye had normal acuity in a few weeks, and the other by the blinder-treatment is steadily gaining. Headache, etc., at once disappeared, and from the day of applying the glasses the child never "wet the bed" again.

Besides these cases I have had others in which I am moderately certain that the eyes were the ultimate or a contributing cause of the affection under discussion, but in which the cure was either more slow or the etiology more suspicious, and I do not include them in this report.

MEDICAL PROGRESS.

Traumatic Ophthalmoplegia Improved by Operation.—Gutmann (*Berliner klinische Wochenschrift*, 1894, No. 41, p. 933) has reported the case of a man, thirty-six years old, who struck upon the head in a fall down stairs, suffering a fracture at the base of the skull. He was unconscious for three weeks, and when he came under observation, four weeks later, he presented complete left-sided oculo-motor palsy. There existed ptosis, and the eyeball was directed outward in abduction. There was no movement upward, and only so much of movement downward as could be effected by the fourth nerve. The pupil was dilated, and accommodation was paretic to the degree of three diopters. Slight movement inward was possible under great effort. In the hope of affording relief operation was undertaken. A fold of the upper lip, about 10 or 15 mm. (0.39 or 0.59 in.) wide, was made with its base about 3 mm. (0.11 in.) above the margin of the lid, the fold being freed at an elevation of between 10 and 15 mm. Above the brow a horizontal incision of from 15 to 20 mm. (0.59 to 0.78 in.) long was made. The skin between the upper margin of the fold and the incision above the brow was freed, and the fold slipped under the bridge of tissue thus formed, its upper margin being sutured in the upper wound. As a result the lid could be conveniently elevated and depressed. After waiting for three months, without noteworthy improvement in the activity of the internal rectus, this muscle was advanced, while the external rectus was freed. With the aid of lenses, + 3 D upon the left and + 1 D upon the right, the patient was afforded useful vision. In the course of a short time, however, the internal rectus induced a secondary strabismus convergens, so that now its tendon was divided. A slight degree of diplopia, however, persisted, for the relief of which a prism five degrees, base out, was directed. The movement of the eyeball upward and downward was, of course, not affected. Three years later the result was still found to be satisfactory.

Acetonuria Following Anesthesia.—The occurrence of several cases of fatal diabetic coma following anesthesia, led Becker (*Sitzungsber. d. niederrh. Gesell.*, Bonn., 1894; *Centralbl. f. Chirurgie*, 1894, No. 38, p. 895) to investigate whether or not anesthesia induces acetonuria in healthy persons. Seven hundred individual observations were made upon 188 anesthetized persons, with a

positive result in two-thirds of the cases. The acetonuria began as a rule several hours after the anesthesia and lasted for several days. The result was independent of special form of anesthesia, the duration of the anesthetic period, as to whether it was preceded or not by injections of morphin, or if attended by more or less excitement. If acetonuria existed before the induction of anesthesia, the condition was considerably intensified. In one case of ethyl-bromid intoxication enormous quantities of acetone were excreted in the urine. The conclusion is reached that small quantities of acetone circulating in the blood during and subsequent to anesthesia are not toxic, but that it remains to be demonstrated whether or not such an effect is produced in cases in which accidents happen. The occurrence of acetonuria is viewed as an indication of increased albuminous disintegration, and it is thought possible that in patients with profound metabolic disturbances acetonemia may prove a serious complication.

The Pathology of the Spinal Lesions of Divers' Palsy.—Sharples (*Journal of Nervous and Mental Diseases*, vol. xxi, No. 10, p. 636) has reported the case of a deep-water diver who, after descending to a depth of twenty-one feet and reaching the surface, complained of sharp pains in the arms and legs, and almost at once became unconscious, thus remaining for about one-and-one-half hours. The arms and legs were motionless, while some sensation remained in the arms, although completely absent in the legs. The tendon-reflexes in the arms and legs were wanting, as were also the skin-reflexes. The rectal and vesical sphincters were paralyzed. Symptoms of pneumonia appeared, cystitis and bed-sores developed, and death resulted from septicemia. Upon post-mortem examination evidence was found indicative of the occurrence of numerous hemorrhages in the cervical cord, with secondary softening and inflammatory changes affecting especially the posterior and lateral columns of the cervical and upper dorsal portions.

Gangrene of the Lung Following Pleuro-pneumonia.—Goelet (*North Carolina Medical Journal*, vol. xxxiv, No. 5, p. 217) has reported the case of a man, twenty-three years old, addicted to alcoholic excess, in which, on the sixteenth day of an attack of pleuro-pneumonia, the expectoration became offensive, and in a short time unequivocal symptoms of gangrene of the lung appeared. Under treatment with spirit of turpentine, 5 drops, fluid extract of eucalyptus, 5 drops, and beechwood creosote, 2 drops, every two hours, with frequent inhalations of the vapor of turpentine, marked improvement soon ensued, and in the course of a month the patient was able to sit up, and the temperature and bowels had become normal. At the inferior border of the left scapula there persisted an area of dulness on percussion, some three inches in diameter, in which the respiratory sounds were not to be heard.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—At a recent meeting of the Medical Society of Hamburg, Rumpf (*Münchener medicin. Wochenschr.*, 1894, No. 47, p. 938) reported the results obtained in the new General Hospital from the employment of Behring's antitoxin in the treatment of diphtheria. Twenty-six cases were thus treated, the clinical diagnosis being confirmed by the results of bacteriologic examination in all of the cases but one. Eighteen of the cases came under observation on the second day of the disease, 3 on the third day, and 5 later. All were in children between the ages of ten months and 12 years. Among the whole number there were 2 deaths (8 per cent.): 1 among the group of 18 cases, the other among the group of 5. Four of the cases were mild, 8 moderately severe, and 13 severe. Tracheotomy was performed in 7 cases; among this number were 2 fatal cases. The injections were made into the abdominal wall. In not a single instance was there any local reaction. In 11 cases the temperature appeared to be influenced by the injections; in 3 it rose, while in 8 it declined. In several cases the false membrane continued to spread. Albuminuria was found in 8 cases, in 1 of which it had not been present before the injection. The complete statistics for several months showed that there had been 91 cases of diphtheria in the hospital, with 11 deaths (12 per cent.). On bacteriologic examination of the kidneys and spleen from all fatal cases of diphtheria for a given period it was possible to isolate streptococci in 27 of 42 cases.

The Treatment of Anemia, Particularly Chlorosis, by Means of Sweating.—Künne (*Deutsche medicinische Wochenschrift*, 1894, No. 44, p. 846) reports the employment of sweating in the treatment of forty cases of anemia, including twenty-three of chlorosis. He employed a spring mattress, within which passed hollow coils, and over which was placed a support of wire netting, which was covered in turn with sail-cloth, and upon this the patient was placed and covered with woollens. By means of a spirit-lamp the air passing through the coils within the mattress is heated, and the warmth is in this way conducted to the patient. The application is thus continued for from an hour and a half to two hours and a half, after which the patient remains for a similar period in an ordinary bed. In the cases treated in this manner the number of corpuscles in the blood and the amount of hemoglobin rapidly increased, as a rule reaching four-millions of the former and 80 per cent. of the latter in the course of from six to eight weeks; at the same time there was appreciable increase in bodily weight. The subjective symptoms likewise receded, the menstrual derangement persisting longest. In conjunction with the sweating iron was also administered, and gentle out-of-door exercise was recommended.

Nitro-Glycerin for Singultus.—Griswold (*Journal of the American Medical Association*, 1894, vol. xxiii, No. 17, p. 646) has reported a case of obstinate singultus in an habitual alcoholic fifty years old, which, after the failure of other measures, was controlled by the administration of a pill of nitro-glycerin, gr. $\frac{1}{150}$, given at intervals of three hours. The hiccup ceased after the administration of the fifth pill.

For Intercostal Neuralgia.—

R.—Linimenti belladonnæ . . . f℥j.
Linimenti chloroformi . . . f℥iv.
Linimenti opii . . . . ad f℥iij.
Misce et fiat linimentum.
To be well rubbed over the painful area.

SATURDAY, DECEMBER 15, 1894.

THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

Serum-therapy is the logical outgrowth of the modern doctrines concerning the infectious diseases. The fundamental ideas underlying it have for a long time been appreciated, and we have to thank the bacteriologists for rendering of practical therapeutic value our knowledge concerning immunity. The present methods of producing immunity are merely modifications of those used by Pasteur in dealing with chicken-cholera and with anthrax, and by his followers with symptomatic anthrax and the pyocyanean infections. Pasteur's work was inspired, no doubt, by the success of Jenner's vaccination, the latter having been led to his experiments by observing the insusceptibility to smallpox of individuals who had survived the disease whether contracted from ordinary exposure or by inoculation, after Lady Montague had brought back that method from China.

In the earlier immunizing experiments, the living virus in some form, either in full strength, or weakened by heating or by the action of chemic agents, was introduced into the animals experimented upon. Some time later, Toussaint, Chauveau, Salomon and Smith, and Charrin, showed the feasibility of chemic vaccination, *i. e.*, they proved that the products of the bacteria causing a specific infection were capable, when injected into certain animals, of setting up in them immunity from the disease. Koch's treatment of tuberculosis consisted simply in the injection of a glycerin extract (tuberculin) of cultures of the tubercle-bacillus, and was really an attempt to produce immunity by the action of the chemic products of the bacilli.

It was early learned that immunity is not reached immediately after the introduction of the vaccinating substances into the body. There must first be a reaction on the part of the organism (the tuberculin-reaction is an example familiar to all) to the virus or toxin, after which a greater or less degree of immunity or lessening of susceptibility follows with the lapse of a certain time. The workers were agreed that the only way to arrive at a knowledge of the changes brought about in the body through an infectious disease which renders the animal subsequently insusceptible to the same disease lay in a careful examination of the tissues and fluids of the body before, during, and after the period of infection. The work of Fodor, Grohmann, and especially of Nuttall demonstrated conclusively the germicidal power of normal blood-serum, a property which the serum possesses in common with its globulicidal and antitoxic activities (Buchner). Whether these properties are possessed by the serum entirely independently of the cells of the body, or whether they are due to the presence of substances in the serum which have had their origin in the cells, are still disputed questions, though there can be but little doubt that the latter view will prove ultimately to be the correct one. It has been thought that natural immunity, or the natural resistance which an animal offers to an infectious agent is to be explained by the presence in the blood-plasma of these protecting substances (alexins).

Nuttall, in his experiments, proved that the blood-serum taken from an animal rendered artificially immune from anthrax was capable of killing a greater number of anthrax-bacilli than the blood-serum of an ordinary healthy animal. Héricourt and Richet demonstrated that the blood of a dog which had been inoculated with a culture of the staphylococcus pyosepticus, and had recovered from the infection, when injected into rabbits rendered these immune from the same virus. Behring and his co-workers went a step further, and showed that

blood-serum taken from an immunized animal was capable not only of producing immunity from the same infectious agent in another animal, but also of curing or "healing" an infection already in progress. In 1890 BEHRING established these facts for diphtheria, and soon after in association with KITASATO proved the same to be true for tetanus.[1]

The early skepticism with regard to the possibility of the production of immunity against diphtheria was attributable, no doubt, to the fact that diphtheria, like pneumonia, is a disease of which an individual may have more than one attack. As a matter of fact, a patient who has once had diphtheria seems after a certain time to be more susceptible than an ordinary person of being attacked by the same disease. The creation of an artificial immunity to smallpox or scarlet fever would have seemed more easily understandable than that of an artificial immunity from diphtheria or from pneumonia. Nor is it surprising that the same misunderstanding should have existed concerning anthrax until it was shown that animals could by artificial means be rendered immune from the disease. The conception of immunity had, therefore, to be widened considerably, and it seems necessary to make it a relative term; there are varying grades of resistance to infection, and varying lengths of time during which such resistance is valid, so that we can speak of a partial or a complete, of a temporary, or of a permanent immunity. In diphtheria and pneumonia it is probable that a surviving patient does not become immune immediately after the cessation of the serious symptoms; it would seem rather that changes gradually occur in the body, bringing about immunity until a period of acme is reached which lasts for some time, and after which protection against reinfection becomes less and less certain, until finally the individual is quite as susceptible, or even more so, than one who has never passed through the disease.

LOEFFLER was probably the first to render an animal immune to the virus of diphtheria. A guinea-pig which he inoculated with a small quantity of a pure culture of the bacillus recovered from the infection, and afterward proved to be resistant to repeated inoculations with virulent cultures. BEHRING, FRAENKEL, BOER, LÜBBERT, and WERNICKE have tested various methods for producing artificial immunity from diphtheria, among them vaccination with sterilized bouillon-cultures, with bouillon-cultures treated with iodin trichlorid, or with tissue or tissue-juices of animals sick or dead of diphtheria, and also by feeding with the toxins of the diphtheria-bacilli. BRIEGER, KITASATO, and WASSERMANN in the beginning of 1892 grew diphtheria-bacilli in thymus-bouillon, thinking, according to BEHRING, erroneously, that the thymus-extract exercised an antitoxic influence on the specific diphtheria-poison. They used the product thus obtained for purposes of vaccination. Results have taught, however, that immunity against diphtheria can be most successfully produced and can be carried to the highest grade by beginning with injections of much weakened and highly diluted virus.

The principal drawback to the application of serum-therapy to human beings has lain in the difficulty of securing a serum which holds the healing or so-called "antitoxic" substances in sufficient concentration. Large animals have to be used, and these must be inoculated repeatedly with gradually increasing quantities of virus or toxins until the serum has acquired a tolerably high degree of antitoxic activity. The preparation of the serum according to BEHRING'S method at Höchst-on-the-Main is carried on at considerable expense. The cultures, standard toxin-solutions and control-experiments are made in a well-equipped bacteriologic laboratory. Near by are the stables in which the larger animals, such as horses, cattle, and sheep are kept. For the preparation of the diphtheria-antitoxin young horses, healthy except, perhaps, for slight blemishes, are kept under observation for some days, after which the first injection of the virus is given. The animal receives subcutaneously in the region of the shoulder a quantity of an old bouillon culture of diphtheria-bacilli which has been nearly freed from organisms by filtration or simply by decantation; to this is added 0.5 per cent. of carbolic acid. The mixture is well diluted with water, and sufficient is injected to set up a mild reaction, the temperature reaching 39° C. or a little more. The animal loses its appetite, fails in weight, and there is edema in the neighborhood of the site of the injection. If the dose has been rather too large there may be paresis of the posterior limbs. It

[1] It would almost seem as if Mithridates, a hundred years before Christ, had some glimmerings of immunity and blood-serum therapy. His skill in devising chemic antidotes for deadly poisons is well known; but he went even further than this, for Pliny states that having noticed that the ducks of Pontus fed on poisonous substances, he used their blood to mix with his antidotes, so as to make these even more efficacious; *sanguinean anatum Ponticorum miscere antidotis quoniam veneno viverent.*

is sometimes difficult to estimate just the amount which will evoke the proper reaction, although control-experiments on guinea-pigs serve to a certain extent as a guide to the toxicity of a given injection-fluid. The injections must not follow one another too quickly; the animal is allowed to fully recover before a second dose is administered.

A horse, after receiving injections at intervals of from one to four weeks, becomes only very gradually immune, and it is not until the end of from four to six months that the serum has gained any considerable antitoxic power. The amount and strength of the virus are gradually increased as the immunizing process proceeds, so that finally an animal is able to bear several liters of undiluted toxin-solution. It is to be noted, however, that the antitoxic value of the blood-serum of the immunized horse bears no definite relation to the amount of toxin that has been introduced into his system. The antitoxic strength of the serum of the horse has to be tested from time to time by experiments on guinea-pigs, the serum being tried not too soon after an injection of the virus. When the desired antitoxic strength has been attained, from one to three liters of blood are drawn through a canula from the jugular vein into sterilized vessels, and cooled in the ice-box for from twelve to fourteen hours. The serum is then poured off, and after 0.5 per cent. carbolic acid has been added its exact antitoxic strength is tested upon animals. After the blood has been extracted the animal is usually hungry and thirsty. If it bears the blood-letting well the process may be repeated two or three times in the course of eight days, after which there must be a renewal of the vaccinations for several weeks.

(To be concluded.)

EDITORIAL COMMENTS.

Foot-ball Rowdyism, we had hoped, would have ended with the "Thanksgiving games," but worse than the fact, now come interminable defenses of the fact. The disgrace of the games was bad enough, but the defenses of the present-day game are so much worse that deaths (of which there have been one or two more since our last issue) and broken bones and sluggings and brutality are as nothing to it. The sly silences, the tricks of logic, the evasiveness, the wrigglings, "bluffs," bravado, and "whitewashings" of foot-ball would be most amusing if it were not the sorriest, the saddest spectacle of the day. The subterfuge and illogicality of calling this brutality "athletics" is unpardonable. Foot-ball and its defenses are, of course, as great crimes against athletics as against education. The spirits of the men who endowed institutions of learning for purposes of mental and moral training will yet rise from their graves and demand an accounting on the part of the modern holders of the trust. These will be found in time to have done education the greatest of all injuries, as they have by their own action largely lost the respect and confidence of the community, and in future rich men will, we fear, consider too well the clauses in their wills that give money to institutions for the discouragement of intellectual and scientific athletics and for the encouragement of the intercollegiate foot-ball variety. For a time, it is true, the "student" is the master, and the professor is his devoted flatterer and servant.

But for a time only. Luckily enough, there are signs that in the colleges there are still left some lovers of true athletics and of true education. They have too long kept still in face of the noisy degraders of both. Luckily enough, also, the "common people" have not also lost their heads. Everywhere mothers and fathers and guardians are looking about them for colleges whose chief aim is not to advertise their "educational" institutions by foot-ball matches. Mothers have been known to go on the "gridiron" and take their sons off from the fire. In the last fifteen years the growth in the academic department of Yale has been from 612 to 1159, and in the scientific department from 190 to 665. In Harvard, in the same time and in the respective departments, it has been from 843 to 1667, and from 37 to 320. Thus the growth at Harvard has been much greater than at Yale, and yet during the same years Harvard has won but a single foot-ball game with Yale and only four boat races. Thus the very fundamental premise of foot-ball logic is a proved fallacy. Still another sign of coming sanity (would there were more) is the public announcement by one great institution (Pennsylvania) that would-be players must henceforth be "amateurs, bona fide students in good standing, of one year's residence at the University, and who have passed the annual examinations upon a full year's work." But how soon shall we hear of the greatest scholar being honored by his college and by his fellows, as to-day is the flattered, bepictured, and bepraised hero of the gridiron? Despite the "athletic" craze in England, the senior wranglers are the most honored of the children of the universities. But who is most honored with us? The nation that values brawn and brutality more than intellect and learning will assuredly get what it wishes. But will what it gets be the best thing for it, or for civilization?

The Removal of Foreign Bodies from the Cornea.—Mechanics and workmen have learned from oculists (who should have taught them better) the method of removing foreign bodies from the cornea by "picking them out" with some sharp or slightly blunted metal instrument. In every factory or workshop every day, and often many times a day, it occurs that pins, knives, etc., are thus blunderingly used, frequently with great injury to the cornea, with the resultant formation of corneal ulcers, keratitis, iritis, or at least, leucomata. All text-books of ophthalmology advise the use of the "corneal spud" for removing such particles, and every young physician supplies himself with the instrument. But it is the most outrageously ill-adapted for the purpose conceivable. It is impossible for any patient to hold the eye still enough to permit any hand thus to remove a

partly-imbedded grain of sand, or emery, or what-not, without wounding the epithelium of the cornea. For this purpose a rigid tool is absurd, and a rigid metal instrument is the acme of absurdity. Every physician should teach workingmen how easy it is, and how free from any danger of injury, to remove the great majority of foreign bodies on the cornea with a simple wisp of cotton. Any particle not thus removable should not be sought after with pen-knives, awls, pins, or spuds, but the patient should be sent to a physician. Twist a little wisp of absorbent cotton, having long fibers, upon itself until the fibrils are well caught, but are not too densely packed, upon each other. Fold the roll upon itself and grasp it half an inch from the rounded or curved extremity. The eyelids are held apart by the fingers of the left hand, and the patient instructed to look in such a direction as to bring the foreign body into view. By delicate, though firm pressure, the wisp of cotton is brushed, not too quickly, across the cornea, or it is given a slight twist or screw-like movement when deftly pressed against the cornea. Almost invariably the dust-particle is removed at the first trial, being entangled or caught by the fibrils of the cotton. Cocain, blepharostat, spud, time, labor, and injury, are all dispensed with and happily spared. The procedure may not be for the commercial advantage of the specialist, but it is worth more to the world than seven "original researches" and prize-essays.

Great caution is needed in the matter of supply of the antitoxin of diphtheria. Analyses have been made of some samples in the market, and, while these have been found harmless, they have also been shown to be absolutely inert. A report is current that ARONSON has separated the active principle from the serum, and that he is "working in association" with a noted firm of chemists which is proceeding to patent the invention. Should such an outrage prove true, it will be a great scandal to medicine. The *New York Herald* has started a subscription, itself leading off with $1000, to provide serum for the poor. The lay public and the newspapers should leave this matter in the hands of the medical profession. Such a movement as that of the *Herald* can only bring harm in the long run. In the present condition of the public pulse, and with the infinitesimal amount of the antitoxin obtainable, it can have no other effect than to enormously enhance the price of what serum is to be had. Moreover, it is by no means certain, despite all that has been reported, that the agent is of so great therpeutic value as it is considered to be. Perhaps the whole thing may prove a failure. Above all, let us have no silly or insane haste, and no debasing commercialization of the means of treatment. Let science and professional experiment dictate and guide, and let us wait until the assurance and the guidance is beyond all doubtfulness and deceit.

CORRESPONDENCE.

CASTRATION FOR THE CURE OF HYPERTROPHIED PROSTATE.

To the Editor of THE MEDICAL NEWS,

SIR: The evidence summarized in my communication on page 664 of this number of THE NEWS obviously and amply justifies the suggestion made by me last year, and which was not made without hesitation. Having observed with disapprobation the undiscriminating assaults of some extremists upon the urethra the tubes, and ovaries, and more recently upon the appendix, I did not want to be responsible for a similar attack upon the testicles. I therefore took pains to say that I had as yet arrived at no definite conclusions, but was still seeking further light on the subject, knowing that the step from experiment to operation is and should be a long one, and feeling the responsibility involved in proposing any new operation, especially one of this character, easy of performance, with a low mortality and intended for the relief of a condition of enormous frequency. , This appears to me to have been a proper attitude, but Mr. Mansell Moullin has recently twice gone to the trouble of calling attention to the way in which I introduced the operation, each time coupling his remarks with the statement (made by him once before) that he suggested it to a patient in November, 1892. If his motive for this thrice-repeated assertion is the apparent one of a claim of priority of thought, it would be easy for me to establish the facts that I told Dr. John S Billings, of Washington, my views on the subject in the early summer of 1892, and that I outlined my experiments and instructed my assistants in regard to them in October of the same year. This would antedate both Mr. Moullin's "suggestion" and Ramm's operations. But these are puerilities. I believe that the surgeon who, before submitting his patients to a hitherto untried operative procedure, seeks the criticism of his colleagues, occupies a sounder position than he who, with neither experimental evidence nor professional backing, bases his advice on what, in this instance, must have been little better than guesswork. As I have already said, I have no wish to claim operative priority, and the question of vague suggestions to anonymous patients is too insignificant to merit attention. But I would like to be credited with having been the first to undertake a series of experiments to determine the effect of castration on the prostate, and the rapidity of that effect, with a view to the therapeutic value of the operation, and then with having, with what still seems to me proper caution, presented for the first time the whole subject to the profession, with the evidence upon which my suggestion was based. The operation appears to have come to stay, and in view of the wide field which it may some day occupy, it is not unnatural that I should desire to have my relation to its introduction and adoption kept straight as a matter of record. I am, sir, yours, etc.,

J. WILLIAM WHITE.

THE TREATMENT OF TUBERCULOSIS WITH YEAST-NUCLEIN.

BY VICTOR C. VAUGHAN, M.D., PH.D.,
OF ANN ARBOR, MICHIGAN;
PROFESSOR OF HYGIENE AND DEAN OF THE DEPARTMENTS OF MEDICINE AND SURGERY IN MICHIGAN UNIVERSITY.

(Continued from page 659.)

CASE I.—A. W., was born in Ann Arbor, of German parents, in 1869. His father and mother were living at the time the treatment was begun, and no member of the family had given any evidence of tuberculosis. He had been employed in a drug-store for nearly ten years, the last three years at Calumet, Michigan. For the past four years, possibly longer, he had been drinking excessively. Dr. Pomeroy, of Calumet, sent him to me about the first of April, 1893. At Christmas, 1892, he weighed 138 pounds. About this time his cough attracted the attention of Dr. Pomeroy, who examined his sputum and found tubercle-bacilli present in large numbers. During the first four months of 1892 the disease made rapid progress. During April the evening temperature ranged from 102° to 103°. The man took from one-fourth to one-half grain of morphin each night to allay the cough. Night-sweats were constant, profuse and exhausting. During this time he staid in doors, and the hygienic condition of the house in which his parents lived, and where he staid from his coming home until his death, was extremely bad. Situated on low ground, without cellar, heated by stoves, unventilated, and damp, it furnished a most unsuitable abode for the patient. I recognized this fact all the time, but being unable to change his habitation, I thought that the results, whatever they might be, would be interesting, inasmuch as I would learn what could be done under such unfavorable conditions. On the first day of May, 1893, I began the nuclein-injections, and I insisted that however he might feel, or whatever the weather might be, he should walk to my office, a distance of about half a mile, every morning, and that in good weather he should be out of doors as much as possible. On this day he weighed 113 pounds. The use of morphin and all other drugs was prohibited. The upper third of the left lung and the apex of the right contained small cavities. The cough was severe and the expectoration measured half a pint or more daily. During the first three weeks of treatment he was compelled to rest several times on his way to the office each morning. The solution used contained 0.9 of one per cent. of impure yeast nucleinic acid, and 0.25 per cent. of potassium hydroxid. The injections were at all times made in the muscles of the chest. I began with three minims of this solution, and gradually increased the dose to eighty minims. The temperature, which was taken three times a day, with a tested thermometer, rapidly fell until May 12th, when it was normal all day. From this time until August 31st the maximum temperature was not above 99°, with the following exceptions: June 1st, he had a sharp diarrhea and an evening temperature of 100°. June 16th, he had an evening temperature of 101°, followed by a profuse sweat. July 13th and 14th he had a temperature of 100°, following unusually large injections of the nuclein. On July 21st his midday temperature was 101°, and the following day 100°. During these days he had no injections, but he took a solution of nuclein containing 0.5 per cent. alkali three times daily in tablespoonful doses. This was discontinued and the temperature became normal. August 4th and 11th, he had an evening temperature of 100° without any assignable cause. From August 21st to 25th he had a diarrhea, of unknown cause, and twice during this time the temperature registered 101°. August 29th, the temperature went to 100° after an injection.

The man's weight gradually increased, some weeks losing a little, others gaining, until August 31st he weighed 119 pounds. The cough and expectoration gradually decreased until my last August record on this point, which is as follows: "August 19th, examined the sputum. The amount is very small. He brought all that he raised this morning, not more than a teaspoonful. Before the treatment was begun he would cough and raise all night, unless he had a large dose of morphin. The sputum, however, though small in amount, is rich in germs."

I could not see that during this time there had been any marked alterations in the physical conditions, except that there was an absence of râles over the involved areas. The patient could now run two or three blocks without getting short of breath, but the cavities were still there. I should say that from May 12th to August 31st the progress of the disease was arrested or so modified that its advance could not be detected. I must admit, however, that I cannot speak with the confidence that some do concerning very slight alterations in the lungs as determined by physical signs.

From August 31st to September 12th I did not see the patient, although I provided for the continuance of the treatment through the kindness of my colleague, Dr. Clark, who did his duty thoroughly. But the patient took this time, as I afterward learned from his mother, to go on a protracted spree. She reported that he was frequently out at night until very late hours, and that more than once he came home intoxicated.

After my return he had only a few treatments, and some weeks passed without my seeing him. Late in October, the sickness and death from typhoid fever

of another member of the family depressed him very much. He began the use of morphin again, and a return of the high temperature, frequent cough and abundant expectoration showed the rapid progress of the disease. The last injection was given September 29, 1893, and he died March 17, 1894.

Just how much of the temporary improvement which accompanied the nuclein-treatment was due to this I cannot say. I am inclined, however, to attribute no small part of it to the temporary abandonment of bad habits and the getting out of doors, which took him for a considerable portion of the twenty-four hours from the unsanitary house. Moreover, open doors and windows during the summer reduced the ill-effects of his unsanitary surroundings to a minimum. I am glad to report this case, because it plainly teaches, in my opinion, that the sanitary conditions of the domicile and the habits of the patient are important factors in the treatment of tuberculosis. I believe that they are of much greater importance than climatic conditions.

CASE II.—F. M., a student from Kansas City, aged twenty-two; knew of no tuberculosis in the family. He had his first hemorrhage in 1891, and has had several recurrences since, the intervals becoming shorter. He had a quite profuse one six weeks before, and another the day before he first consulted me, which was late in April, 1893. He had weighed 125 pounds the preceding Christmas; his weight at the time of beginning treatment was 115½ pounds. Moist râles were heard over both lungs both anteriorly and posteriorly. No cavities could be detected. The sputum contained numerous tubercles half the size of peas. On crushing these between cover-glasses and straining, each was found filled with bacilli. The daily maximum temperature for three days before beginning the treatment averaged 100.3°. He had had a night-sweat every night for some weeks.

Treatment was begun May 1, 1893. The same solution in the same quantities as in the preceding case was used. The last treatment was given June 30, 1893. The temperature did not reach 100° after June 2d; it seldom went higher than 99°, and during the last four days it was normal continuously. The râles disappeared, and diminished resonance over the upper lobes was the only physical evidence of the diseased condition. During the treatment there was no gain in weight, the record for June 24th showing 114½ pounds. Night-sweats were occasional and slight during June. The cough and expectoration decreased, and some mornings during the latter part of June he failed to raise anything when asked to bring the sputum for examination; but when sputum was raised and examined, the bacillus was always found.

After leaving Ann Arbor he spent one week at the World's Fair, and then went home. A letter of July 10, 1893, states that his cough had been very infrequent, and the highest temperature observed was 99°, though it was taken somewhat irregularly. Later in the same month the young man, accompanied by his father and brother, drove in a light wagon from Kansas City to Boulder, Colorado, where a position had been tendered him, and where he has since lived. During this journey he lost some flesh, weighing 111 pounds after reaching Boulder. Since that time he has very slowly gained in weight, having increased to 125 pounds in June, 1894, when he visited Ann Arbor. I examined him carefully at that time, and could not detect any marked alteration in the physical signs from those observed one year before. He seldom coughed, sometimes not for several days, but when he did raise anything I could easily find the bacilli. He calls himself well, but the infection remains. He has had no nuclein since June 30, 1893. It is impossible to say whether or not the improvement would have continued, or whether or not the bacilli would have remained, had the treatment been kept up. To attempt to answer these questions would be to theorize, and this would be neither scientific nor profitable.[1]

CASE III.—H. H., a student from Silver Springs, N. Y., had been home during the spring vacation of 1893, and returned with a letter from Dr. Straight, of that place, to me, in April. He was twenty-four years of age, and his usual weight had been for some time 140 pounds, but the first day of May his weight was 127. His maternal grandfather was said to have died of pulmonary tuberculosis, but he knew of no other case in the family. He had never seen this grandfather. His father and mother were living and well. He had had a hemorrhage in the spring of 1892, but during the early winter of 1892–93 he had felt especially well. However, during the latter part of this winter he had felt depressed and weak. Late in March he had another hemorrhage. The upper lobe of the left lung was extensively involved, and contained a large cavity. The apex of the right lung contained a smaller cavity. The evening temperature averaged 100.4.° Cough and expectoration were free, and the sputum consisted of a purulent fluid containing numerous tubercle-bacilli. The patient was very weak, and should have been compelled to discontinue his work, which was that of a student in mechanical engineering, demanding considerable exertion, but he was to graduate in a few weeks, and insisted on continuing his labors. He had the same treatment as the preceding two, taking his last injection July 7, 1893. During this time he gained three and one-half pounds, and during the last week of his stay here his daily maximum temperature averaged 99.4.° There was no detectable alteration in the physical signs, and the sputum remained substantially the same. He then returned to his home in New York, where he took cod-liver oil and malt. For some weeks he sent me a daily record of his temperature. The average maximum was 100.5° for the week ending July 28th. After this he was for eight weeks in a sanitarium at Lakewood, New Jersey. He also sent me a partial record of his temperature while there, but

[1] Since writing the above I have learned that Mr. F. M. had several hemorrhages recently.

as he was taking antifebrin whenever the temperature rose to 100°, the record is of no value. On his return from the sanitarium to his home he sent me some of the sputum, in which I found no evidence of improvement. In February, 1894, he sent to me for some nuclein to be used by Dr. Straight, but a letter from the doctor told me he regarded the case as hopeless. However, he did use the nuclein for some weeks, but the disease progressed, and death occurred October 1, 1894. I do not believe that the nuclein could have been of any material benefit in this case had it been continuously employed.

CASE IV.—Dr. M., aged twenty-six, consulted me June 21, 1893. At my request he wrote at that time the following short history of his case: "In February, 1892, I was not feeling well, and attributed this to the want of exercise, as I was closely confined in the laboratory, but had no symptoms to attract attention to the urinary tract. One day, while examining various urines, I accidentally discovered pus in mine. I took boric acid, then salol, pichi, and lastly buchu, without effect. Stone was suspected, and Dr. Nancrede passed a sound with negative result; but after the sounding the urine became almost normal, and remained so for several weeks, then gradually became as cloudy as ever. In July, 1892, Dr. Warthin discovered tubercle-bacilli in small caseous masses deposited in the urine. I then took a capsule containing one grain each of quinin and iodoform and one-thirtieth of a grain of strychnin sulphate, three times daily, from August, 1892, to February, 1893. I took also during this time six bottles of malt. During August and September, 1892, I used injections per catheter of iodoform in oil, but this set up such a violent inflammation that I desisted from all local medication. In February, 1893, my appetite completely failed, and thinking that the iodoform caused this I discontinued it. Then I began hypodermic injections of iodin and gold, taking at the same time about two ounces of cod-liver oil per day. I took during February, March, April and May, 1893, about sixty injections of iodin and forty of gold, ten minims in each injection. The cod-liver oil became nauseating, and had to be discontinued, after having taken about one gallon in seven weeks, and gaining seven pounds. My weight when bacilli were discovered in July, 1892, was 119 pounds; in September, 124 pounds. After taking the cod-liver oil my weight reached 131, but soon fell after discontinuing the oil, and now it is 122. I have never had night-sweats, or rise of temperature. My appetite is good, but my bowels are constipated. The local symptoms are scarcely noticeable, but there are slight irritation and pain in the perineum on urinating."

A few days ago I wrote to Dr. M., who is now practising in Nebraska, and asked him to give a short synopsis of his case from beginning the nuclein-treatment to the present time. I insert his answer without alteration:

HEMINGFORD, November 16.

"Yours of the 16th instant to hand this morning, and I enclose an account of my past and present condition. I keep nuclein on hand all the time, and it promptly relieves any vesical irritation. I have used it with marked benefit in two cases of pulmonary tuberculosis—one is now quite well, the other is dead. I used it with good effect in several cases of acute naso-pharyngeal catarrh. My own health I consider as fully restored. On June 21, 1893, I had first injection of nuclein, about 5 mg. On June 22, 23, and 24 I had increasing doses, and June 25 had 25 mg., which caused severe local inflammation, chill and fever.

On June 28th, I had another small injection. On June 30th I went to Manistique, Mich. My weight then was 121½ pounds. On July 12th I began the use of nuclein, 4 c.c. per day hypodermically, and continued for four weeks, when I weighed 124½ pounds. At this time I had a severe attack of diarrhea. On August 18th I received more nuclein, which I used as before until about September 12th, when I left Manistique and went to Chicago for two weeks. On September 26th I returned to Ann Arbor and again used nuclein hypodermically, from 6 to 12 c.c. per day. On October 4th I commenced injecting directly into the bladder about 2 oz. nuclein plus 2 oz. normal saline, after first washing out the bladder with normal saline solution. My weight was 119 pounds. I had so much irritation of the bladder that I had to take tincture of hyoscyamus constantly. I injected nuclein hypodermically twice a day and into the bladder once or twice a week till about November 26th. I used only vegetable diet. My weight was 123½ pounds. I had to discontinue injections into the bladder on account of irritation. I had much stomach-trouble, and on December 23d I weighed 118½ pounds. On December 23d I discontinued all injections and took nuclein only by the stomach, about 3 or 4 oz. per day. I took also iron and ergot for two weeks. I changed diet from vegetable to chiefly proteid food, and took a little cod-liver oil, which disturbed the digestion. On January 6, 1894, I felt much better. Irritation of the bladder had ceased, digestion was much improved, and my weight was 120 pounds. On March 14th, the bladder was very irritable, and incontinence of urine was very troublesome. I had to use a rubber urinal. I used nuclein hypodermically and also injected it into the bladder. I took uva ursi for vesical irritability. On April 4th I left Ann Arbor for Nebraska. The bladder was very painful, and urine could not be retained for more than two or three hours at any time. My weight was 118 pounds. On June 15th I had improved very much. I have used altogether four gallons of nuclein-solution, mostly injected into the bladder. I had no incontinence and very little irritation of the bladder. The urine still contained pus. My weight was 125 pounds. On July 27th I had a severe attack of acute cystitis, lasting three weeks, and I passed a small phosphatic calculus about a quarter of an inch in diameter, after which the cystitis rapidly improved and soon ceased entirely.

November 19th. Since July I have steadily improved, and have used no treatment of any kind except an occasional injection into the bladder of an emulsion of iodoform. I have no incontinence and scarcely noticeable irritation. I am feeling

better generally than during any time the past ten years. I am heavier than for twelve years and have gained 7½ pounds in the past two weeks. The urine is still slightly cloudy, mostly from mucus, as there is little pus. I sent a sample to Dr. Warthin last week to be examined for tubercle-bacilli.

A. L. Muirhead.

Dr. Warthin reports that he could find no tubercle-bacilli in the urine.

Case V.—G. T., aged twenty-two, first consulted me in October, 1892. At that time he had considerable irritation at the neck of the bladder, frequency of micturition, and a deposit of blood in the urine. He was sent to Dr. Nancrede with the request that he be sounded for stone. Dr. Nancrede failed to find a stone and suggested tuberculosis. Examination showed tubercle-bacilli abundantly present in the urinary sediment. Salol, quinin, iodoform, and other remedies were tried, both internally and by injection into the bladder, but the progress of the disease was in no wise arrested. In the spring of 1893 T. went to Colorado. He remained in the West, in Colorado and New Mexico until the first of April, 1894, when he returned to Ann Arbor to try the nuclein-treatment. Evidently his stay in the West had not retarded the progress of the disease. When he went West the disease was confined, so far as the symptoms indicated, to the bladder. On his return the left kidney formed a tumor as large as the head of a newly-born child, and could be plainly felt through the thin walls. Nearly every day he was compelled to take morphin in order to allay the severe pain due to the passage of tuberculous masses from the kidney to the bladder. This pain came on in paroxysms, and often seemed as severe as that due to the passage of calculi along the ureter. The urine contained a large amount of pus and blood, in which tubercle-bacilli were easily detected. Sleep was often prevented by the pain. With the exception of the bladder and kidney there was no evidence that other organs were involved in the tuberculous process.

The nuclein-injections were begun April 12, 1894, and with a few exceptions they have been continued daily from that time to the present writing (November 20). A one-half per cent. solution was used until about the middle of October, since which time a one per cent. solution has been employed. Ten minims constituted the first dose, and the amount was rapidly increased to eighty with the weaker solution and forty with the stronger. The injections are made deeply into the muscles on each side of the spine, over the kidneys. There is no evidence of enlargement of the right kidney, and the greater number of the treatments have been given on the left side.

The greatest weight reached before his illness was 132 pounds. The decrease was gradual and constant to the time of beginning the treatment, when he weighed 114 pounds. Since beginning the treatment the weight has steadily increased and is now 138 pounds. The temperature at first often reached 102.5° and sometimes 103° in the evening. It has not been above the normal since early in October. The urine will be wholly free from sediment for several consecutive days, and then there will be a little pus in which the bacilli can be detected. There is still some undue frequency of micturition, and at times a sensation that the bladder has not been wholly emptied at the close of the act. The kidney has decreased in size but is still abnormally large. There has been no pain from the passage of tuberculous masses through the ureter since the latter part of May. Of course, it is possible that the disease may extend again. I shall not call this a cure until the urine becomes permanently normal, and this may never happen. But even should this not occur, the history of the case is unique.

Case VI.—This case is reported out of order chronologically, in order to bring together the cases of urinary tuberculosis which I have treated with nuclein. R., a physician, practising in Wisconsin, ordinarily very robust and weighing about 200 pounds, aged forty-three years, had not been feeling usually vigorous for some months, and had lost about 15 pounds. In February, 1894, he noticed traces of blood in his urine. Some of this was sent to me for examination. The tubercle-bacillus was detected and a guinea-pig was inoculated with the sediment. Twelve days later, Dr. R. came here, and both of us being anxious to know whether or not the microscopic finding would be confirmed by the inoculation-experiment, the pig was killed. There was a tuberculous nodule containing bacilli at the place of inoculation, and two smaller ones in the peritoneum. The next day, March 19th, the treatment was begun. There had been no elevation of temperature before this, and a general feeling of lassitude and the deposit in the urine were practically the only things to attract attention. Ordinary doses of nuclein were followed in this case by a marked elevation of temperature, so that after the first few weeks not more than 30 minims were given. The deposit wholly disappeared in a short time. The injections were continued up to August, since which time no treatment has been used. The lost flesh has been regained and the urine remains normal. Evidently, in this instance, the disease had not progressed very far.

Case VII.—Mrs. Z., came to me June 25, 1893. Her condition was bad. She had a large abscess from pyosalpinx, from which an umbilical hernia resulted. The left lung was involved throughout its entire extent and contained a large cavity in the upper lobe, and the upper lobe of the right lung was consolidated. She had been treated for some months with injections of gold and iodin. Her weight was 117 pounds. The treatment was begun June 25, 1893, and was continued to September 19th of the same year. Although there was some slight gain in weight (to 123 pounds), the disease steadily progressed. In September she went to Arizona, where she remained until June, 1894, when she returned to Ann Arbor, and, failing constantly, died early in September.

Case VIII.—Mrs. C., had been known to have "consumption" for two years. Her weight was reduced to 80 pounds, from 115 in health. Both lungs were filled with cavities. The evening tem-

perature ranged from 102° to 103°. Nuclein was used two or three times per week without the slightest effect.

CASES IX to XVI inclusive were all instances of extensive involvement and with cavities. A detailed report of these would not be of special interest. Suffice it to say that although there were in some marked evidences of temporary improvement while under treatment, the disease, on the whole, has progressed. I am not inclined to attribute the temporary improvement in these cases to the treatment. One who has had any large observation of this disease knows how often these false promises are made under all forms of treatment and even when no medication is employed.

CASE XVII.—A. W., a colored man, a student, who is paying his way through college by acting as general servant in a fraternity house, came to me for examination and treatment June 5, 1894. He was then twenty-five years old and weighed 140 pounds. In the spring of 1893 he weighed 154 pounds. He went to the World's Fair, and thinks that he "took cold there." He began to cough, lose weight, and have a "tired feeling." When he came to Ann Arbor in October, 1893, he weighed 148 pounds. He had been coughing quite violently for six weeks before he consulted me. His mother and one brother died of pulmonary tuberculosis, the first many, the second, three years ago. He had had sharp pains in the lower lobe of the left lung for some days, and this had caused him to consult a physician. The upper lobes of both lungs are filled with moist râles, and there is a pleuritic effusion on the left side. I am not sure about cavities; if any, they are small. The sputum was abundant, purulent, and filled with tubercle-bacilli. Guinea-pigs were inoculated with the sputum and died from tuberculosis in from four to six weeks. His evening temperature for some days after beginning the treatment was 100°. W. continued his duties as a servant and his studies until the close of the college year in June last. In July he went to the Oakland Hotel, at St. Clair, where he acted as waiter and general servant during the season. He returned to Ann Arbor in October and took up his work again. He has not lost a day from his work during this time. The conditions under which he lives are not the most favorable for one in his condition.

The injections were begun January 5, 1894, were continued until the close of the college year, were occasionally administered by Dr. Burtless at the Oakland during the summer, and were resumed by me on his return to Ann Arbor in October. From the beginning until October a one-half per cent. solution of nucleinic acid was employed, and latterly a one per cent. solution. The injections have all been made into the muscles of the back, and in amount have averaged about thirty minims.

He now weighs 140 pounds, just what he did when I began the treatment, though he continued to lose for a while, and reached the lowest point, 132 pounds, about three weeks after beginning the treatment. The pleuritic effusion disappeared in a few days, and the moist râles in as many weeks. His evening temperature fell about one degree, and has averaged about 99° ever since. The amount of sputum is now small, but it contains bacilli. There is lessened resonance over the upper lobes on both sides, but there is no evidence that the disease has progressed. He works hard, sleeps well, looks and feels well, but he is still infected.

I believe that in this case the progress of the disease has been retarded by the treatment—I will not say arrested, because so long as the infection remains there also remains the probability that it may at any time become progressive.

CASE XVIII.—E. W., aged twenty-three, a bookkeeper in a bank at Chelsea, Michigan, consulted me February 19, 1894. His mother had a cough for some years before her death, which occurred in 1886. His father is living and well. He has no brother or sister. In the spring of 1893 he weighed 140 pounds; his weight at time of first examination was 134 pounds. He had been coughing and raising abundantly since the last of August, 1893. He passed an examination for life-insurauce September 6, 1893. This, however, is no proof that he was sound at that time. The expectoration was very abundant, thin, purulent, and contained numerous bacilli. There was a small cavity in the upper lobe of the right lung, and an extensive pleuritic effusion upon the left. Some of this effusion was drawn with a needle and found to contain tubercle-bacilli.

Treatment was begun February 19, and has been continued with occasional interruptions until to-day, November 23. The kind and amount of nuclein-solution used were the same as in the preceding case. This young man has continued his work, getting at it early and leaving it late. In addition to his work, he has come to Ann Arbor, a distance of eighteen miles, daily, except Sunday, for treatment. This he has done through all kinds of weather, sometimes waiting until late at night for the return train. Surely these conditions have not been most favorable.

In this case the pleuritic effusion was very slow in disappearing, and to-day there is diminished resonance over the left lung. I cannot see that there has been any material change in the upper lobe of the right lung. The sputum is not so abundant, but the relative number of bacilli has not been altered. The temperature varies with the amount of work which the patient does. When he is very busy, the evening temperature goes as high as 102°. When he has a day of rest it seldom rises above 99°. This has been the case all the time, though the average temperature is higher now than it was last February, and, judging by this more than by the physical signs, I think that the disease is slowly progressing. His weight now is 135 pounds.

CASE XIX.—Miss H., twenty-seven years old, a saleslady in a dry-goods store, consulted me December 31, 1893 Three years before she had weighed 146 pounds, had been gradually losing, and at the time of examination weighed 115 pounds. She had been coughing and raising "a little" in the morning during these three years. She had no night-sweats. There is no family history of tuberculosis.

The upper portion of the upper lobe on the right side was consolidated, and moist râles were heard over the upper lobe on the other side. The sputum was not purulent, but contained tubercle-bacilli.

The treatment was begun January 4 and continued daily until the middle of July, when it was given twice a week, and since the 1st of October once a week. The average daily maximum temperature was, during the first six weeks, 99.8°; then it gradually fell to the normal by March 5th, and since that date no elevation of temperature has been found, with one exception, although observations were made, with occasional lapses, three times a day. The germs in the sputum, which was tested once a week as long as there was any, gradually decreased, and the first record of "no tubercle-bacilli" was made March 28. None has been found since. November 14 Miss H. had quite a sharp attack of bronchitis, with a temperature of 101°, cough, and expectoration, lasting through three days. This sputum was most carefully examined for tubercle-bacilli, with negative results. The weight has gradually increased and has reached 126 pounds. Miss H. discontinued her duties as a saleslady from the beginning of the treatment until May 1st, since which time she has been at work. In taking the treatment she walked daily, without reference to weather, from her home to my office, a distance of about one mile, and back. Did I not know that her lungs had been infected I do not think that I would be able to detect any evidence of it from a physical examination.

CASE XX.—Miss W., aged twenty-three, first consulted me February 12, 1894. She is of German parentage. Her father's family was said to be "consumptive," though the father died three years ago of chronic nephritis. The mother is not robust, but has never been sick. She has one brother twelve years old, who is well. During the spring and summer of 1893 Miss W. did not feel well and declined in weight from 125 to 114 pounds. She went to the World's Fair in September, and while there she had frequent and exhaustive pulmonary hemorrhages. The physician called in at the time pronounced the disease tuberculosis. She was brought home and kept closely confined to the house for fear of another hemorrhage. This fear was realized December 31, when the flow of blood was quite profuse. From this to the time of my seeing her her movements were still more restricted. Such in brief was the history given me, and from it one would infer that the infection had occurred in the winter of 1892-93, but on baring the breast for examination of the lungs a large scar just above the clavicle on the right side was seen, and on inquiry I learned that some three years before a gland had enlarged, suppurated and discharged, and other glands as large as hickory-nuts were found in the same region. In all human probability these glands were tuberculous, and the patient had been infected much earlier than the history previously given would indicate. Moist râles were heard over the apex on each side. No cavities could be detected. The sputum was small in amount, very ropy, and not purulent. The tubercle-bacilli were numerous. Guinea-pigs were inoculated with the sputum and died of tuberculosis after from six to ten weeks.

I made it a condition of my undertaking the case that Miss W. should walk to my office, a distance of about half a mile, every morning. The treatment was practically the same as in the preceding case. During the first two weeks the highest temperature observed was 99.5.° This sometimes occurred in the morning, more frequently at noon, and very seldom at night. Since the last of February the temperature has never been found above the normal. The bacilli gradually decreased in numbers. The last found was on March 28, when three bacilli were found on four cover-glasses. The patient continued to raise a little each morning until about the first of July. Since then there has been no cough. The weight increased to 122 pounds. The enlarged glands have markedly decreased in size, but can still be felt. There has been no hemorrhage. There is impaired resonance over the apex of the left lung; the other seems normal.

CASE XXI.—Mrs. M., aged twenty-six, with one child, six years old, came to me November 15, 1893. She had been coughing and raising for a little more than a year. She had lost during this time about fifteen pounds. The sputum was small in amount, consisting principally of glairy mucus. Bacilli were found, but not more than half a dozen on each slide. The evening temperature stood quite uniformly at 99°. Mrs. M. had thirty drops of a one-half per cent. solution of nucleinic acid daily from the date mentioned to the last of June. Since that time she has had an occasional injection. The germs disappeared before January 15th, and have not reappeared, She weighs more now than she ever did, and there is no cough. The physical signs in this case were never sufficiently marked for me to attempt to define them, and after repeated examinations I could not positively say that there was any abnormality.

CASE XXII.—Mrs. R., a married woman, with three children, and who did washing for a living, came to me May 21, 1894. She had three years before weighed 140 pounds; then her weight was 106. She has done no washing, save for her own family, since I began to treat her, but she has done all of her own household work and has taken care of her children. She has walked to the office, a distance, during a large part of the time, of about one mile. The sputum in this case was at first abundant, but non-purulent. Bacilli were few. The upper lobe of the right lung was filled with moist râles. This patient has had about thirty drops of a ½ per cent. solution of nucleinic acid daily from the time of beginning treatment until the middle of October. The improvement was slow until recently, when it has progressed most rapidly. Since the middle of October she has had an injection every other day. The bacilli disappeared in July, and her weight is now 122 pounds. The cough has ceased, and there is no expectoration. No râles can be detected.

CASE XXIII.—Mrs. C., aged forty-five, a farmer's wife, and the mother of ten children, came for treatment May 17, 1894. She was coughing very much, but raised little. The sputum was non-

purulent, and contained but few bacilli. During the previous six months she had been reduced from 130 to 115 pounds. She had treatment from May 17 to July 7; none since. In June the cough ceased, and she has raised nothing since. She now weighs 135 pounds.

Case XXIV.—E. H., twenty-one years old, with no family history of tuberculosis, lived on a farm until seventeen years old, then went into a general merchandise store for two years. The past two years he has been book-keeper at Alexandria Bay, on the St. Lawrence. He has worked in-doors about sixteen hours per day. Four other employés of this firm have developed pulmonary tuberculosis. H. felt perfectly well until July 13, when he had a hemorrhage, losing about "a teacupful of blood." He quit work for three days, but had another hemorrhage September 3. He has had cough and night-sweats since the first hemorrhage. He came to Ann Arbor September 28, weighing 134 pounds. Cough and expectoration were slight; few bacilli were in the sputum. These had been detected by a physician at Alexandria Bay. There is slight dulness over both apices. This patient had in all thirty-four injections of a 1 per cent. solution of nucleinic acid. The cough and night-sweats disappeared after the twelfth injection. No bacilli could be found after this in the small amount of fluid sputum brought up. The weight increased eight pounds.

These persons had no other medication, with the exceptions already stated, beside the nuclein.

These cases will be sufficient, I think, to enable me to draw the following conclusions:

(1.) In pulmonary tuberculosis which has progressed to the formation of cavities, nucleinic acid from yeast will not produce a cure. Unfortunately, these are the cases that we are expected to cure. These are the cases in which any proposed remedy for the disease will be tried, and I wish to state here most emphatically that I do not claim anything for nucleinic acid in these conditions. Indeed, I know, probably better than any one else, of how little value this agent is in these cases.

(2.) Even when the tuberculosis is of long standing, and when the extent of tissue involved is great, *so long as secondary infection with pyogenic germs has not occurred*, the proper use of the remedy may *retard* (I do not say arrest) the progress of the disease.

(3.) In initial cases of pulmonary tuberculosis, when there is no secondary infection, and when the area involved is small and the resistance of the patient not too much reduced, the proper employment of this agent may produce at least a temporary cure. I say "at least a temporary cure," because none of these cases has been under observation a sufficient length of time for me to say that the bacilli will not reappear.

(4.) In the few cases of urinary tuberculosis that I report in this paper the results have been remarkably satisfactory.

The results that I have secured so far encourage me to continue the work. There is no reason for supposing that the nucleinic acid obtained from yeast has any properties superior in a curative way to the nucleins contained in other substances. The number of nucleinic acids is limited only by the kinds of cells in existence, and I shall compare others with this one.

The early detection of tuberculosis is now a possible, not to say an easy, thing, but it is a lamentable fact that to many practising physicians it is an impossible thing. This will be the case so long as our most popular and most numerously attended medical schools fail to give any adequate individual instruction in bacteriology. The sputum of every patient who raises any should be examined for tubercle-bacilli, and urinary sediment containing pus, blood, or much epithelium should be similarly tested.

I must not close this paper without mentioning another point: I am convinced, especially from my experiments on animals, that nucleinic acid, improperly used, may do harm. It acts, as I have elsewhere shown, by stimulating the organs that elaborate the polynuclear corpuscles, and these may be over-stimulated. Nucleinic acid fails to be of service unless these cell-forming organs respond. They may fail to respond on account of lowered vitality, or they may be paralyzed, as it were, by an excessive dose of stimulant. The agent is not one to be used indiscriminately. Already some physicians are supplying tuberculous patients with hypodermic syringes and solutions of nucleinic acid, and telling them to go ahead and treat themselves. Such practice as this may make the study of this subject result in a misfortune.

ON THE VALUE TO THE SURGEON OF ANTIPYRIN, OF MUSTARD, AND SUGAR, AND ON THE PREPARATION OF CERTAIN SURGICAL DRESSINGS.

By ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO; SURGEON TO THE BUFFALO GENERAL HOSPITAL.

(Continued from page 664.)

ON THE USE OF MUSTARD AS AN ANTISEPTIC.

It has been long known to surgeons that mustard is a powerful deodorant, and among chemists it has been well and long known that the essential oil of mustard is a most powerful antiseptic. In fact, among some it has been classed as the most powerful of all. Years ago it had been my custom in teaching anatomy to use mustard as a deodorant upon the hands after working with anatomic material. After considerable use with it in this way I gained such confidence in it that later I did not hesitate to go at once from the dead-room, or from

a post-mortem examination, to operate upon the living patient, after having disinfected my hands thoroughly with this material. For several years it had been my custom to thus resort to mustard, until the vagaries of surgical fashion led me to discontinue it and to disinfect my hands with potassium permanganate, sulphurous acid, or other more unpleasant or irritating materials, of which I soon got tired and from which my hands used to more or less continuously suffer.

A year ago or more I was enabled to subject the mustard again to such a rigid test that it seemed to me sufficient to give it the highest place in professional confidence. It was my fortune to care for two cases of diphtheria, upon both of whom I operated, and from one of whom I myself contracted the disease. Both died, and upon the day before I became sick myself I went to the house to withdraw the intubation-tube that had been inserted the day before. The case had been malignant in its clinical aspects, and the mouth and pharynx were filled with horribly offensive material. Prying apart the jaws I succeeded in reclaiming my tube, and then the problem was to disinfect my finger. From this house I had to proceed at once to another patient, upon whom I was to operate for varicocele. I spent twenty minutes or more with hydrogen dioxid, and with alcohol, endeavoring to disinfect my hands, particularly my left index finger. Even after this time the odor still clung about it, and I would not trust it for any operative work, especially about the veins. Upon arrival at the house of my patient I called for some ordinary flour of mustard, and while washing my hands for the operation spent some ten or fifteen minutes in rubbing this mustard, made into a paste, into all the crevices and cracks about my hands and finger-nails. All odor was thereby at once removed. I proceeded with the operation as usual, and never had a more satisfactory result. The next day I was taken sick myself, which shows that there were about me at that time the germs of the disease, but that they did not cling to my hands. This restored all my early confidence and liking for mustard for this purpose, and since then I have used it practically to the exclusion of everything else both in my hospital and private work.

The object of this therapeutic note then is to publish the foregoing facts and to urge most strongly upon those who need antiseptics or deodorants to give mustard a thorough trial. In fact, the range of applicability of ordinary flour of mustard as found in the kitchen of every household is very large. The ordinary physician is often called upon to get his hands into material which is offensive and malodorous, and many are the expedients to which he resorts in order to rid himself of the tell-tale odor. After making post-mortem examinations, after removing decomposing placental masses, and cleaning out the uterus in cases of abortion, after opening various deep and fetid abscesses, after handling gangrenous cases, there is nothing that I know of so readily at hand and so effective as mustard. After handling infectious and contagious cases, like erysipelas, diphtheria, or anything else about which inheres odor or contagion, there can be no more satisfactory antiseptic than this. The circumstances under which it cannot be procured are most rare, and are simply those emergencies that preclude the use of any of the antiseptics generally in favor.

ON THE USE OF SUGAR AS AN ANTISEPTIC.

I have often been surprised to find how little the valuable preservative properties of sugar have been taken advantage of by the profession. The present note is intended not as a plea for its general and deliberate use, but to call attention to the fact that in it we have a valuable substance that may frequently be of service in emergency cases. Even in the backwoods, wherever men may congregate, there is virtually always some sugar to be had. If sugar will preserve fruit and meat and various other substances put up for domestic consumption, it will also preserve human flesh; and in the case, for instance, of a serious compound fracture, when nothing else is at hand, I have often suggested to my students that they use ordinary granulated sugar, which can be poured into an open wound, or which can be done up in a bag and wrapped around a wounded part, or which can be used in ways that will suggest themselves at the time. Dilute sugary solutions may serve as culture-media for bacteria; but neither pathogenic forms nor saprophytic organisms grow in concentrated solutions or syrups. Consequently, so long as a sufficient quantity is used, one need have no fear of harm from such a source. More than this, even in the deliberate care of patients when facilities are at hand, I have often resorted to sugar, particularly so in time past, when some of the older methods were more in vogue, and when it was still customary, for instance, to use a fracture-box. When used deliberately for this purpose it may be well to add and mix thoroughly with it a small proportion of naphthalin —a mixture that I first saw used in Luecke's wards in Strassburg in 1882. I shall never forget my first visit to these wards. Immediately upon entrance my nostrils were saluted by an odor to which they were previously a stranger. This, I soon learned, was due to naphthalin, which at that time was extensively used by Luecke. So pleasantly did the odor strike me, and so happy seemed the effects of its use, that I took some home with me, and was, so far as I know, the first to use naphthalin in this

country as an antiseptic in surgery. From time to time since then I have written of its virtues, and I still regard it very highly, while its relative cheapness speaks also strongly in its favor. A mixture of one or two per cent. of naphthalin with granulated sugar certainly enhances the efficiency, and I think will commend itself to any one who chooses to use it.

UPON THE EASY PREPARATION OF EFFICIENT SURGICAL DRESSINGS.

One of the problems with which I have to concern myself has been that preparation of dressings which should make them most portable and at the same time most reliably antiseptic. In the ordinary operating-case that one carries in going to a distance, either for emergency or deliberate work, he wishes to have everything that may be needed, and at the same time to have it in the most compact and portable form. For the past few years I have resorted to the following general expedients, some of which were suggested to me, or elaborated for me, by my former assistant, Dr. Meyer.

A collection of surgical needles, adaptable to any sort of a case, is put into a small vial with a screw-top, a little cotton being inserted in the neck of the vial before screwing the cap down. This bottle can be placed in the dry sterilizer or in an oven whenever needed, and so baked that its contents are absolutely sterilized. My catgut is wound in short pieces upon small pieces of glass tubing, two or three feet being wound around each tube. A quantity of both of these, prepared in the usual way, is then sterilized together by being put into a tightly-stoppered flask with alcohol, which is then boiled under pressure, the temperature being raised to that of boiling-water. A few of these rolls of catgut—and, by the way, silk may be prepared in the same way—are then taken out and put into little portable bottles full of alcohol, from which they are withdrawn as necessity requires. They are thus kept absolutely sterilized. My iodoform-gauze is cut into small strips, a little fruit-jar or similar flask filled with them, the top screwed down, and the whole placed in the dry sterilizer and baked. I also usually carry naphthalin-gauze —which is made from surgeon's gauze as it comes from the shop, cut into compresses of any desired size, and packed into a fruit-jar, at the bottom of which a teaspoonful or more of crystals of naphthalin is dropped. After the jar is filled with gauze and its top fastened down, this is put in the dry sterilizer and also baked. By the heat the naphthalin is volatilized and well dispersed through the gauze, which at the same time is absolutely sterilized. I carry in my travelling-case a saturated alcoholic solution of hydronaphthol, of which a little may be put into boiling-water, which will then dissolve all of it that it can take up, and in which solution the instruments may be dropped when they cannot be otherwise sterilized. My drainage-tubes and some small pieces of green silk protective are also sterilized and carried in strong antiseptic solutions, so that they may be utilized at any time when called for.

It is my custom frequently to anoint the parts after an operation with some unguent which shall prevent the dressings from clinging too tightly as they dry, by which comfort is enhanced at the time of the first redressing. For this purpose I ordinarily use albolene or one of the coal-tar preparations, which is put into little ointment-jars along with sufficient naphthalin to make an ointment of from 3 to 5 per cent. strength, and sometimes with a little essential oil to give it a pleasant odor. These jars of ointment are put in the sterilizer with the caps screwed down, are kept at a temperature of from 100° to 120° C. for an hour or two, by which their contents are absolutely sterilized, so that I have no fear in applying this ointment directly over the wound or upon the dressings that are to be applied to it.

These are little hints concerning practical matters, which, however, are of sufficient importance to justify their publication here, in the hope that by the simplification of the details of sterilization of dressings a more general adherence to the principles of *a*septic rather than of *anti*septic surgery may be stimulated.

MYXEDEMA AND ITS DIFFERENTIAL DIAGNOSIS FROM CHRONIC NEPHRITIS.

By M. ALLEN STARR, M.D., Ph.D.,
Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, New York; Consulting Neurologist to the Presbyterian and Orthopedic Hospitals.

(Continued from page 651.)

In the first place, we need to remember that edema occurs under two forms of nephritis in very different degrees. 1. In the acute form of nephritis with scanty urine of high specific gravity, large amounts of albumin, and many casts, when all the general symptoms are intense and convulsions are imminent, the edema is usually extreme. The face, body, arms, and especially the legs, are much swollen and pit upon pressure, and it is evident that the edema is governed not a little by gravitation, for it is more extreme in the dependent parts of the body —the feet, ankles, and legs, if the patient is up and about; in the back, if he is in bed. Now in myxedema, even when the swelling is very marked, it has characteristics entirely different from those just described. It affects the forehead as well as the face, it is as intense in the upper eyelid as in the lower, it never fails to cause a thickening of the bridge of the nose, and of the lips and tongue. In all these respects it differs from the edema of nephritis. It

is more intense over the masseter muscles and in the supra-clavicular spaces than anywhere else, forming pads of soft tissue almost like lipomata. These spaces are not often swollen in nephritis. It affects the surface of the body quite uniformly, but is more noticeable on the abdomen than on the back, no matter what the position habitually assumed. Nor is it all affected by gravitation. The legs are uniformly swollen all the way down, not particularly about the ankles or tibia, and the hands and arms are quite as much affected as the feet. The very soft parts about the genitals are not excessively swollen, as in nephritis. In fact, as a rule, the extreme swelling in myxedema is usually in the face and neck, and not in the feet and legs—just the reverse of the condition in nephritis. Finally, in myxedema there is no pitting upon pressure, and no evidence that fluid beneath the skin can be displaced by manipulation. Aside, then, from the fact that the the slow onset and gradual course of a case of myxedema contrast markedly with the acute and severe symptoms of acute nephritis, it is possible by an examination of the edema to differentiate between these two diseases.

2. But there is another form of nephritis that produces edema, viz., chronic nephritis with contracted kidneys, hypertrophied heart, and increased arterial tension. This is the form with which myxedema is most frequently confounded. An excessive amount of urine of low specific gravity, scanty traces of albumin, and a few hyaline casts are commonly observed in both diseases. In both the symptoms are of slow progress; in both cerebral and gastric symptoms are prominent; and in both the pallor and yellowish tint of the skin are known to occur. Here again it is to be remembered that the edema is entirely different in the two diseases. In chronic nephritis the edema is not very marked, but when it is present it is uniformly noticed about the ankles after standing, or along the tibiæ; it never affects the hands and arms; when it appears in the face it is under the eyelids, never on the forehead, lips, or tongue. In a word, it is located in dependent parts of the body, and is determined by gravitation, or it appears in the parts where the normal tissues are loose and where the subcutaneous tissue has spaces in which fluid can easily collect. The description already given of myxedematous swellings contrasts in every point with these particulars. Hence, it is evident that in the second form of nephritis, in which edema occurs, the examination of the patient should suffice to detect the differences from myxedema.

But there are many other points of differentiation. I have alluded to the color of the skin and the pallor as common to the two diseases. In myxedema the skin is remarkably dry and usually in a state of active desquamation. The patients have the appearance of having been recently powdered, and by rubbing the surface gently, scaly white particles of epithelium are easily brushed off. This condition of the skin is certainly not common, if it occurs at all in nephritis.

Again, in myxedema there is no suggestion that the skin is unduly stretched, as in ordinary edema, and it is not thin, and smooth, and flossy. While, as a rule, in myxedema the color of the skin is yellowish-white, all observers have noticed a bright-red blush over the cheek-bones, which sometimes gives the impression that the patients, who are usually women, have been rouged. This high color is not seen in nephritis.

The entire absence of perspiration in myxedema, the inability of the patient to get into a perspiration by any exertion or exposure to heat is another symptom not particularly noticed in nephritis.

The condition of the hair—thin, bristly, coarse, and dry—is characteristic of myxedema. Inquiry will also usually elicit the fact that from all parts of the body where hair appears there has been a marked falling of it, so that the patient may be noticeably lacking in it; in the axillæ or about the genitals, as well as on the head. In nephritis the growth of hair is not affected.

Lastly, it is to be remembered that the thyroid secretion has an important function in regulating the body-temperature, and that in myxedema there is a uniform depression of temperature, the thermometer registering only 97° or 97.5° in the mouth. Such a condition is not observed in nephritis or in any other disease. It is accompanied by a subjective feeling of cold, which is one of the most annoying symptoms to those who live in the North. It is one of the immediate results of the thyroid treatment that the temperature rises under the use of the extract. I have tried the extract in other diseases, and have never seen it produce this effect excepting in cases of myxedema. In cases of akromegaly, in which it seems to have a beneficial effect, it does not cause any elevation of temperature; and in a case of megalocephaly, in which it was very thoroughly tried to the extent of ten tablets daily, it had no such effect. It is by watching the temperature and the pulse that the proper dosage of the extract is to be determined in each case. It is better to begin with small doses, one tabloid (5 grains) daily, or 10 drops of the glycerin extract of Dr. Crary[1] daily, and gradually increase the amount, than to give large quantities and cause disagreeable symptoms. In the case here reported the cardiac distress caused by the extract was very marked, and could not be counteracted.

[1] New York Medical Record, June 17, 1893.

While in the case reported there were no mental symptoms present, I think it is right to call attention to the fact that a considerable proportion of the cases of myxedema suffer from hallucinations, from great mental depression, from defects of memory, and from decided inability to use the mind. Three out of the thirteen cases that I have seen were brought to me because of the mental symptoms. The type of derangement which is present in myxedema is somewhat different from that ordinarily seen in mental diseases. While there is a depression and a decided melancholic tendency, there are very rarely any delusions, and never the typical facial expression of melancholia; nor are there intercurrent periods of mental depression and self-accusation which often occur in melancholia. The patients do not wake early in the morning with the intense depression that is seen in that disease. In melancholia hallucinations are exceedingly infrequent, while almost all myxedematous patients when affected mentally will describe hallucinations of sight and, sometimes, of hearing, occurring frequently at night; animals and faces are seen, and voices are heard, yet, as a rule, these hallucinations are recognized as products of the mind; they are not firmly believed in, and they do not become the cause for excitement as in hallucinatory insanity.

The prevailing mental tendency in myxedema is toward a demented condition; the patients are stupid, dull, sit listless, doing nothing, prefer to be left alone, take no interest in their surroundings, and appear to be lacking in all spontaneous mental processes; yet even this form of dementia differs decidedly from the primary dementia or the terminal dementia of insomnia, for the patients can be aroused to thought, show few defects when excited to mental action, and none of the incoherence of speech which betrays a mind permanently shattered. The entire disappearance of all these mental symptoms is one of the gratifying results of the treatment with thyroid extract. The three patients to whom I have alluded remain in a state of mental as well as physical health so long as they continue to use the extract. It is not at all improbable that a careful search in the asylums of this country would result in the discovery of a number of cases of myxedema now supposed to be instances of chronic dementia, but really capable of cure.

The Treatment of Infectious Diseases with Antitoxin.—It is said that to Dr. Geo. H. F. Nuttall, formerly of Johns Hopkins Hospital, but at present attached to the Hygienic Institute of Hamburg, really belongs the credit of having established the principle upon which depends the treatment of infectious diseases with their respective antitoxins. The results of his observations were contained in a thesis presented for the degree of the University of Göttingen four years ago.

AN EPIDEMIC OF PARALYSIS IN CHILDREN, WITH A REPORT OF ONE-HUNDRED-AND-TWENTY CASES.[1]

BY ANDREW MACPHAIL, B.A., M.D., M.R.C.S. ENG., L.R.C.P. LOND.,
PROFESSOR OF PATHOLOGY AND DISEASES OF CHILDREN IN THE UNIVERSITY OF BISHOP'S COLLEGE, MONTREAL.

(Continued from page 625.)

CONCLUSION.

THE diagnosis is yet not free from doubt, as most diagnoses are which are based upon clinical considerations alone and unsupported by the results of pathologic examination. It rests between cerebro-spinal meningitis, multiple neuritis, and poliomyelitis, or a combination of the last two.

1. Cerebro-spinal meningitis may, I think, be set aside under the force of the facts already alluded to. Epidemics of this disease are common enough, and its general course is definite, with a special symptomatology. In the present case there was almost an entire lack of those symptoms, and there were besides manifestations which have never been noticed in epidemics of cerebro spinal meningitis.

2. H. Oppenheim, Berlin, in his work on *Diseases of the Nervous System*, emphasizes the view that poliomyelitis is due to an infective microörganism, and in the present epidemic there was much evidence pointing to the operation of such an agent. Medin, of Stockholm, reported at the Tenth International Medical Congress an epidemic of infantile paralysis, an account of which appears in the *Centralblatt für klinische Medicin*, September 5th, 1891. The cases numbered forty-four, and occurred chiefly during the months of July and August, but they were spread over five months in all. The disease appeared in children who were previously healthy and with no apparent cause. The initial symptoms were fever, somnolence, indigestion, diarrhea, or constipation and vomiting in rare instances. Paralysis now supervened, and the fever shortly subsided. In three cases there was facial monoplegia, and facial paralysis, and polyneuritis in five cases. Abducens paralysis was present in five cases, twice with ordinary poliomyelitis, once with polyneuritis, once with polio-encephalitis, and in one fatal case. On examination it was found that the nuclei in the pons and medulla corresponding physiologically and morphologically with the cells of the anterior horns of the spinal cord were affected. At the time of the meeting Heubner stated that he regarded the disease as an infective one. Henoch found the same difficulty which now presents itself, namely, the presence of cerebral symptoms.

There is every inducement to regard the present outbreak as of a similar nature. Clinically the

[1] An addendum received too late for insertion in the issue of December 8.—Editor THE MEDICAL NEWS.

course of the disease was the same as in poliomyelitis, as a reference to the cases makes clear. There was the initial feverishness, aching pains, abrupt paralysis of the nature commonly known as "infantile," and with a distribution highly characteristic. If it were not for the disturbance of the vagus one would have no hesitation upon clinical grounds in pronouncing the epidemic one of poliomyelitis. The mode of onset, the paralysis itself, the age of the patients, the season in which the epidemic occurred, the distribution of the paralysis, and the subsequent behavior of the muscles, all point to this disease. Besides, it is not uncommon to have cerebral disturbance in poliomyelitis, with convulsions and coma; even diplopia has been noted. In the cord of a child dead of this disease the lesion is not confined to the cells of the anterior horns; there may be, as I have said, a general hemorrhagic myelitis, and even obvious meningeal involvement. There may also be pain, referred occasionally to the course of the nerves, and simulating a peripheral neuritis. In an epidemic including so many cases it is not probable that they would all adhere to the usual standard, and it is to be expected that some would overflow into the class of neuritis or cerebro-spinal meningitis.

3. The evidence in favor of the outbreak being due to peripheral neuritis rests upon the disturbance of the vagus. But if one regards, with Gowers, "symmetrical weakness of the extensor muscles situated in the forearm, and in the corresponding muscles in the lower part of the leg," as the leading motor symptom, then it will not explain the present malady, since this condition was absent in far more than half the cases. Indeed, the paralysis was "characteristically random in distribution," that is characteristic of poliomyelitis; and Gowers further affirms that the nerve-trunks are sometimes probably inflamed in the latter affection.

Finally, one is driven to the conclusion that the cases constituting the epidemic mainly followed the type of poliomyelitis, but that in some there were elements suggestive of multiple neuritis, either as an independent affection or the common result of a common cause.

CLINICAL LECTURE.

MULTIPLE NEURITIS, WITH THE DEVELOPMENT OF UNILATERAL FACIAL PARALYSIS LATE IN THE COURSE OF THE DISEASE.

By J. T. ESKRIDGE, M.D.,
of Denver, Col.,
Professor of Nervous and Mental Diseases in the Medical Department of the University of Colorado; Neurologist to the Arapahoe County and the St. Luke's Hospital.

We shall study to-day the case of D. F., fifty years of age, colored, single, a male laborer, born in Kentucky, but who has been living in Colorado since 1872. As a child he was well and strong, and thinks he did not suffer from any of the diseases incident to early life. When two years old he had an attack of smallpox, and was ill about four months. At his thirtieth year he contracted a chancre. He has never indulged in alcohol to excess. During the last twelve years he has worked in damp places, and frequently contracted colds. Ten years ago the glands of his neck suppurated, and about that time he experienced numb and tingling sensations in the feet and legs below the knees. These sensations would pass away on exercising, but when at rest his legs would become stiff and painful. After suffering with these symptoms, which increased for some weeks, he had to quit work a week; he was then able to resume work, although for some months he was not entirely free from uncomfortable sensations in the legs and feet. Subsequently to this trouble he remained in good health until December, 1893, when, after working in a damp and cold place, he first felt numb and tingling sensations in his toes and in the anterior portions of the soles of the feet. In a few days these sensations had spread all over the feet, and extended up the legs nearly to the knees. About this time his ankles seemed weak, so that he could not stand without some support. As he expresses it, he "rocked on his feet." Within two weeks from the time the numb and tingling sensations were first experienced in the feet he found his legs were paralyzed from the knees downward. About the time the legs were first paralyzed he felt a burning sensation in his hands, especially in the palms, and a numbness in the fingers, and a week or ten days later his arms were paralyzed from the elbows downward. A few weeks after the paralysis became manifest he was troubled less from burning and numb sensations. From December, 1893, to March, 1894, he was treated for rheumatism. About the latter date a disagreeable tingling sensation, which later assumed a distressing burning character, appeared in the feet, and was worse at night and during cloudy and inclement weather. Similar sensory disturbances soon afterward manifested themselves in the hands, but to a less intense degree. He was admitted into the nervous wards of the Arapahoe County Hospital, August 11, 1894.

Examination.—He lies in bed with all muscles below the knees completely paralyzed. Foot-drop is well marked, with extreme plantar contraction, and toes flexed, the great toes being flexed to the greatest possible degree. By using considerable force I am able to dorsally flex the feet at right angles with the legs. The legs lie straight at the knees, and he can flex and extend the legs at these joints, but the muscular power is slight. Flexion and extension at the hips are fairly good, but the muscles that make these movements are rather weak. Moving the legs and thighs at the knees and hips causes some pain, or a drawing sensation in the calf and posterior thigh-muscles. Extreme wasting has taken place in all the muscles below the knees, and to some extent in the thigh-muscles. The greatest amount of muscular atrophy is found in the interossei of the feet and in the anterior tibial and peroneal groups. The trunk-muscles are nearly normal. Wrist-drop is present, with flexor contraction of the muscles of the hands and wrists. Both hands ordinarily lie in the wrist-drop position, yet with considerable effort he is able to extend the left wrist on a line with the forearm, but he cannot extend it beyond this point. Marked

atrophy is present in the muscles of the hands, most pronounced in the interossei and in those forming the thenar eminences. The muscles of the forearms are wasted, but to a much less degree than the muscles of the legs below the knees. The muscles of the upper arms are fairly strong, and present but slight wasting; the muscles of the shoulders appear normal; none of the muscles below the knees or elbows responds to the strongest faradic current from a large-sized Flemming battery. All these muscles show reaction of degeneration. The muscles of the neck, face, and larynx are not involved.

Sensory phenomena. Tactile sense, when tested by the contact of a feather, is lost on the feet and legs from a point about midway between the ankle-joints and knee-joints downward; the sense of touch is present down to a point about six inches above the ankle-joints; in the right hand and arm the feather in contact is not felt from a point four inches above the wrist-joint downward, and in the left, from a point about six inches above the wrist-joint downward, while a feather in motion can be felt over the greater portion of the backs of the hands and wrists, but is not perceived on the dorsal surfaces of the fingers, the palmar surfaces of the fingers and hands, and the anterior surfaces of the wrists, and the anterior surfaces of the arms from a point about two inches above the wrist-joints downward. Tactile sense is present and nearly normal over all other portions of the body. Pain-sense is present throughout the body, but is not normally acute in the areas of tactile anesthesia until the skin is pierced. Temperature-sense is lost all over the feet, delayed, uncertain, and lessened over the ankles and areas of tactile anesthesia of the legs, and much perverted over the hands, but not lost as in the feet. Localization-sense is greatly disturbed, especially over the feet, as a sensation produced on the leg is referred to the foot, and sometimes to the foot of the opposite side. Pressure-sense is disturbed more in the hands than in the feet. Joint-sense and posture-sense are present and about normal. Muscular sense is absent.

The knee-jerks, the plantar, cremaster, and forearm reflexes are absent; abdominal and iritic reflexes are present. Taste, smell, hearing, and vision are about normal. The internal and external ocular muscles, and an ophthalmoscopic examination show no abnormalities.

During the five weeks he has been in the hospital there has been a steady but rather slow improvement of his condition. The contractures of the flexor muscles of the feet, the legs below the knees, the hands and the arms below the elbows, were so great that we were compelled to give the patient an anesthetic before the deformities could be overcome. After this procedure the hands and arms were put on padded splints, and by means of adhesive plaster the feet have been kept forcibly dorsally flexed. The apparatus was removed every second day, allowed to remain off several hours, and the parts thoroughly masséd. By the end of two weeks we had pretty well overcome the contractures in the flexors of the feet and ankles, and since then sand-bags laid at the soles of the feet have been sufficient to keep the feet in proper position. We have not been so successful in getting rid of the contractures of the hands and wrists, but these are much less than when the patient entered the hospital. The splints are now kept on the hands and arms about half the time. The muscles will not respond to the faradic current, and in consequence this is at present valueless in the treatment. The continuous and interrupted galvanic current is the most useful form of electricity for nerves and muscles in this stage of the disease. His food has been as nutritious as the hospital affords, with abundance of soups, meats, and eggs. In the way of medicine, iron, arsenic, and strychnin have seemed most appropriate. To-day he is able to slightly flex and extend the right foot. No movements of the left foot have been regained. He is now able to extend both wrists. Tactile anesthesia is slightly less than when he entered the hospital. Peripheral paralysis of the left side of the face developed after the patient had been in the hospital two weeks.

Let us consider the nature of our patient's trouble. In the first place, I wish to call your attention to the marked symmetry of the disease, limited as it is mainly to the distal portions of the extremities; the failure of the muscles to respond to the faradic current, and changed reaction to the galvanic; the pronounced muscular atrophy with motor paralysis; loss of and disturbed sensory function. There are many diseases with which a case of this kind may be mistaken by the casual and superficial observer. The least likely is rheumatism, yet the patient tells us that he was treated during all of last winter for this affection. In the present instance only gross ignorance or criminal negligence would permit such a mistake. In rheumatism there sometimes occurs paralysis early in the disease, either of an inhibitory or hysterical origin; but this is rare, and it only lasts for a few days. I have seen one such case. The man was apparently unable to move a hand or foot, but the ankle-joints and knee-joints, not the nerves, were very tender, and were the seat of severe pain. Suspecting the character of the trouble, large doses of sodium salicylate were given, and within two days the patient began to move the hands and feet. Late in rheumatism there may be partial paralysis and well-marked wasting of the muscles below the affected joint in which adhesions have occurred, producing a condition known as arthritic muscular atrophy; but there is no loss of sensation, the affected muscles respond to the faradic current almost normally, the disease is not symmetrical nor limited to the distal portion of the extremities. The temporary paralysis in the early stage of acute rheumatism, and the arthritic muscular paralysis usually affecting one limb, apparently from rheumatic inflammation of a large joint, are about the only points of similarity between rheumatism and the symptoms presented by the patient before us, while the symmetry of his disease, the distal portions of the limbs being as a rule alone affected, the electric changes, the sensory phenomena, and the nerves, instead of the joints, being involved, are abundantly sufficient to prevent a mistake in the diagnosis if care and judgment are used in the examination and summing up of the case.

In poliomyelitis the absence of objective sensory phenomena and the symmetry of the paralytic symptoms serve to distinguish this disease from the one before us. Spinal pachymeningitis is attended with radiating pains from the spine, with involvement of the trunk-muscles and those of the upper portions of the limbs, with severe pain on moving the muscles of the back, and with incomplete paralysis and sensory loss, distrib-

uted irregularly, symptoms very unlike those present in our patient. In acute ascending paralysis the feet, legs, thighs, trunk, and arms become affected in the order named. The ataxic symptoms manifested by the man before us, with loss of the knee-jerk, has more than once misled careless observers to mistake the disease for locomotor ataxia, but the latter disease has shooting pains, prominent eye-symptoms, anal and vesical disturbances, absence of paralysis until very late, when it is incomplete, and wrist-drop and foot-drop are never present. There are many other points of difference, but these are the most prominent. Myelitis affects the anal and vesical sphincters, the muscles of the trunk up to the level of the spinal lesion, and when the lower portion of the cord is the seat of inflammation, anesthesia of the external genitalia and the parts around the anus is present. We can then exclude myelitis in this patient.

The character of the paralysis, the distribution of the anesthetic areas, the extreme muscular wasting and the well-marked electric changes which have taken place in the muscles, enable us at once to dismiss the suggestion of hysteria, an affection which should always be allowed to obtrude itself in the mind of every one when engaged in arriving at a diagnosis by exclusion in cases attended with paralysis and loss of tactile sense. We have left but one other affection, multiple neuritis, which will likely account for the condition of this man. The symptoms that this patient presents are typical of multiple neuritis. The symmetry of the parts affected is almost complete; the parts invaded are the extremities, in the arms below the elbows, and in the legs, principally the regions below the knees, although motor weakness is found in the muscles of the thighs, and to a slight extent in those of the hips, but no loss of sensation is found above the knees; the feet and hands are affected more than the forearms; wrist-drop and foot-drop, profound muscular wasting, with electric changes and absence of the deep reflexes—all go to make up a clinical picture the like of which is found only in multiple neuritis. When we call to mind that the vesical and anal sphincters have not been affected, and that the nerves were at one time tender and the seat of pain and distressing sensations, there seems to be no room to doubt the correctness of the diagnosis.

As the management of individual cases of multiple neuritis depends somewhat upon the cause of the inflammation, it will be well for us to inquire into the etiology of this man's attack. This man suffered from syphilis twenty years ago, but syphilis in its tertiary stages attacks mainly fibrous and connective-tissue elements. I have not observed, or seen the report of a case of typical parenchymatous multiple neuritis caused by syphilis. It seems to me that we may dismiss the consideration of the syphilitic poison as a causative factor in this man's case. The principal causes for us to consider in the present instance are diphtheria, alcohol, malaria, exhaustion, insufficient nourishment, gout, rheumatism, and exposure to wet and cold. In the absence of the history of diphtheria or involvement of the muscles of the iris and palate, and the long duration of the disease (diphtheric multiple neuritis running its course in two or three months), we are justified in excluding the effects of diphtheric poison. The patient has never been addicted to the steady or excessive use of alcohol; he has not been exposed to malaria for more than twenty years; his work has not been exhausting; he has been able to obtain plenty of nutritious food, and he has never suffered from gout, so that we may as well dismiss all causes first enumerated except rheumatism and exposure to wet and cold. His occupation during the last twelve years has necessitated his being more or less exposed to damp and cold, and undoubtedly the slight attack of nervous disturbance from which he suffered some ten years ago was of the same character as the present one (though much lighter). He tells us that he has never suffered from attacks of acute rheumatism, and that he enjoyed good health from the time of his attack, ten years ago, until the beginning of his present illness, in December, 1893. It is probable, then, that to exposure we must attribute the cause of his trouble.

The duration of the disease is variable. The diphtheric form, as a rule, runs the shortest course, convalescence in the majority of instances being pretty well established, so that the patient is able to walk about, by the end of the second or third month from the time the neuritis first became manifest. The alcoholic form is not infrequently slow in reaching its height. I have under my care at present a patient who suffered from neuritic pains, with absent knee-jerks, for eight months before the paralysis became so great that he was compelled to remain in bed. During the last two or three months of this period he was decidedly ataxic in the legs. In the majority of cases of multiple neuritis not due to diphtheria the disease is one or two months in reaching its acme; then it remains stationary for one, two, or three weeks, after which apparent recovery takes place in from a few to several months. It must be remembered that the muscular strength is not regained for several months after the patient is able to resume his duties. The parts that are first affected are usually the most seriously involved, and are the last to resume a normal condition. The legs, as a rule, improve before the hands and arms, although occasionally this order is reversed. The feet, and sometimes the hands, especially around the nails, remain hyperesthetic long after all spontaneous pain has subsided. Relapses greatly lengthen the course of the disease.

The vast majority of cases of multiple neuritis result in recovery. In a few cases the trunk-muscles, including the intercostals, are affected; then if the diaphragm becomes paralyzed, death takes place from failure of respiration. These are acute and rapid cases, and not infrequently end in death at the end of from six to ten days or two weeks. Cardiac failure in alcoholic and diphtheric cases sometimes causes sudden death. In a few the patient is worn out by pain, the annoyance of bedsores, and the presence of bronchitis. In such cases it is probable that the spinal cord is affected. In alcoholic cases, cardiac, renal, and hepatic complications may lend gravity to the prognosis. Mental failure is a common complication of the alcoholic variety of multiple neuritis, but it usually passes away during convalescence. Sometimes there is simple failure of memory for recent events, but in typical cases patients become delusional and conceive the idea that they go out each day and take long walks, although they may be so completely para-

lyzed that they are unable to stand or even flex and extend the feet.

The treatment in the early stage of the acute cases consists of rest in bed, protecting the extremities from changes in temperature by means of flannels (when there is pain the flannels next to the skin should be kept moist by frequenly wringing them out in hot water), warm daily baths, if they do not inconvenience the patient too much, keeping the bowels open, and giving a febrifuge when there is a rise of temperature. As soon as the acute stage has subsided, massage and electricity and the internal administration of strychnin, arsenic, quinin, and iron are indicated. The nutrition should be maintained throughout the course of the disease by means of good, nutritious food, of which animal food should form a large proportion during convalescence, and cod-liver oil may be added to the list of nutrients. Relapses may be prevented, as a rule, by protecting the affected parts from cold by means of flannels worn next to the skin. Massage should not be resorted to while the nerves and muscles are sensitive, but gentle rubbing of the limbs from the distal portions toward the body is often grateful to the patient early in the disease. It is doubtful how much the galvanic current hastens resolution of the nerves and muscles, but the nutrition may be partially maintained and extreme atrophy of muscular tissue prevented, by causing gentle contraction of the paralyzed muscles until the patient regains voluntary control over them. When the muscles readily respond to the faradic current this may be used, but the current should be no stronger than is necessary to effect gentle contraction of the most affected muscles. In the majority of cases the faradic current will not produce muscular contraction in the extensors of the wrist and the anterior tibial and peroneal groups. For all muscles that will not respond to the slowly-interrupted faradic current of moderate strength the interrupted galvanic must be used, taking care not to exhaust the muscles by prolonging the séances to too great a length, and effecting too vigorous contractions. From three to five minutes is long enough for each of the largest groups of muscles, and a slight muscular contraction is less likely to do harm, and is capable of doing more good than vigorous movements. Electricity for this purpose may be applied daily or every alternate day. It is your duty to prevent troublesome contractures of the flexor muscles of the legs and arms, with resulting deformity of the feet and hands, such as this man presents. This may be done by keeping the feet at right angles to the legs by meane of sand-bags placed at the soles of the feet, and occasionally placing the forearms and hands on padded splints.

I have nearly finished what I had intended to say about this case, but have not referred, except in the examination, to the unilateral facial paralysis. This has come on some nine months after the beginning of the attack of multiple neuritis. At my first visit to this patient there was no paralysis of the face, but about two weeks subsequently I first observed it. He had been lying near an open window, and the affected side of the face was exposed to a draught of air. In all probability it has no connection with his general trouble. It is a local neuritis and does not modify the prognosis at all. Facial paralysis during the acute stage of multiple neuritis would, as a rule, excite grave apprehension, as it would indicate that the trouble was affecting nerves not usually involved in this disease, and fear of cardiac and respiratory failure might justly be entertained.

CLINICAL MEMORANDA.

TYPHOID FEVER.

A Report of Three Cases Treated by the Chlorin-Solution Recommended by J. Burney Yeo, M.D., of London, England.

BY J. MOSELEY KERR, A.M., M.D.,
OF COLUMBUS, OHIO.

IN the treatment of typhoid fever one favors the Brand method, while another advocates the ingestion of large quantities of water, thinking to drown out the offending bacillus. Some place all their confidence in a mixture containing carbolic acid, others in turpentine, and so on. Many of these methods, while successful in some cases, are either too cumbersome or else are too uncertain for general practice.

Always having been interested in this subject, I was at once attracted to Dr. J. Burney Yeo's article (June number of the *American Journal of the Medical Sciences*), in which he advocates the use of a chlorin-solution, a rigid milk-diet, and perfect cleanliness, not only of the outside of the body, but also of the inside.

The solution as made by him is as follows: Into a twelve-ounce bottle put thirty grains of potassic chlorate and pour on this sixty minims of strong hydrochloric acid. A greenish-yellow gas is at once liberated. Close the bottle with a cork and agitate the mixture gently until the bottle is filled with gas, then pour water into the bottle, little by little, closing the bottle and shaking well at each addition until the bottle is half filled. Add to this mixture from twenty-four to thirty-six grains of quinin, and then fill the bottle with water. Syrup of orange-peel can be added to disguise the taste. The dose Dr. Yeo recommends is one ounce from every one to four hours according to the severity of the case. His methods are so plain and easy, and his reasoning so clear, that I decided to adopt his suggestions at my first opportunity. He urges very strongly the early administration of this combination, before the bacilli have had a chance to spread or do their destructive work.

CASE I.—H. B., was a little girl, three-and-a-half years old, of good family history, well-nourished and of good previous health. The child took sick gradually, and for several days the only symptom noticed by the parents was an unusual listlessness.

I was not called until July 23d, after the child had been complaining for about a week. I found her somewhat stupid, complaining of pain in the epigastric region, the bowels constipated and occasional vomiting. The temperature on the first day seen was 102.8° in the morning and 103.6° in the afternoon. It was not until July 27th that I made a positive diagnosis of typhoid fever, when I ordered the patient placed upon an entire milk-diet, and a teaspoonful of the chlorin solution, to be administered every two hours. The bowels were watched carefully and kept open by enemata and occasional doses of calomel. The temperature from the time this solution was commenced ranged as follows: July 27, A. M.,

101.2°, P.M., 103°; July 28, A.M., 100.2°, P.M., 102.4°; July 29, A.M., 101.2°, P.M., 102°; July 30, A.M., 99.8°, P.M., 100.2°. It kept gradually falling until by the 5th of August it had reached normal both morning and evening, the morning temperature having been normal for several days. The child convalesced nicely and made an uninterrupted recovery.

CASE II.—A. A., was a young man, nineteen years old, a laborer, of good family history, with comfortable surroundings, and who had always enjoyed good health. He was taken sick August 11th with a severe headache, loss of appetite and marked drowsiness. I was not called until the 15th, when in the morning his temperature was 103.6°, the pulse 106, and respirations 20. In the afternoon his temperature rose to 104.4°. The symptoms pointed so clearly in my mind to typhoid fever that a bottle of the chlorin-solution was ordered, a teaspoonful to be given every hour. The only nourishment he received was diluted milk in quantities that seemed to be easily assimilated. During the first and a portion of the second week there was considerable delirium and several mild hemorrhages from the nose. The dose of the medicine was doubled, the symptoms subsided, and he rested quite comfortably during the balance of the attack.

On September 8th the young man had for several days been taking a preparation of beef-peptones and was convalescing without incident. I copy from my notes of this case a record of his temperature: August 15, A.M., 103 6°, P.M., 104.2°; 16th, A.M., 101.2°, P.M., 102.4°; 17th, A.M., 100.4°, P.M., 101.6°; 18th, A.M., 100.2°, P.M., 102.2°; 19th, A.M., 101.8°, P.M., 103° (dose doubled); 20th, A.M., 101°, P.M., 102.2°; 21st, A.M., 100.6°, P.M., 101.8°; 22d, A.M., 101°, P.M., 102°; 23d, A.M., 100°, P.M., 102.4°; 24th, A.M., 99.8°, P.M., 102.2°; 25th, A.M., 99.8°, P.M., 101.4°; 26th, A.M., 99.8°, P.M., 101°; 27th, A.M., 99°, P.M., 100.8°; 28th, A.M., 99.4°, P.M., 100.6°; 29th, A.M., 98.8°, P.M., 100.2°; 30th, A.M., normal, P.M., 100°; 31st, A.M., 98.2°, P.M., 99.6°; September 1, A.M., normal, P.M., 100°; 2d, A.M., 98.8°, P.M., 99.4°; 3d, A.M., normal, P.M., 99.6°; 4th, A.M., 98.2°, P.M., 98.8°; 5th, A.M., normal, P.M., normal.

CASE III.—L. E., was a four-year old boy, of a healthy though neurotic family. His health had been previously good. This case and Case I are similar in many respects. I did not see the patient until the middle of the second week, when he was brought to my house by his sister, who said she wanted to know what was the matter with the boy. He was usually very lively, but for the preceding ten days he had been peevish and stupid and had no appetite, complaining of pain in his stomach and bowels. His temperature was found to be at that time 104.4°, the respiration and pulse rapid. He was sent home immediately and ordered put to bed. Calomel in $\frac{1}{10}$ gr. doses was prescribed for him every half-hour until the bowels acted, and aconite in minim-doses every hour for the fever. The temperature the next day was 103.6° and 104.6° in the morning and evening respectively.

When the possibility of his having typhoid fever was suggested to his parents they made light of it and said they were positive it was not, as they said the first symptom they noticed was a bright scarlet rash which completely covered his body, but which also disappeared quite rapidly, no trace of it being apparent when the child was first seen by me.

However, I placed him on teaspoonful-doses of the chlorin-solution every two hours, together with a milk-diet and a care for the bowels. The symptoms and course of the attack clearly indicated typhoid fever, but how he was infected will probably always remain a mystery, as he had not been away from home, and the family used the city hydrant-water, the families in the other two cases being supplied with well-water.

On September 15 the child was allowed to partake of some solid nourishment, and made an uneventful and rapid recovery. The course of the fever in this case was similar to that of Case I.

In all of these cases there was the rose-colored eruption, the furred tongue, the headache, pain in the right iliac region, constipation, and delirium. During the whole course of treatment in each case nothing was given after the diagnosis was made other than the chlorin-solution, except daily sponge-baths, enemata of hot water or broken doses of calomel and Epsom salts to keep the bowels clean. The diet was milk, diluted about one-half with water and given every two hours in quantities that proved to be thoroughly assimilated; the idea being to give sufficient nourishment, but not to have the bowels clogged with undigested and decomposing matter. It will be seen by reference to my notes that the course of the fever did not extend over three weeks, and that the range of temperature was lowered soon after the administration of the chlorin-solution, and that the fastigium did not last over one week. No complications intervened, each case convalesced and made a speedy recovery without relapses or sequelæ.

FLAGELLATE PROTOZOA IN THE FRESHLY PASSED URINE OF A MAN; PRELIMINARY NOTE.

BY GEORGE DOCK, M.D.,
OF ANN ARBOR, MICHIGAN,
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF MICHIGAN.

A. B., twenty-seven years of age, came to me for the treatment of frequent urination. For a number of years the patient lived in Texas, where he had frequent attacks of intermittent fever. About two years ago he had pneumonia, and during convalescence developed hematuria, diagnosticated as malarial. The hematuria finally subsided, but the attacks of frequent urination became more severe and the patient noticed that a whitish cloudy substance was passed with the last few drops of urine, especially at times when micturition was unusually painful and frequent. A few days before I first saw the patient the urine was examined by a colleague, who found pus and blood, and he gave remedies. A few days later I saw the patient. The symptoms were much improved. The urine passed in my presence was clear, acid, with a specific gravity of 1020. It contained numerous whitish specks, about the size of a small pin-head, or slightly larger, somewhat resembling the caseous bits passed in some cases of tuberculosis of the genito-urinary tract, and smaller and less opaque than gleet-threads. (The patient, whose veracity I have no reason for doubting, denies coitus.) Under the microscope these showed pus-corpuscles, epithelial

cells, and a number of bodies slightly larger than pus-cells, of a peculiar hyaline appearance, which struck me as being so remarkable that I immediately began to dictate a note about them. It soon became evident that the bodies were animal parasites, and after a little observation they were identified as belonging to the genus trichomonas. In the identification and further study I have received much valuable assistance from my colleague, Dr. J. Playfair McMurrich, Professor of Anatomy in the University of Michigan, to whom I express my thanks.

The bodies are usually from 0.015 – 0.020 mm. long, and from 0.008 – 0.015 mm. wide, of the shape of an apple-seed, oval, ovoid, or irregular. At one end are from two to four flagella; at the other, sometimes, a flagellum-like tail, though this is not constant. At one side, running back from the base of the flagella, is an undulating membrane. This is not always visible. The structure of the body is finely granular, sometimes almost homogeneous, occasionally containing coarser granules resembling cocci. There is an oval nucleus with a long narrow chromatin-body. There is no mouth and no evidence of internal structures. Vacuoles are sometimes present, but there is no contractile vesicle. Besides the ciliary motion of the flagella, and that of the undulating membrane, the organism is able to change its form, to form pseudopods and to move by expanding and contracting the body.

Since the first observation I have made many others and have demonstrated the organisms to a number of colleagues. The fresh urine always contains the organisms, sometimes in large numbers, always in the bits mentioned; these are passed in the last few drops. The condition of the patient is somewhat improved.

The organisms resemble closely *Trichomonas vaginalis* Donné, as described by specialists. (The descriptions in nearly all books are faulty: that of Bütschli, in "Protozoa," in *Bronn's Klassen und Ordnungen*, Abth. ii, is the best.) Only three other cases in which they have been found in freshly passed urine (not that of women), seem to be recorded; those of Künstler (*Journ. de Méd. de Bordeaux*, 1883-84, xiii, p. 249-250), Marchand (*Centralblatt für Bakteriologie und Parasitenkunde*, Bd. xv, 1894, No. 19-20, p. 709) and Miura (*ibid.*, Bd. xvi, No. 2, p. 67).

In many respects my own case is remarkable and peculiar. I am now carrying on investigations with the organisms, which I purpose to report later, with a consideration of similar and allied observations.

MEDICAL PROGRESS.

Stenosis of the Upper Air-passages from Syphilitic Adhesions.—At a meeting of the Berlin Laryngological Society, Heymann (*Berliner klinische Wochenschrift*, 1894, No. 33, p. 766) reported the case of a woman, thirty-four years old, who, among other syphilitic manifestations, presented ulceration of the posterior wall of the pharynx, which remained uninfluenced by anti-syphilitic treatment, so that after the lapse of a number of months the palate also became involved. At the same time gummatous ulcers had formed upon the epiglottis and at the entrance of the larynx. The ulcerative process was followed in part by thickening and in part by destruction of the epiglottis, together with progressive stenosis of the pharynx. The vocal bands remained unaffected. A complicating acute angina, with peritonsillar abscess-formation, rendered high tracheotomy necessary. From this attack and the attendant operation the patient recovered satisfactorily in the course of ten days. In the sequence of large doses of iodids the lesions in the larynx and pharynx became cicatrized. The posterior arches became adherent to the posterior wall of the pharynx, so that there remained but a small round opening into the nares. The tonsils were distorted toward the middle line. Below the opening into the nares, and upon the posterior wall of the pharynx, were to be seen radiating cicatricial bands, together with reddened areas, in part eroded. The base of the tongue upon both sides was adherent to the posterior wall of the pharynx, and there remained but a small, oval, and somewhat irregular opening, perhaps as large as the thickness of a finger. Changes took place in the right vocal band, which became swollen and restrained in movement. The striking feature of the case lay in the fact that the process could not be stayed by the most active therapeutic measures, and that relief was afforded only after the performance of tracheotomy.

In a second case, a young man with hereditary syphilis remained in fairly good health until the age of fifteen, when hoarseness appeared, which resisted various therapeutic measures. The upper portion of the soft palate presented an opening of irregular size, with smooth, cicatrized margins and absence of the uvula. The right posterior half-arch was adherent to the wall of the palate. The posterior wall of the pharynx presented a small cicatrix. The right half of the epiglottis was smaller than the left, and the epiglottido-pharyngeal ligament was thickened and shortened. The right arytenoid was increased in size and dislocated inward, so that it projected into the cavity of the larynx. The right vocal band was immovable. The left side of the larynx was practically normal. Below the free margin of the vocal bands was a muscular membrane involving the anterior four-fifths of the glottis, and extending further backward upon the left side than upon the right. It was proposed to divide this membrane and dilate the larynx with bougies.

A third case occurred in a girl, eleven-and-a-half years old, affected with hereditary syphilis, who presented an atrophic condition at the base of the tongue and upon the left side a gumma. The posterior half-arches, and particularly the left, were adherent to the posterior wall of the pharynx. The uvula was reduced in size by cicatricial contraction. The root of the tongue was adherent to the lateral walls of the pharynx and in part to the posterior wall. The epiglottis was almost completely destroyed and formed an irregular prominence. From its lower portion a cicatricial fold pursued its way backward toward the arytenoid cartilages. The right vocal band was quite intact; the left was largely destroyed and the remainder distorted from cicatricial contraction.

Auditory Vertigo Caused by Working in Compressed Air.—Curnow (*Lancet*, 1894, No. 3715, p. 1088) has reported the case of a man, twenty-seven years old, who for a number of years had been engaged in the excavation of

tunnels, in some of which compressed air was used. He had never felt any ill-effects from his work, until, on one occasion, after walking nearly three miles toward home, he became faint quite suddenly, and would have fallen had he not been supported. He experienced a sudden noise in his left ear and felt quite deaf, although previously his hearing had always been good. He also felt giddy, neighboring objects appearing to revolve about him. He had also slight cutting pain in his knees. He had no epitaxis, although he stated that this is common among workers in tunnels. When seen, he was in a collapsed condition, with great pallor and a cold sweat on the forehead. The respiration was hurried; the pulse 66; the temperature 96°. He was tremulous and unable to stand. He complained of intense giddiness, which was not influenced by position, and was experienced when sitting down and when lying in bed, surrounding objects appearing to revolve about him. He had loud, booming noises in his ears, particularly in the left. These were uninfluenced by inflation of the tympanum. He vomited repeatedly when the attack came on, and the sickness lasted until after his first night in the hospital. There was well-marked horizontal nystagmus, especially when the eyes were directed to the right. There was also a small amount of vertical oscillation in both eyes. Hearing was much impaired on the left side, a loud-ticking watch being only faintly heard on contact with the mastoid. When the watch was placed on the forehead or between the teeth it was always better heard on the right than on the left side. Both tympanic membranes appeared quite healthy, and in neither auditory canal was there an undue accumulation of cerumen. There was no oculo-motor palsy. The pupils reacted well to light and in accommodation. In both eyes the fundus was normal. Taste and smell were not affected, and there was no headache. The gait was uncertain and hesitating, but spastic and ataxic signs were absent. In walking there was a tendency to reel and fall toward the right, which became more marked on turning around to the right. When the eyes were closed the station was unsteady. As the effects of the shock passed off, the patient's general condition improved, but the vertigo, nystagmus, tinnitus, and deafness persisted. Walking for any distance was attended with reeling. It is reasoned that the most probable explanation of the case is hemorrhage from the vessels distributed to the semicircular canals, resulting from the difference between the ordinary pressure of the air and that under which the man was working.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—BÖRGER (*Deutsche medicin. Wochenschr.*, 1894, No. 48, p. 902) has reported the results obtained from the employment of Behring's serum at the medical clinic of the University of Greifswald. Thirty cases were treated between August 6 and November 3, 1894, in all but two of which diphtheria-bacilli were found. Two cases died, a mortality of 7 per cent.; 28 recovered, 93 per cent. Tracheotomy was necessary in 5, one of which died. Among 313 cases of diphtheria treated from October, 1893, to September, 1894, 46 died, a mortality of 14.5 per cent. Deducting 20 cases treated with the antitoxin and 70 others in which either bacteriologic examination was not made, or the diagnosis was not indubitable, there remain 223 cases, among which there took place 46 deaths, a mortality of 20 per cent. The employment of the antitoxin was, as a rule, followed by improvement in the appearance of the diphtheric process and by reduction of temperature, but the albuminuria was not prevented, and no direct influence upon the heart was observed.

At a recent meeting of the Medical Society of Königsberg, HILBERT (*Deutsche med. Wochenschr.*, 1894, No. 48, Suppl. No. 18, p. 142) made a report of the results obtained in the prevention and treatment of diphtheria with the antitoxin. A statistical study had shown that one-fifth of the cases originated by contagion at home. Protective inoculations with the antitoxin were made in 64 cases in 25 families, four strengths of serum being employed, of which at first 0.5 c.c., and subsequently 1 c.c., was employed. The diagnosis in the cases of the sick children was established bacteriologically. Of 10 children treated with Behring's normal serum, 4 were attacked with diphtheria; of 8 treated with the sixfold strength of Aronson's serum not one was attacked; of 18 treated with the thirty-fold strength of Aronson's serum 2 were attacked; and of 28 treated with the sixty-fold strength of Behring's antitoxin 1 was attacked. In the inoculated children attacked the disease pursued a mild course and terminated favorably. In the families treated four adults not inoculated were attacked with diphtheria. Eleven cases of diphtheria were treated with Behring's serum; 8 were either mild or of moderate severity; in 1 the larynx was slightly involved; in 2 there was marked stenosis of the larynx. All recovered.

Untoward Effects of the Antitoxin of Diphtheria.—CNYRIM (*Deutsche medicin. Wochenschr.*, 1894, No. 48, p. 898) has reported the cases of two clinical assistants who were attacked with angina, attended with deposits in the pharynx, and in both of which serious symptoms followed the employment of Behring's serum. In one of the cases the diphtheric nature of the affection was established by bacteriologic examination. In the first case an injection of 10 c.c. of serum No. 2 and another of 10 c.c. of serum No. 3 were made on successive days, and the throat-affection soon subsided. In the course of a few days, however, an urticarious eruption appeared, with elevation of temperature, increased frequency of pulse, glandular enlargement, coated tongue, headache, general malaise, and articular and muscular pains. These symptoms continued for nearly two weeks, gradually disappearing, but leaving the patient in a debilitated and irritable condition. In the second case a single injection of 10 c.c. of serum No. 1 was made. Several days after the throat-manifestations had disappeared the appetite became impaired and the sleep disturbed. There was a constant sense of heat, with free perspiration on slight exertion, malaise, jerking of the lower extremities, pains in the neck and arms, elevation of temperature, glandular enlargement, urticarious eruption, paresthesia, and loss of flesh. The symptoms in this case likewise continued for two weeks, also leaving the patient debilitated. The injections were made with the greatest of care, and the serum was derived from a responsible source, so that the untoward symptoms in both cases are ascribed to a direct action of the serum.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

(Continued from page 673.)

For the quantitative estimation of the strength of solutions of diphtheria-antitoxin, BEHRING has set up as a standard a so-called "normal serum," by which all others may be measured. Of this one-tenth of a cubic centimeter when injected together with ten times the minimal dose of diphtheria-poison fatal for guinea-pigs weighing 300 grams prevents the occurrence of any ill effects. One cubic centimeter of the "normal serum" is spoken of as a "normal antitoxin-unit" (BEHRING), or as an "immunizing unit" (EHRLICH). The serum No. I, as prepared at Höchst has from fifty to sixty times the strength of BEHRING'S normal-serum, and, as the antitoxic value varies slightly in different samples of serum, the fluid is usually put up in small vials, to be used at one dose, each vial containing 600 antitoxin-units (8 to 12 c.c.). EHRLICH, KOSSEL, and WASSERMANN immunized goats and obtained a serum of which 1 c.c. contained 60 immunizing units, which they used in the treatment of some two-hundred children in the Berlin hospitals. ARONSON, who carried on extensive immunizing experiments in the large chemic works of Schering, claimed to have prepared a serum by special methods which possessed two-hundred times the strength of BEHRING'S normal-serum. Some of ARONSON'S serum has been tested by BEHRING and BOER, who state that the Schering manufactory has made a mistake of more than 60 per cent. in favor of its product. The strongest serum as yet prepared is the Höchst serum No. III, which is one-hundred-and-forty times the strength of the normal-serum, and is sold in vials each containing from 1500 to 1600 antitoxin-units.

Concerning the clinical use of the curative serum one fact seems to be definitely established. The earlier the treatment is begun the less is the amount of antitoxin required and the greater are the chances of success. When we consider how quickly after the onset of a diphtheric infection alterations histologically demonstrable may appear in the nerves, heart-muscle, and kidney, the reason is obvious. If we are to believe the statistics that have been published, almost 100 per cent. of the cases treated with the serum at the beginning of the disease or during the first forty-eight hours recover. That the results in general are startling and very gratifying, no one will deny. The cases treated in Germany, France, England, and America now number many hundreds, altogether over one thousand, and the death-rate as given by BEHRING, EHRLICH, and KOSSEL in Berlin, and by ROUX and others in Paris, is certainly considerably lower than under any other method of treatment.[1] It is claimed that the results might have been even more favorable had larger doses of the serum been employed. EHRLICH, KOSSEL and WASSERMANN recommended for mild cases a first dose of 200 units, for severe cases a first dose of 400 units, and suggest that the total amount required for a single case will, according to the severity, vary from 500 to 1500 units. SEITZ recommends intervals of ten hours between doses, and states that complications like pneumonia are not to be considered as contra-indications. KOSSEL suggests that 600 units (the contents of one flask of No. I serum) be given for fresh cases on the first or second day of the disease; that 1000 units (one flask of No. II serum) be the dose for cases of longer than two days'

[1] Loeffler in a recent article asserts that the local application of a mixture of ferric chlorid, toluol, menthol and alcohol in fresh cases of diphtheria, kills the bacteria almost immediately, and claims that the cases treated in this way showed a greatly diminished mortality as compared with others occurring in the same epidemic in which ordinary methods of treatment were employed.

duration, or for especially severe cases on the first or second day, or for cases in which the larynx is already implicated; and that from 1500 to 1600 units (one flask of No. III serum) be given to adults or even to children in whom the gravest form of the disease is encountered. In favorable cases the amelioration of the general symptoms, and the lowering of the temperature and of the pulse-rate soon become apparent. It is claimed, further, that sequelæ, acute nephritis or heart-paralysis for example, are rendered less frequent by the serum-treatment; but these have occurred in a number of cases, and already relapses, sometimes fatal, after injection are on record.

Preventive injections have been used with success to a considerable extent. If an epidemic continues, the preventive injection must be repeated after a certain interval. The serum in the doses employed appears to be harmless. It was at first stated that one-tenth of the dose required to cure a mild case of infection once started was sufficient to immunize against infection, that is to say, 60 immunizing units would represent an ordinary protecting dose. BEHRING and EHRLICH have lately found that this dose is occasionally insufficient (out of 10,000 individuals receiving 60 units, 10 developed the disease), so that 150 units are now recommended for preventive inoculation. It appears, too, that the protective influence of the serum lasts the longer the greater the number of antitoxin-units injected. While a dose of 60 units in the majority of cases protects an individual from infection for from two to six weeks, it may be expected, according to BEHRING, that a dose of 150 units will protect for from ten to fifteen weeks.

Mild cutaneous eruptions have occasionally been observed following the injections—a simple erythema, an urticaria, and in one case an outspoken erythema multiforme. There are a few observations recorded in which after from eight to fourteen days complaint was made of pains in the joints and limbs, in a few cases accompanied by swelling, and in one by considerable fever; but such symptoms were always transitory. It was thought by VON RANKE that patients treated with the serum showed a marked tendency to develop a peculiar form of pneumonia, an opinion which his later experience corrected.

The serum apparently has a definite effect on laryngeal complications, and it is held that if at the time of injection the larynx is not involved it does not become diseased later (KOSSEL).

The percentage of cures after tracheotomy is increased somewhat by the serum-therapy. In France, where intubation is common, the time during which the tube has to be retained is shortened. In the reports of ROUX, MARTIN, and CHAILLON, it is stated that in future tracheotomy in diphtheria will be entirely replaced by intubation and that "*le tubage est le complément de la serum-thérapie.*"

One serious limitation to the success of the antitoxin treatment which must have been foreseen, and which has been made evident by autopsies, is to be found in the fact that mixed infections frequently occur in diphtheria. Streptococci are very often present in the throat in association with the diphtheria-bacilli, undoubtedly contributing to the general intoxication, and it is a notorious fact that in many of the severer cases of diphtheria we have not to deal simply with a local infection, with absorption and intoxication, but in addition with a general systemic infection with pyogenic cocci. In cases such as these but little can be hoped for from the treatment with diphtheria-antitoxin, if it is antidotal only to the products of LOEFFLER'S bacillus. On the question of the specificity of the action of the serum of immunized animals we shall have more to say on a subsequent occasion.

There are a whole series of interesting points concerning the origin, nature and action of the antitoxic substances which are worthy of consideration, but a few only can be here referred to. The consensus of opinion just now seems to be that the antitoxins are to be looked upon as the products of the animal cells and tissues, that in fact immunity is at bottom like the processes of metabolism, a *cellular* problem. It has been shown (for tetanus) that if blood be taken from time to time from an immunized rabbit, until finally a quantity has been removed equal to the total amount of the blood normally present in the body, there is no marked diminution in the antitoxic activity of that which remains.

As to the action of the serum, it would seem that the term antitoxin is a misnomer if by it a direct chemic antidote is understood. BEHRING thought that inasmuch as on mixing a solution of the diphtheria-toxins and the serum of an animal immune to diphtheria in a test-tube the mixture when injected proved innocuous, the substances in the serum must have *destroyed* the toxin. BUCHNER has always combatted this view, and has brought experimental

evidence forward to confute it. ROUX has also recently formulated objections to BEHRING's original view, and proves that in all probability the action of the antitoxin-serum is *indirect*, and that it influences the living cells of the tissues, lessening their susceptibility to the bacterial poison. BUCHNER thinks that serum-therapy must be looked upon as a rapid method of immunizing the cells of the body. If this be the case, however, the *passive* immunity conferred by the injection of the serum must differ very much from the *active* immunity which a patient acquires when he has recovered from a genuine infection.

What the ultimate fate of serum-therapy will be it is as yet too early to say. Diphtheria offers an excellent field for the testing of an antitoxin-treatment, for (in the absence of accompanying secondary infections) it is an excellent example of an almost pure bacterial *intoxication*; the bacilli are generally confined to the throat, the poisons and scarcely any of the bacilli going over into the blood and tissues. The disease is acute, the death-rate is ordinarily high, so that it does not take long to pass judgment as to the result of any therapy. The disease, as BUCHNER has pointed out, is a much more preferable one for study than is tuberculosis, since the latter approaches more nearly to a pure *infection*. Moreover, tuberculosis being chronic in its course and subject to spontaneous exacerbations and ameliorations, conclusions as to the efficacy of new therapeutic measures directed against it must always be associated with a certain degree of doubt.

It is ardently hoped that the serum-treatment of diphtheria will not prove so disappointing as the tuberculin-treatment of tuberculosis. Both are founded upon a scientific basis—both are the outcome of animal experiment in connection with artificial immunity; both represent attempts to approach the *vis medicatrix naturæ*. The antitoxin-treatment is evidently a step in advance of the tuberculin-treatment, for, while in the latter toxins (bacterial proteins in the main) were introduced into the human being, there to set up a reaction which was to lead in time to the formation of healing substances, in the former the toxins (metabolic products with some bacterial protein) are inoculated into an animal, the animal suffers the reaction, and manufactures in its body the curative substances, which are then transferred, ready-made and active, to the human being. That healing substances are present in the serum of immunized animals is certain; that as EMMERICH has lately said, careful, quiet work will in the long run lead to results which will insure a satisfactory therapy for infectious diseases, seems probable. But now, as always, there should be hesitation before transferring the results of laboratory-experiments to the field of clinical medicine, where, as in manners, the advice of TALLEYRAND holds good, "*Surtout, messieurs, peu de zèle.*"

SHALL PHYSICIANS, OR SHALL LAY TRUSTEES, BOARDS OF CHARITIES, ETC., DECIDE AS TO MEDICAL MATTERS?

IN THE MEDICAL NEWS of December 8th we adduced a flagrant instance of the outrageous impertinence of laymen in their office of hospital-trustees in disposing of the services of physicians in a dictatorial and unjust manner. We little expected that a more striking illustration of the same spirit would so soon be shown, as happened the next week in Philadelphia. A member of the visiting staff of a great hospital was displaced ignominiously and without warning, without an official charge being made against him, or an official opportunity being offered him for replying to possible charges. Not even an official notice was sent him of his summary dismissal. From newspaper reports one learns that the reasons for this remarkable proceeding were that the physician thus contemptuously treated, in order that he might obtain blood from the patient's finger for purposes of diagnosis and investigation, had not given quinin to a patient so soon as he might have done.

Now, supposing that this information is correct, it must have come from some one. If it came from the birds of the air, or from patients, or from nurses, in the name of frankness let the spies be interrogated; let the charges be made openly. If it came from some rival or envious physician, then all the more imperative is the reason for disclosing the fact. To sentence a man on secret charges, supplied by anonymous persons, without hearing but the side against him, without giving him a chance to know of, or to reply to the indictment—all this seems to betray the consciousness of those who know their cause cannot bear examination in the light of day and by dispassionate minds.

By this action the lay officers of the hospital by implication adopt as a rule of the hospital that experimental studies shall not be allowed by the

medical staff. In rebuttal of this rule they should be asked a few questions :

1. How about the justice of *ex post facto* legislation? Would it not much better become officers of a public trust to first make the law and then punish the subsequent law-breaker, rather than to punish him for breaking a law as yet not enacted?

2. Instead of an unwritten decision of this kind as to experimental medicine, would it not be more orderly and business-like to enact such a rule in proper form, notifying all concerned, and thus give the medical staff (and the world!) an opportunity to know what rules shall guide professional practice?

3. In enacting such a law would it not be politic to exhibit some sign of becoming modesty by asking expert advice in a matter of the nature of which the legislators must of necessity be profoundly ignorant?

4. In enacting such an unwritten law in the recesses of their own self-supposed infallible private consciences, would they not avoid possible error and the derision of scientific men everywhere by first inquiring what is the rule of practice in the greatest hospitals throughout the civilized world?

5. Does the temporary possession of *power* to do an unjust thing give the *right* to do it, and give the right to do it discourteously, brutally, and without opportunity of the accused to defend himself?

About five years ago (January 4, 1890) the editor of THE MEDICAL NEWS, burning with righteous indignation, wrote justly bitter words against the action of the Board of this same hospital in a matter precisely similar to the recent occurrence of which we speak, and, bearing in mind the merit of consistency, we are to-day glad to put THE NEWS in evidence in the same cause.

In doing so, however, we must repeat and reemphasize what we have often said before, that the fundamental guilt of this disgrace lies upon the professional conscience itself. If medical men were not so shamelessly greedy for these positions, if they were not so slavish to the dispensers of them, the lay dictators would not be so ludicrously arrogant in their distribution. No man having the good of his profession at heart should accept a position coming to him in such a way. If the profession had a proper self-respect, and if there were any decent professional unity, even a semblance of professional *esprit de corps*, such an indignity would be simply impossible. The entire staff should first protest, and if their protest is ignored, they should in a body resign, and professional opprobrium be visited upon any that should dare to take their places. If the profession were thus united, how long would the hospitals be carried on without physicians? The profession has the power to be the master, but it seems to prefer to be the obsequious servant. The good of medical science is in the long run for the good of the patient. This the fanatics forget or affect to ignore. Laymen should be taught that even medical men have some rights, and that a becoming respect is due the medical profession for the enormous charitable work it does.

The limits of proper experimentalism in medicine can be set only by medical men. The progress of medicine is of the utmost importance to the community, and laymen are not fit judges of the methods of the outworking of that progress. The growing spirit of dictation and arrogance on the part of self-constituted lay judges must be met by the voice of the whole profession in asserting that in medical matters pertaining to hospital management the decision shall rest with medical men.

EDITORIAL COMMENTS.

Protective Inoculation Against Cholera.—We have on previous occasions referred to the results of inoculations practised by Haffkine in some parts of India as a protective measure against cholera. The work is being continued as occasion warrants and opportunity offers. An unequivocally fair test of the value of the inoculation has not yet been recorded. Three interesting series of observations have, however, been recently made.

Four cases of cholera appearing among a population of 200 in a portion of Calcutta, 116 were inoculated, none of whom subsequently contracted cholera, while 9 cases and 7 deaths occurred among those that were not inoculated. Five of these nine were the only ones attacked in five respective houses, the inhabitants of which had in some instances been inoculated and in others not. The remaining 4 occurred in one house with 18 occupants, of whom 11 had been inoculated. Of 111 people in seven houses, 51 that had been inoculated were not attacked, while of the 60 not inoculated 7 were attacked with cholera, with 5 deaths. The most noteworthy fact is the absence of cholera among those inoculated.

At a gaol at Gya cholera broke out on July 9th, 6 cases occurring up to the 17th, with 5 deaths. On the 18th, 147 persons were inoculated, and on the 19th, 68 more, a total of 215 out of the 433 present at the time. Secondary inoculations were performed four or five days later.

Inoculated and non-inoculated were treated exactly alike in all respects. From July 20th to 24th, when all were in gaol, there occurred among an average of 211.2

inoculated 5 cases of cholera, with 4 deaths, and among 209 non-inoculated 7 cases, with 5 deaths. On July 25th it became necessary to remove the greater portion of the prisoners into camp, inoculated and non-inoculated being represented in fairly equal proportion. From this date to August 2d there remained in the gaol an average of 32.5 inoculated and 48.55 non-inoculated; among the former there was but a single case of cholera, and in this recovery took place, while among the non-inoculated there occurred 7 cases, with 3 deaths. During the same period there were in camp an average of 171.42 inoculated and 146.5 non-inoculated. Among the former there occurred 2 cases of cholera, with 1 death; among the non-inoculated 6 cases of cholera, with 2 deaths. It appears that any protective influence exercised by the inoculations became manifest increasingly toward the end of the treatment, *i. e.*, after a certain period of incubation, for during the first five days after the first inoculation there occurred among the inoculated 5 cases, with 4 deaths, and among the uninoculated 7 cases, with 5 deaths; during the first three days after the second inoculation, among the inoculated 3 cases, with 1 death, and among the non-inoculated 5 cases, with 3 deaths; and during the last six days there were no cases among the inoculated, while among the non-inoculated there were 8 cases, with 2 deaths.

At Lucknow one of the regiments was attacked in July with cholera, which had been present in a virulent form among the native population some months previously. The total strength of the regiment at the time was 773, of whom 133 had been inoculated in May of the previous year. Of 620 not inoculated, 120, or 18 per cent., were attacked, and 79, or 12.3 per cent., died; while of 133 inoculated, 18, or 13.5 per cent., were attacked, and 13, or 9.7 per cent., died.

These observations are interesting and significant. They seem to show that the inoculations have at least a temporary beneficial effect, of which practical advantage could be taken in the event of an epidemic of cholera.

Gonococci in the Blood in Cases of Gonorrheal Rheumatism.—As to the liability to constitutional infection in cases of gonorrhea an abundance of evidence has accumulated. The best known of the complications of this condition is inflammatory involvement of one or more synovial membranes. Less common, perhaps only less frequently observed, is involvement of the endocardium. The undoubted specificity of the secondary lesions, however, has hitherto not been incontestably demonstrated, and the question may fairly arise whether these be infectious or toxic from the circulation in the blood either of the gonococcus or of the products of its vital activity.

An interesting contribution to this important subject has recently been made by HEWES (*Boston Medical and Surgical Journal*, vol. cxxxi, No. 121, p. 515), who cites four cases of gonorrheal rheumatism, in one of which gonococci were, upon bacteriologic examination, found in the blood. Of five other cases of gonorrheal rheumatism, gonococci were isolated from the blood in two. In both sets of cases gonococci were present in the urethral discharge. The victims of specific urethritis appear to be unaware of the gravity of their disease, as regards both extension by continuity and systemic infection and transmission to others; and the facts are, perhaps, not sufficiently noted by medical men. The prophylaxis is simple and effective, and consists only in social purity and sexual abstinence.

The Advertising Newspaper and the advertising doctor are old friends and cronies. What an excellent opportunity the diphtheria-antitoxin business gives all the old regulars to air their opinions in the daily papers! They appear with astronomic (or gastronomic ?) precision just at the proper time. Every new treatment that flashes upon the bewildered public eye, but especially such as that by tuberculin and by antitoxin is certain to produce the same crop of interviews, in exactly the same style, and from precisely the same men. "Same old drunk!" Men who never treated a case of pulmonary tuberculosis or of diphtheria, and who never made a slide in their lives, pronounce with ludicrous dignity and authority (always according to newspaper desire and public prejudice) upon the whole matter. We would suggest to the newspapers that they save reportorial expenses by keeping already stereotyped the old forms of the interviews condescendingly given by their old medical standbys five and ten years ago. Barkis will always be willin', and the pronunciamentos, with the interchange of a few words, will always be identical. The doctor and his reporter have it all stereotyped; why should not the journal also?

Efficiency of Small Filters.—Messrs. Woodhead and Wood have presented to the *British Medical Journal* a special report on the efficiency of many forms of filters sold for domestic uses. They find that there is much irregularity in the quality of the same filter, and that nearly all forms allow organisms to pass. Experiments were made with water containing milk and very finely divided charcoal and ultramarine in suspension.

Tests were made of several filters which had been long in use without cleaning, and it was found that water which before filtration contained less than one-hundred points of microbic life to one cubic centimeter furnished a filtrate containing many hundred colonies. The fact that uncleaned filters may add largely to the microbic life of water passing through them has been generally suspected. The full report is not yet at hand, but it will be a valuable contribution to sanitary literature.

Low Death-rate in England.—The last quarterly returns of the Registrar-General for England show a marked decrease in the death-rate throughout the whole of England. In a total population of over twenty millions living in cities, the rate for the months of July, August, and September was 14.9 per thousand per year, while in rural populations aggregating nearly ten millions it was 12.7 per thousand per year. London has shown as marked a decrease as any part of England, and the diminution of sickness has been distinctly noticed. The favorable condition is ascribed to the cool, wet season that has prevailed. The deaths from zymotic diseases and from diarrhea have been especially low.

Subscription to the Index Medicus is a duty which every reader of these lines owes to his profession. Since our comment in THE NEWS of December 8th we have learned that it is highly improbable that the publication can be

carried on at Government expense. Unless a sufficient number of subscriptions can be received to pay the cost of continued publication this most valuable journal will be discontinued with the December number. For this purpose 800 subscriptions are necessary at $10 each. It would be a good plan to have blank forms pledging subscriptions and support laid before all medical societies, and the attention of members drawn to the duty.

SELECTIONS.

THE PURIFICATION OF DRINKING-WATER.

A REGULAR meeting of the Wistar Biological Society was held at the Wistar Institute on November 9, 1894. General Isaac J. Wistar presided. There was a discussion of the subject of "The Purification of Drinking-water, with Special Reference to the Water-supply of Philadelphia," which was participated in by Dr. William Pepper, Dr. A. C. Abbott, and Dr. Henry Leffmann.

After a brief introductory address by General Wistar, Dr. Abbott spoke of the natural methods of filtration of water through the soil, and said that the deeper the soil the poorer it was in bacteria. This change, however, was not the only one, as there was a marked change in the constitution of the water as found by its passage through the soil. Organic matter will have been found to have disappeared. Surface water in going through soil undergoes not only bacteriologic but chemic purification, and the most desirable water is that obtained from the deepest strata. It becomes important, he said, to know how Nature can be imitated so as to obtain this water, and the method is that of filtration by sand, passed through large stones, then gravel and sand to a fine sand at the top of the filter. The first waters passed through such a filter simply wash away the bacteria. This method, he said, was preëminently a biologic one. It is Nature's way, and is not only satisfactory, but meets sanitary requirements.

Dr. Abbott then alluded to the cholera-epidemic in Hamburg and a neighboring city in 1892, both of which obtained their water from the river Elbe. Hamburg supplied its people with water directly from the river, and with a population of 635,000 there were 18,000 cases and 8000 deaths, while in the other city, which filtered its water, in a population of 145,000, there were but 516 cases, with 316 deaths. There were 283 deaths to every 10,000 people where unfiltered water was used, and only 36 to every 10,000 where the water was filtered.

The biologic phase of the question, he said, was to consider the effect that impure water may have on health. In this connection he discussed the prevalence of typhoid fever, which, he said, was very high in Philadelphia, the average being 6.31 to 10,000 of the population. This is lower than that of Chicago, but higher than that of New York, Boston, Berlin, and Paris. It looked, he said, as if this disease should be charged to something used in common in the community—air and water—and the latter, by common consent, is believed to be the one that causes typhoid fever. The places where the deaths are fewer are where the water-supply has been purified. He showed how, in Chicago, the death-rate from the disease had been reduced by putting the in-take further out in the lake, and similar results had been obtained in other large cities, both in this and in foreign countries. If steps are taken here to correct the water-supply he believed that it would result in a reduction in the mortality that would exceed the most sanguine expectations.

Dr. Leffmann, who followed, pointed out that the main object of the precipitation-methods is to economize the filtering area, and that, by introducing in the water some ingredient which will collect the suspended matter in a coagulum, the operation of filtration takes place with greater rapidity. The best substance used to-day in the purification of water, he said, is aluminum sulphate, as such, or in the form of alum. In explaining the operation of this material, he said it removes any color from the water, as well as any turbidity, etc.

Dr. Leffmann also discussed the sand method of filtration, and that by the use of iron turnings. In the latter process the small pieces of iron are placed in a cylinder about as large as a hogshead, through which the water constantly passes. The iron is ground up slowly by the friction and rubbing, and by the chemic change that takes place the water is purified. He stated that he had had considerable experience with the iron method of filtration, and was satisfied that it was capable of doing good work, especially in waters decidedly turbid.

In reference to the subject of typhoid fever, Dr. Leffmann said that from the records of the Board of Health he found that in 1893 there were 453 deaths from the disease in the city proper. The district supplied by the East Park Reservoir, which includes Kensington, is tolerably free from typhoid fever, while in Kensington, when it received its water-supply from the station at Otis Street wharf, the mortality was much greater. In fact, the disease has mostly disappeared from the district, while in the district west of Broad Street, which receives its water-supply direct from the river, the disease is more prevalent. In Girard College, which is in this district, and which has about 2000 boys, there is scarcely a case of typhoid fever, because filtered water is used.

Dr. Pepper said that no community was in more urgent need of purified water than Philadelphia, where water is used to a larger extent than perhaps any city in the world. It was quite important, he said, that a method of filtration that had been shown to be so economical should at least be tried, pending a determination of the question of the ultimate water-supply of the city. He complimented the stand taken by Mayor Stuart and Director Windrim in advocating purification of the water by asking Councils for an appropriation for a filtering-plant at Belmont, and urged the members of the society to use their influence in promoting the scheme. For himself, he said, he did not permit his family to drink Schuylkill water unless it had been boiled, and the amount of drinking-waters purchased by people, he said, was enormous and scandalous.—*University Medical Magazine.*

A SUBSIDIZED PRESS.

THE *Druggist's Circular* tells us that the eleventh annual meeting of the Association of Manufacturers and Wholesale Dealers in Proprietary Articles was held at Delmonico's, in New York, on the first and second days of October. From a report of the proceedings we abstract the following:

Mr. Cheney, of Toledo, stated that he had a point to

give to advertisers. He has a clause in his contracts with publishers of newspapers to the effect that if the Legislature of the State in which the newspaper is published or Congress shall make any law interfering with or restricting the sale of proprietary goods the contract shall be void. When such a bill is introduced in the Legislature of any State, all he has to do to stop its passage is to call the attention of the newspapers in such State to the clause in their contracts with him, and they "do the rest." This, Mr. Cheney explained, was much cheaper than keeping a lobbyist at the various capitals, and subscribing $300, as he had been asked to do in the State of Illinois, to be used in the suppression of blackmailing measures. Mr. Cheney said that if it was the sense of the meeting to put his plan into the form of a resolution he would do so, but an amendment, thanking Mr. Cheney for his suggestion, was substituted and adopted.

We do not know who Mr. Cheney is nor the name of the medicine or food he makes, but we do know that the proposition he made, and which seems from the report to have been formulated and adopted by the association, is an attempt to subsidize the entire press of the country, and which is truly alarming.—*Cincinnati Lancet-Clinic.*

REVIEWS.

TUMORS, INNOCENT AND MALIGNANT: THEIR CLINICAL FEATURES AND APPROPRIATE TREATMENT. By J. BLAND SUTTON, Assistant Surgeon to the Middlesex Hospital, London. With two-hundred-and-fifty engravings and nine plates. Small 8vo, pp. 511. Philadelphia: Lea Brothers & Co., 1893.

THIS is a very interesting and instructive book. Mr. Sutton proposes a new classification of morbid growths on lines similar to those employed in biology, arranging them in four groups, each divided into genera, and these again into species, each of which may present one or more varieties.

The groups are: connective-tissue tumors, epithelial tumors, dermoids, and cysts. Of these groups the first contains twelve genera, and each of the others four. Among those of the first group we note neuromata, angeiomata, and lymphangeiomata; these, as representing tissues of special function, might perhaps be more properly placed in a separate group. The second group contains papillomata, epitheliomata, adenomata, and carcinomata. Under the third are found sequestration-dermoids, tubulo-dermoids, ovarian dermoids, and dermoid patches. The fourth includes retention-cysts, tubulo-cysts, hydroceles, and gland-cysts; the last-named having under it a subgroup of "pseudo-cysts," embracing four genera—diverticula, bursæ, neural cysts, and parasites.

Appended to the discussion of dermoids there is a chapter on teratomata, which is interesting, but seems to be superfluous. It is introduced, the author says, because certain species of these malformations are so very likely to be confounded with dermoids; but he mentions only one such instance, and that one of no material consequence.

Did space permit, we should very gladly give a further analysis of the views presented as to the species and varieties of morbid growths, and of the practical deductions drawn from them. A peculiar and valuable feature of this work is the very frequent reference to the analogous formations met with in the lower animals of the vertebrate class. Especially is this notable in the portion relating to dermoids, and it is emphasized in a chapter devoted to the zoological distribution of tumors.

As a general rule, we agree with Mr. Sutton's views in regard to treatment. But we are constrained to take issue with him when he says that in a large majority of instances of rectal carcinoma it is impossible to determine the seat of the disease, and advocates a preliminary celiotomy in the median line for the mere purpose of manual exploration, to be followed (the wound first made having been closed) by the formation of an artificial anus at a suitable point.

The chapter on the causes of tumors is a very interesting one. The problem of the genesis of morbid growths is to physicians somewhat as that of the origin of moral evil was to the theologians of a former time. In both cases we believe that in the last analysis the trouble is found to be a misplacement, or a hypertrophy, or an erratic development, of what is in itself normal. Mr. Sutton thinks with Cohnheim that, except in the sarcomata, epitheliomata, and carcinomata, an important part is played by *vestiges* and *rests*. By the former term are indicated "structures that are remnants of organs functional in vertebrates lower than man; those organs that are of importance to the embryo, but useless in the adult; and a few which, though utilized in the male, are useless or almost useless in the female, and *vice versâ*; as well as those structures which, as far as we know, serve no useful purpose in any vertebrate at present living, but were doubtless of importance in their ancestors." By *rests* are meant "detached fragments of glands and isolated portions of tissue and epithelium."

With regard to carcinoma our author justly says that a correct appreciation of its morphology is of the first importance as a prelude to the study of its cause. He thinks that in a large class of cases the coccidian theory may be accepted, although it fails altogether to explain the phenomena in many others. We should have been glad to find this whole topic of etiology discussed at much greater length; but indeed throughout the entire work the style adopted is very terse, as was needful for the treatment of so extensive a subject within such narrow limits.

On page 419 it is stated that "cervical cysts in children and cervical air-sacs in monkeys are *on all-fours*." What is meant by this absurd phrase we can conjecture; but it seems to us as inelegant as any of the "Americanisms" with which our brethren on the other side of the water are so prone to find fault.

The value of this book is greatly enhanced by profuse illustration and by clear and correct typography. We predict for it a deserved success.

A CLINICAL MANUAL OF DISEASES OF THE EYE, INCLUDING A SKETCH OF ITS ANATOMY. By D. B. ST. JOHN ROOSA, M.D., LL.D. Illustrated by one-hundren-and-seventy-eight engravings and two chromolithographic plates. New York: William Wood & Co., 1894.

THIS is an astonishing book! It seems to have been written to promulgate the author's peculiar and well-

known views concerning the diagnosis and treatment of refraction-anomalies. There is nothing in the work besides these views that is new and that required the writing of six-hundred pages to tell. To repeat the old saw, what is new in the book is not true, and what is true in it is not new. We sympathize entirely with the author in his denunciation of the excesses of the tenotomists, but that any sane ophthalmologist should assent to his own extravaganzas is beyond belief. His absurd worship of the divine ophthalmometer, his ignoring of anisometropia, and of any but of extremely high errors of refraction, his ignoring of muscle-imbalance, his distaste for mydriatics, his detestation of the idea of reflex neuroses due to eye-strain, his scorn of the thousand truths believed in and well-established by hundreds of careful and conscientious ophthalmologists—all these things are silly, wearying, and oppressive. The parts of the book referring to these things are crammed with as many reiterated errors as it is possible to be. The author should perform *harikari*, and name the advertising optician as his residuary legatee. A worse book to put in the hands of the student of medicine, the general physician or the young oculist, we cannot imagine.

But we advise the experienced and conscientious oculist to buy the book, in order to see how in the practice of medicine (*sic*) the very existence of the troublesome, the doubtful, or the mysterious can be denied existence, how the life-long experience and problems of careful men can be sneered at and dogmatized down, how far business, guesswork, and machinery, can be supposed to carry in the diagnosis and treatment of disease. If disgust can be conquered by a lively sense of the ridiculous, such a reader is promised much amusement.

On Chorea and Choreiform Affections. By William Osler, M.D., Fellow of the Royal College of Physicians, London; President of the Association of American Physicians; Professor of Medicine Johns Hopkins University, and Physician-in-Chief Johns Hopkins Hospital, Baltimore; formerly Physician to the Infirmary for Diseases of the Nervous System, Philadelphia. 8vo, pp. x, 125. Philadelphia: P. Blakiston, Son & Co.

As stated in the preface to this monograph, its contents are largely based upon observations made at the Philadelphia Infirmary for Nervous Diseases, an institution unique for the richness of its service, the fulness of its records, and the care given to the study of its cases. The work is a faithful reproduction of a disorder at once well known, and in some respects obscure, and accurately portrays the current conceptions of chorea in its varied aspects. In the introduction the following useful description is given: Chorea minor, classic chorea, as described by Sydenham; chorea major, an hysterical affection; pseudo-choreas, including the various forms of local or generalized habit-spasm or tic; and secondary or symptomatic choreas, dependent upon degenerative and irritative lesions of the motor cortex or path. Only the first and third of these groups are here considered, together with the chronic progressive forms of the fourth group described by Huntington. The general etiologic features and the clinical picture of chorea minor are given at length, but little light is shed on the morbid anatomy and pathology, although the suggestion is given that at least some cases are of infective origin. A relationship between chorea and acute rheumatism is maintained, but its nature is not explained. Not less interesting than the consideration of chorea minor are the chapters devoted to the pseudo-choreas and to chronic progressive chorea. Appended to the text is an analysis of seventy-three fatal cases of chorea minor. Altogether this monograph will stand as an authoritative statement of existing knowledge upon the subject of chorea, and will add luster to the reputation of its distinguished author.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. de Schweinitz, Edward Martin, and Barton C. Hirst. New (fourth) edition, revised and enlarged. Octavo, 740 pages. Philadelphia: Lea Brothers & Co., 1894.

We cannot better call attention to the new edition of this work than by quoting the author's words in the preface:

"The fourth edition of this work having been called for in less than four years after the appearance of the first, the author has taken advantage of the opportunity to rewrite and add to many of the articles on drugs, remedial measures, and diseases, and to insert practical information concerning the value and prescription of the really useful new remedies. Articles on methylene-blue, chloralose, pyrogallol, condurango, convallaria, duboisin, and other remedies have been added to the part of the work dealing with drugs. In the part dealing with remedial measures other than drugs, articles have been written on hypodermoclysis and enteroclysis, lavage, and upon mineral springs and climatic treatment. The latter article is not intended to be exhaustive, but to give the general practitioner an idea of the therapeutic value of certain well-known resorts, in order that he may offer rational advice to his patients as to where they should go in search of health. Several new articles in the part devoted to the treatment of individual diseases have been inserted, and new or modified applications of the older remedies carefully noted throughout the entire book."

Aseptic Surgical Technique, with Especial Reference to Gynecological Operations, together with Notes on the Technique Employed in Certain Supplementary Procedures. By Hunter Robb, M.D., Associate in Gynecology, Johns Hopkins University; Professor of Gynecology, Western Reserve University. Illustrated. Philadelphia: J. B. Lippincott Co. 1894.

Though there are still some men practising surgery whom the amazing contrast of the results of latter-day operations with those of twenty-five years ago has not yet converted to belief in the doctrine of wound-infection through bacterial agency, their number is happily

small, and is constantly diminishing. Every surgeon whose mind is not hopelessly incapable of welcoming new truth has embraced the great principle first presented by Lister, and, in proportion to his conscientiousness and capacity for close observation and accurate reasoning, has followed with delight the progress of the method from the first crude applications of chemic antiseptics to the present elaborate and wonderfully successful system.

The volume in hand is the latest literary product of American surgery and contains the most approved rules for the achievement of asepsis, based not only upon experience in the operating-room, but also upon close study in the bacteriologic laboratory. The author is an extremist, but he is a reasonable one, stating the case with judicial fairness and admirable clearness, insisting with emphasis upon the thorough employment of the means recommended, but without the least display of the righteous indignation at the unregenerate which made a certain book on modern methods at once picturesque and popular. The lazy and indifferent will object that the minuteness of precautions here enjoined is unnecessary; but those who have taken pains to keep pace with the times, and who consequently know that the best results of wound-treatment are obtained only by precise attention to such details, will welcome the book as an embodiment of the best rules which the largest opportunities and most faithful research have as yet devised. We trust that this valuable and interesting publication will receive the wide attention to which its merits entitle it.

THE MEDICAL NEWS VISITING LIST FOR 1895. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated for 60 patients weekly per year). Philadelphia: Lea Brothers & Co., 1894.

THIS useful and popular visiting list has been revised and brought up to date. The text contains an alphabetical table of diseases, with the most approved remedies, and a table of doses, sections on examination of urine, artificial respiration, incompatibles, poisons and antidotes. diagnostic table of eruptive fevers, and the ligation of arteries. The classified blanks are arranged to hold records of all kinds of professional work, with memoranda and accounts. Great care has been exercised in the selection of the contents and much judgment in the arrangement of the record-blanks. The mechanical execution of the book is satisfactory, and special attention seems to have been given to the quality of the paper and the strength and style of binding.

When desired, a ready reference thumb-letter index is furnished. A new and praiseworthy feature is the provision for obstetric memoranda. The list will fit an ordinary inside coat-pocket.

CORRESPONDENCE.

A FOOT-BALL ACCIDENT.

To the Editor of THE MEDICAL NEWS,

SIR: THE MEDICAL NEWS having recently contained a number of reports of accidents from foot-ball, I wish to report an accident that is rather uncommon under any circumstances and more particularly as a result of the game of foot-ball.

G. H. S., about nineteen years old, a student, while playing foot-ball was thrown down, striking his hand violently on the ground. He noticed some numbness of the hand, which later developed into pain, more especially in the little finger. The finger becoming swollen, the young man consulted a physician. Being dissatisfied with the result of the treatment, I was consulted, and found a small swelling to the proximal side of the terminal joint of the little finger and complete loss of power to extend the distal phalanx after flexion. My diagnosis of laceration of the extensor tendons was verified when, under cocain-anesthesia, I cut down on the tendons and found an interval of more than half an inch between the ends, the tear being a ragged one and situated less than one-eighth of an inch from the attachment of the tendon. Being unable to approximate the ends, owing in part to the delicacy of the tendons and in part to the length of time intervening between the time of the accident and the operation (about one month), I transferred two strands of large-sized catgut to the wound, filling the gap between the ends of the torn tendons, and stitched the wound with silk. I was gratified to get an almost complete recovery of the use of the finger, there being a slight incompetency of the extensor, due, I think, to a slight increase in its length following the graft.

Although taking the same precautions as regards asepsis in this operation as I do with my celiotomies, I was unfortunate enough to have pus in the wound, which necessitated the removal of all the stitches on the fourth day, but after thorough irrigation with 1 : 30 solution of carbolic acid, no further trouble was experienced, and I blame the suture-material for the pus.

Respectfully. JOHN A. HAWKINS.

105 JACKSON ST., ALLEGHENY, PA.

THE CONTROL OF HEMORRHAGE FROM THE SPLEEN AND OTHER ABDOMINAL VISCERA.

To the Editor of THE MEDICAL NEWS,

SIR: Dr. L. McLane Tiffany, in THE NEWS of November 17, 1894, p. 546, relates how he checked hemorrhage from the spleen by deep interrupted silk sutures. Mattress or square sutures of thick catgut, introduced by long, slender darning-needles, are, perhaps, still more efficient and innocuous in almost all hemorrhage from the abdominal viscera, and indeed would be well worth a trial in wounds of the lung. The kidney, even its pelvis, may be thus perforated as often as required with impunity. Were silk used in the pelvis of the kidney it is probable that calculous formations might result. By the suture alluded to a quadrangle of tissue is compressed. Sincerely,

FRANCIS L. HAYNES.

LOS ANGELES, CAL.

NEWS ITEMS.

Foot-ball Civilization.—From sheer weariness and lack of space we discontinue the English "crop-reports" of deaths, broken bones, and depravity, but continue a few American specimens.

Will Washington, D. C., friends tell us if Captain Bahen is still alive?

"Ugh! Dirty, cowardly work! It reads nice in cold type, does it not? It is the method of the footpad, who steals up from behind and knocks you down with a slungshot."—[Casper W. Whitney on "Foot-ball Methods" in *Harper's Weekly*.]

The treasurer's report of the receipts of the Yale-Princeton foot-ball game has been issued, and shows that the game has netted a snug sum for the two college foot-ball associations. Each will receive $12,104.58 as its share of the profits of the game. The total receipts were $33,468; the total expenses, $9258.83. The receipts of the game last year were $39,439.12, but the expenses were also larger, so that the profits this year were nearly as great as they were a year ago.

Stewart Cravens, aged twenty-four, a student at the Culver Military Academy, Maxinkukee, Ind., died December 5th from an injury received in a game of foot-ball played three weeks ago between the cadets of the academy and the Indianapolis High School team.

The "men" honored by the college world are those conspicuous for their athletic achievements or possibilities. The god of undergraduate idolatry is the foot-ball player, the member of the university crew, the lucky fellow that gets on the base-ball nine or the intercollegiate team. The youths for whom the universities were founded by our wise and pious ancestors, as the Massachusetts Constitution says of the founders of the university at Cambridge, are of no account in the public opinion of their college. They are scrubs, or grinds, or digs. They are despised and looked down upon. This is not the case at Harvard and Yale and Princeton merely, but it is the case at every college of age or reputation in the East. The student who studies is a non-entity. The student who develops his muscles is admired and famous. The institutions founded for the development and propagation of scholarship among men are not true to the purpose of their founders. If cultivation and research exist among them, they exist furtively and without honor. Where are the names eminent in literature, in art, in philosophy, of the college graduates of the last ten years? What the colleges are producing is the professional athlete, the professional instructor in athletics, the professional college man. Take Yale College, for instance, as the most illustrious exemplar of athletic triumphs. What is Yale producing? What is the type of the Yale man now? Is it the poet, or the philosopher, or the man of science? Not much. It is the professional Yale man, or the Yale professional.—*New York Sun*.

"In another game I witnessed one of the players was bleeding slightly, and I noticed that there was frequently a sort of scuffle between him and the man opposite him. When time was called at the end of the first half I said to him, 'Your man is slugging, as you call it, is he not?' He answered with tears of rage in his eyes, 'He strikes at me every time he passes me.' 'Why don't you complain to the umpire?' He made no answer, and the next day denied that there was any 'unnecessary roughness on the part of the opposing players.'"—["A Yale Graduate" in *New York Evening Post*.]

"Had the most benevolent person lived in a country in which the excellence of these games was deemed axiomatic, had he been taken to them in his very childhood, and accustomed to associate them with his earliest dreams of romance, and had he then been left simply to the play of the emotions, the first paroxysm of horror would have soon subsided, the shrinking repugnance that followed would have grown weaker and weaker, the feeling of interest would have been aroused, and the time would probably come in which it would reign alone."—[Concerning the Roman Gladiatorial "Games," from Lecky's *History of European Morals*.]

Claude G. Campbell, a crippled student of Stanford University, was hazed by California University students for applauding the defeat of their team. His head was shaved on one side, his eyebrows and eyelashes cut off, and he was branded with initials on his cheeks.

The Centenary of the Discovery of Vaccination.—The directors of the German Vaccine Institute, at Weimar, are arranging for a celebration, to be held in 1896, in commemoration of Jenner's discovery of vaccination. In connection therewith there is to be an exhibition of old and new vaccine-instruments, of apparatus for the preservation of lymph, etc.; of original manuscripts on smallpox and vaccination; on the inoculation of sheep-pox and cattle-plague in pre-Jennerian days; of squibs on vaccination, of medals, portraits and autographs of prominent inoculators, vaccinators, and anti-vivisectionists, etc.

A Bacteriologic Laboratory for Denver.—Dr. L. E. Lemen, Health Commissioner of Denver, Col., has established a bacteriologic laboratory to be devoted to thorough research in cases of infectious and contagious diseases. Physicians will upon request be furnished tubes with instructions for placing therein pathogenic deposits, sputa, etc., after an examination of which a report will be returned.

The Journal of Medicine and Science is a new monthly publication, the first number of which bears date of December, 1894. It is the official organ of the Maine Academy of Medicine, and is edited by Dr. E. E. Holt, with the assistance of Dr. J. A. Spalding, in conjunction with the officers and fellows of the academy. It is published at Portland.

Le Nord Medical is the name of a new bi-monthly journal published at Lille under the editorial direction of Messrs. Doumer, Lemoine, and Phocas.

Dr. H. Augustus Wilson has resigned as Clinical Professor of Orthopedic Surgery in the Women's Medical College of Pennsylvania.

THE TREATMENT OF LACTIC-ACID EXCESS IN THE STOMACH.[1]

BY ALLEN A. JONES, M.D.,

INSTRUCTOR IN PRACTICE AND CLINICAL INSTRUCTOR IN MEDICINE, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

FROM a series of recent investigations Boas has concluded that lactic acid is not present at any time during digestion in a normal stomach; whereas, it has been taught heretofore that lactic acid is present in healthy digestion during the first thirty or forty minutes after the ingestion of food. It is stated that it is absent not only at that time, but also at all periods of the digestion of a test-meal, whether early or late, whether or not the motion of the stomach is normal or tardy, whether or not dilatation exists, and whether or not hydrochloric acid is present. Only one morbid condition of the stomach, so says Boas, is accompanied by the presence of lactic acid, and that is carcinoma. In this disease lactic acid is said always to be present, and Boas further holds that when it is found in the stomach after a test-meal it is diagnostic of gastric carcinoma.

Notwithstanding that Boas[2] has found lactic acid only in gastric carcinoma, my experience in the matter has been quite different. I have found lactic acid in the stomach during the first part of normal gastric digestion, and also under abnormal conditions, such as persistent diminution in the secretion of hydrochloric acid, an absence of free hydrochloric acid, sluggish motility, gastrectasia, and malignant disease, especially when so located as to cause pyloric stenosis.

In the large majority of cases the treatment of lactic-acid excess simply resolves itself into the treatment of its cause, but in some cases the cause cannot be removed except by surgical intervention, as in gastrectasia from cicatricial pyloric stenosis, and in these cases remedies are demanded that, as far as possible, lessen the production of lactic acid and neutralize it after it is produced, thereby preventing the nausea, vomiting, vertigo, headache, or other distressing symptoms that are largely due to lactic-acid poisoning.

In a short paper upon "The Rôle of Lactic Acid in Gastric Digestion"[1] I mentioned several of the causes of an abnormal presence of lactic acid in the stomach. The first of these causes is deficient secretion of hydrochloric acid, which may result from chronic catarrhal gastritis, gastric carcinoma, debilitating disease, such as tuberculosis, or from what may appear as a secretory neurosis.

The presence of hydrochloric acid in the stomach in normal quantity is usually antagonistic to lactic-acid fermentation, owing, probably, to its antiseptic properties. The endeavor should, therefore, be made to reëstablish a more abundant secretion of hydrochloric acid, by treating the cause or the causes of its diminution. In the case of catarrhal gastritis, lavage, with the use of boric acid or boroglycerid solution, and the aqueous fluid extract of hydrastis, is very useful. It is a good plan to wash out the stomach three or four hours after a meal, so that some contents yet remain for chemic and microscopic study, using at first, until the viscus is empty, simply warm water, preferably that which has been filtered or boiled, then using boric acid or boroglycerid solution; and finally to pour in a mixture of bismuth subgallate with the aqueous fluid extract of hydrastis, a part or all of which may be left in the stomach according to the amount used. At another sitting a weak solution of silver nitrate (2 grs. to 8 oz.) may be used after the mucous membrane is perfectly cleansed. This is one of the most effectual washes in catarrhal gastritis.

The scope of this paper does not permit a detailed discussion of the local and general treatment of gastric catarrh, but I wish to emphasize the importance of removing the causative elements underlying lactic-acid fermentation.

While the various measures used to restore the proper secretion of hydrochloric acid when it is persistently below normal are being carried out, the administration of hydrochloric acid about thirty or forty minutes after meals, in twenty-drop doses of the dilute acid, assists materially in temporarily staying lactic-acid fermentation and in relieving the patient of the sensation of weight, distress, and flatulency.

If the cause of lactic-acid excess is found to consist chiefly in impaired motility of the stomach, strychnin or nux vomica in liberal doses before meals or two hours after meals is attended with benefit. The application of the interrupted cur-

[2] The Medical Week, September 7, 1894.

[1] THE MEDICAL NEWS, December 30, 1893.

rent directly within the stomach stimulates and strengthens the musculature, and thus the stomach is often made to empty itself in due time after each meal, and so fermentation from food-stagnation is prevented. For this purpose also expert abdominal massage by one who reaches deeply, coaxing and pushing the stomach-contents toward the pylorus, often materially assists the stomach to empty itself. Emersonian exercises and certain Swedish movements seem to aid in emptying the stomach, while they certainly indirectly improve its tone.

Theoretically, physostigma increases gastro-intestinal peristalsis, and in some cases of atony it may be used to advantage. The extract may be given in quarter or half-grain doses three times daily, combined with extract of nux vomica and a little extract of belladonna.

Antiseptics are remedies that may sometimes be used to advantage in conditions of deficient hydrochloric-acid secretion, impaired motility, and gastrectasia, but they are not so effectual actually as theoretically they make promise of being.

When from indiscretion in diet, fatigue, or constipation, a sudden attack of gastric fermentation occurs, no drug is better adapted to neutralize the poison and hurry it out of the system than calomel, either in small doses frequently repeated or in one good-sized dose followed by a saline cathartic. Indeed one-twentieth or one-fiftieth of a grain of calomel given about four times daily in a somewhat lasting condition of lactic-acid fermentation acts admirably as a gastro-intestinal antiseptic. The speediest way of ridding the stomach of an excess of lactic acid formed during an attack of so-called "acute biliousness" or "acute indigestion" is by lavage. The noxious elements are washed out, the intestine no longer receives irritating, improperly-prepared chyme, and the mucous membrane of the stomach is immediately soothed. The greatest relief is afforded by lavage in many cases of gastrectasia when the stomach is loaded with acrid, stagnant, poisonous material, some of which has, perhaps, been lying in it for a number of days. No other means as yet practised is capable of giving the relief or accomplishing the good that an occasional lavage does in these cases of food stagnation.

One or two grams of chemically pure sodium bicarbonate one hour before meals promotes gastric secretion and motion, and in some cases lactic acid is found in very much smaller quantities during and after its use. It has been found that soda given later than one hour before meals does not act as well as when it is given in the manner indicated, while if it is given at the beginning of or during a meal, gastric digestion is retarded.[1]

[1] Gilbert and Modiano: The Medical Week, July 13, 1894.

Drugs that are used as gastro-intestinal antiseptics are very numerous. A few seem to be effective in reducing the formation of lactic acid. Benzonaphthol in doses ranging from two to ten grains works well in some cases. It is best given in capsules soon after meals. Resorcin in five-grain doses may be given either in capsules or with glycerin and a little alcohol as a solvent. Oil of eucalyptus is a good gastric antiseptic, and if not administered in capsules it may be advantageously given incorporated in a powder with a little menthol, bismuth subgallate and light magnesium carbonate. When there is much flatulence this combination affords relief, and to it may be added reignited officinal charcoal. Hydrogen dioxid is another antiseptic that has been quite largely used for its effect in the stomach. It is useful in arresting fermentation if given early enough to exert its action before fermentation has gotten well started. Unfortunately the drugs that are used as gastric antiseptics are necessarily given in such small doses that they are "a drop in the bucket" when mingled with the copious mass of semi-fluid, sour, decomposing stomach-contents often present; more especially is this true in gastrectasia with food-stagnation. One of the most effectual drugs in lactic-acid fermentation is pure beechwood creosote in doses of from one to five or more drops given in wine or mucilage after meals. In cases of impaired motility with absence of free hydrochloric acid and with lactic-acid excess, I have seen the latter almost entirely disappear and the former reappear under the use of this drug. Small doses seem to have as much effect as large amounts of the drug.

Sodium sulphite and potassium permanganate are active antiseptics, but in my experience their administration has been attended with a sense of nausea, gastric distress, or vague discomfort, so much so that they have been necessarily discontinued.

There are some cases of dilatation of the stomach due to cicatricial stenosis of the pylorus following gastric ulcer, in which hydrochloric acid is still secreted, but is not found free in the gastric contents when they are withdrawn, because of the overwhelming amount of lactic acid that arises from active fermentation of stagnating contents. In these cases the total acidity is not infrequently raised to 100 or higher, and the administration of hydrochloric acid after meals gives rise to increased distress, amounting at times to a burning pain. While giving hydrochloric acid in such cases I have failed to find it free in the stomach-contents, and at the same time it has been quite noticeable that lactic-acid fermentation seemed rather to be increased than lessened, and the total acidity of already irritating contents was thus raised instead of lowered.

By stopping the administration of hydrochloric

acid and substituting a mixture of cerium oxalate, bismuth subcarbonate, and light magnesium carbonate given between meals and at bedtime, not only was gastric comfort restored, but lactic acid was markedly diminished and free hydrochloric acid was found in the gastric contents. Finally one of the most important of all matters in the treatment of lactic-acid excess is the correction of the diet, the more so as improper diet is the cause of lactic-acid formation in many cases. Milk-puddings, custards, pastry, ice-cream, rich cakes, cheese, thick soups made with milk and cream, fancy entrées made with cream and starches mixed, salads and salad-dressings, all these should be very much restricted or interdicted entirely. It is noticeable that milk and cream when taken alone do not give rise to nearly as much lactic-acid formation as when they are mixed with such starchy foods as creamed potatoes, cornstarch, tapioca, sago, etc.

As a rule, however, it is best to withhold milk at the outset until lactic acid is no longer formed in any but small quantities. Meats, eggs, stale bread, Zwieback, fish, oysters, and other plain foods should constitute the diet until the system is free from the effects of lactic-acid poisoning.

Lowered general health should be overcome by out-of-door life and appropriate exercise, sunlight, proper sleeping-rooms, hydrotherapy, massage, electricity—indeed, all those things that strengthen the nervous system, improve the blood, and increase muscular tone so that the functions of the stomach may benefit thereby.

RURAL HYGIENE.

By HARVEY B. BASHORE, M.D.,
of West Fairview, Pa.

Outside of the great cities sanitation is sadly neglected. In many of the small towns methods for the disposal of refuse and garbage are almost as crude as when the country was first settled; the drainage is bad, very bad; the drinking-water is in constant danger of pollution, and if a case of typhoid fever appears upon the scene an epidemic is very likely to follow. These defects, too, are not so readily remedied as may appear on casual observation, for the people have not yet learned that it is better to pay a physician to prevent disease than to cure sickness. There still linger, too, in many an out-of-the-way place old superstitions about disease which act as a bar to sanitary development. Of course, I except all such places as Wayne, Pa., and Freehold, N. J., which skillful sanitary advice has made into model towns.

Among the many neglected points, that of surface-drainage and deep drainage is worthy a word: the first has and is receiving some attention, but deep drainage, although shown by the labors of Schloesing, Müntz, and Warrington to be of such great value, rarely receives any consideration whatsoever, and consequently damp soils and high ground-waters are constant factors; but it is a good sign of advancing progress to see that the farmers are beginning to underdrain their swamps and lowlands. Ground-air, too, must be accepted as inevitable in ordinary country houses, for no method seems to be adopted to keep it out; primitive soil forms the floor of the cellar, and the upward draft must be enormous, especially in winter. It is needless to state that the floors of all cellars should be cemented or, better still, covered by a layer of bricks, pitch, and concrete.

The drinking-water is another item of interest, for the well is generally located conveniently to the house, irrespective of the position of the privy-vault, the pig-sty, or the stable; the result is that the water is almost invariably polluted, and it is a wonder that there are not more epidemics. I have before me at this moment the analyses of fourteen different wells, and all save two show an excess of chlorin, which, of course, means more or less animal contamination. This examination for chlorin in well-water, by the way, is very important. What does one care about the amount of albuminoid ammonia, for example, if a well-water contains four or five or more parts of chlorin per 100,000, while the river water, perhaps, thirty or forty feet distant contains only 0.4 per 100,000? Still, a fixed quantity of chlorin can not be relied upon for judging of the contamination. A better way, after taking into account the geologic character of the strata, is to make analyses of a series of wells in the same locality, and the one giving the lowest amount of chlorin will then represent the nearest approach to purity for that district, and any variation can be judged of accordingly. Of course, the presence of chlorin in water may mean only past contamination, but I should hesitate to use a well even if it presented evidences of past pollution only, for the fluctuations of the ground-water currents are so variable that no one can tell at what moment such a well may again become polluted. The proximity of a spring or well to the sea does not necessarily imply the presence of chlorin in the water, for I have found recently in a spring not more than three or four feet above high tide, on the shore of Long Island Sound, less than one part of chlorin per 100,000—as free, in fact, from chlorin as water I took from a Croton tap. Although we have at hand a ready means of judging of the pollution of a well-water, for chlorin-examination is easy, the means of preventing the contamination is yet a matter of study; the only way, it seems, to lessen such pollution is either to remove the wells or to remove the source of pollution, namely,

the privy-vaults, pig-sties, the stables, refuse, household-waste, etc.; and the latter method seems to be the most feasible.

The privy-vault as ordinarily made is not water-tight, and who can say what its drainage-area might be. I lately examined a well-water not within even one hundred yards of a privy-vault or cesspool, and still it yielded 5.1 parts of chlorin per 100,000, and is undoubtedly contaminated by sewage, for it is situated in a non-saline bearing strata, and there is no chloritic shale nor anything else save animal excreta to yield the chlorin; as a proof of this a well not over a hundred feet distant, in exactly the same strata, yields but 1.1 chlorin per 100,000.

To be brief, all privy-vaults should be supplanted by the earth-closet or rather ash-closet; the use of sifted coal-ashes for this purpose is admirable, and a constant supply can be readily obtained. The contents of the closet should be emptied into the receptacle for the stable-refuse, and carted away from time to time. To the practical value of the ash-closet I can certify from personal observation of several years. For the disposal of slops and wash-water a small system of sub-soil irrigation in the back-yard is the best; made with agricultural drain-tiles it is cheap and very efficient.

Pig-sties should be relegated to a place far from the abode of man, or else kept in a more cleanly condition than is usually the case. Garbage and house-refuse should be burned in the kitchen-range. Stable-refuse should be received into a cemented, water-tight receptacle, and should be emptied at frequent intervals.

By some such means as these well-water—for wells will continue to be used in the country for some time to come—may be saved from pollution, and the sick-rate from typhoid fever and diphtheria greatly lessened.

Rural hygiene should receive more attention than is generally given it, for it is a great factor in the sanitary condition of large areas. Typhoid fever in the country ten miles from New York or Philadelphia may not seem to the residents of those cities to be of much consequence, but if it affect the Croton or the Schuykill watershed, it might happen to become very important to those who drink Croton or Schuylkill water.

Concurrent Varicella and Scarlet Fever.—Snell (*Lancet*, 1894, No. 3716, p. 1152) has reported the case of a child four years old, whose two sisters were suffering from scarlatina, and who presented a typical varicellous rash upon the face and body, followed on the succeeding day by a profuse scarlatinal rash. Each exanthem ran the usual course peculiar to itself, desquamation subsequently taking place. About ten days later the two children who at first had scarlatina exhibited well-marked varicellous rashes.

THE OPERATIVE TREATMENT OF INFLAMMATORY PHIMOSIS AND THE USE OF THE SHARP CURET AND STRONG BICHLORID SOLUTION FOR CHANCROIDS.[1]

By WILLIAM P. MUNN, M.D.,
Professor of Genito-urinary Diseases and Clinical Surgery in the University of Denver; Genito-urinary Surgeon to the Arapahoe County Hospital, etc.

The treatment of chancroid located in the coronal sulcus and covered by a long prepuce has as a rule always been unsatisfactory. When the inflammatory reaction creates a practically irreducible phimosis, there has been felt the necessity for operative interference, mingled with the dread of further chancroidal infection of the whole of the fresh wound-surface. In so late a publication as Morrow's *System of Genito-urinary Diseases and Syphilology*, Dr. Edward Martin states that in five cases of circumcision for inflammatory phimosis due to sub-preputial chancroid, in every case a complete circular chancroidal infection occurred. My own experience was until recently practically in accord with his and that of other writers on the subject. Within a short time an opportunity has occurred in eight cases to put in practice a method the results of which have been eminently satisfactory both to myself and to the patients.

The procedure is as follows: (1) anesthetize the patient, preferably with chloroform; (2) thoroughly irrigate the sub-preputial space with a strong mercuric-chlorid solution, not weaker than 1 : 1000, and scrub the parts thoroughly with bichlorid gauze pledgets; (3) perform circumcision rapidly, immediately grasping the raw surface left by the retraction of the skin, with one hand protected by bichlorid or iodoform-gauze; (4) slit the mucous membrane of the prepuce dorsally, back to the corona, and immediately scrub it thoroughly with a pledget of bichlorid gauze, which is at once thrown away; (5) with a sharp curet thoroughly scrape the chancroidal ulcer, removing all granulations clean down to healthy tissue; (6) wash away the *débris* with a bichlorid solution, and then mop up the curetted surface, either with Monsell's solution, full strength, or with a 1 : 100 solution of bichlorid; (7) trim the mucous membrane and suture it to the skin with silkworm-gut sutures placed rather close together; (8) rub aristol or iodoform into the line of coaptation and then into the curetted surface; (9) dress with a thick strip of iodoform-gauze held in place by a rubber band.

In every case the results attained by this method have been practically perfect. The circumcision-wound has united throughout by first intention, with the exception, in two instances, of a trifling

[1] Read before the Denver and Arapahoe Medical Society, October 9, 1894.

point of infection, which healed kindly when touched with pure carbolic acid. The original chancroid in every case was converted at once into a healthy, rapidly granulating ulcer, almost entirely free from discharge. The first dressing, as a rule, has been allowed to remain in position three days, although in two instances it remained a week, and when removed healing was practically complete.

In one case only was the dressing changed after twenty-four hours, mainly in order to inspect the glans penis, the integrity of which I feared might be destroyed, as the chancroid had eaten deeply into the body of the penis back of the corona. Inspection showed the deep ulcer filling up with healthy granulations with astonishing rapidity, and in a week the patient was practically well.

This method seems of importance because:

1. It indicates the uniform and satisfactory results to be obtained by the proper application of antiseptic measures in the treatment of a condition that has always been regarded as refractory and disappointing, as well as disgusting.

2. It indicates curettage as the ideal treatment of chancroid.

To the latter conclusion there is the objection that few patients suffering from what they consider a trivial disorder will submit to anesthesia in order to permit of curettage. The objection is weighty as a practical consideration, but does not invalidate the correctness of the method as a surgical procedure. The uniform rapidity of recovery stamps it as superior to other usual methods of treatment for those patients who are willing to submit to it.

I am impelled to notice the attitude of so eminent an authority as Jacobson, who, in his recent work on *Diseases of the Male Organs of Generation*, seems to have little fear of infection of the wound, but does not appear to accomplish primary union nor even to expect it in hospital-cases that have no infective complications. His treatment of the chancroidal sore with nitric acid is certainly radical and antiseptic; but while it destroys the specific infection, it causes sloughs and necessitates the use of warm fomentations and charcoal poultices, to which he advises resort, while at the same time it absolutely interdicts all hope of primary union. The thorough use of the curet followed by momentary application of strong bichlorid solution is open to none of these objections.

CLINICAL LECTURE.

EPILEPTOID MIGRAINE.[1]

By H. C. WOOD, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AND CLINICAL PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE UNIVERSITY OF PENNSYLVANIA.

THE patient before us to-day, a young man, twenty years of age, has been brought from a neighboring city by his physician, with the statement that during the last year there has been on his part a growing inability to understand and remember his studies as a student of law; and also that some years ago he had from five to seven attacks, at long, irregular intervals, of some kind of nervous spells, accompanied by loss of consciousness, and therefore suggestive of epilepsy. It is alleged that there have been none of these attacks within two years; but I find upon careful questioning that, instead of there having been in the first period from five to seven attacks, he had from five to seven groups of attacks, each group being composed of from three to five paroxysms, occurring sometimes within twenty-four hours, sometimes within two or three days, and always followed by some months of normal health. I find, further, that during the last two years there have been numerous "spells," which were similar to the more severe attacks of which he first told, but different in that they have not been accompanied by loss of consciousness. In speaking of the case I shall call these latter *minor* attacks, and the earlier *major* attacks.

According to the statement of the patient, all the attacks from which he has suffered, both major and minor, with one exception, have been ushered in by visual phenomena. A bright star appears, always (the patient thinks, but with distinct uncertainty of memory) on the right side, seemingly at a distance of from six to ten feet, very brilliant, and lasting from five to fifteen minutes, after which it begins to fade out. This fading is accompanied by the appearance of vivid flashes of white light, compared in color to the incandescent electric light, zigzagging about the star, but some distance from it. As the star fades out it is replaced by a spot of darkness; during the next five to fifteen minutes this spot of blindness dilates, until at last it swallows up more or less completely the whole of the field of vision, with disappearance of the scintillations. There has not been any accurate timing of how long these phenomena last, but as far as I can make out they seem to require from twenty to forty minutes for their completion, and are followed by violent temporal headache, with great sickness of the stomach, and a feeling of faintness and general depression, all lasting from two to three hours, and then gradually disappearing. Preceding some, and perhaps all of these attacks, there is a period of some minutes of what seems to be a true mental exaltation, not an emotional exaltation simply, not a great flow of happiness or joy, but a sense of great clearness and power of thought, and an ability to apprehend, not simply to comprehend, the problems of law and of other complicated matters.

In the major attacks the symptoms that have been detailed appeared in regular sequence until they were in-

[1] A lecture delivered at the Neurological Clinic of the University Hospital.

terrupted by an unconsciousness that seems not to have been abruptly but rapidly developed. Mr. X. says that he would try to get as near home as possible before the unconscious period, which shows that there must have been a continuous warning; and he further states that he usually lay down instead of falling when he found he was being overcome. We have no description of what has happened during any period of unconsciousness from any bystander; but it is evident that at least in some of the attacks there were convulsions, as the young man awoke with a badly bitten tongue, and states that bloody foam was about his mouth.

In questioning our patient in regard to the major attacks I elicited the fact that some of them developed in the early morning out of sleep, the patient waking with a cry and lapsing into unconsciousness. This naturally led to the consideration of the possibility of his having nocturnal attacks without knowledge during the last two years. I fail entirely to get such clear proof of the existence of these as would be afforded by a bitten tongue or by urination into the bed. On the other hand, however, Mr. X. is very positive that on two occasions he has awaked in the morning feeling extremely weak and sick, without being able in any way to account for his condition, so that there are good grounds for suspecting that he has had at least two attacks at night.

If there were no history to this case save that of the recent attacks, I suppose any clinician would feel justified in stating to Mr. X. that he was suffering from so-called ophthalmic migraine, that is from migraine accompanied by visual disturbance. On the other hand, if we had only the history of the earlier attacks, the diagnosis of epilepsy would certainly be warranted. Many years ago the brilliant French clinician, Trousseau, asserted that there is a close relation between migraine and epilepsy, and when the symptoms of the two disorders are analyzed side by side certainly a curious parallelism will be seen to exist. Each is an inheritable neurosis; each is essentially a nerve-storm coming on at irregular intervals with a more or less distinct sequence of phenomena. Of these phenomena, in each there is an aura; in each a characteristic central system; in each a final peculiar stage. Then, again, this typical sequence of phenomena is in each disorder variously departed from; and there is in this very departure still a parallelism. In epilepsy the aura is, it is true, most commonly connected with common sensations, and commences in the fingers, in the stomach, in the region of the larynx, etc., as an indescribable mounting wave of feeling; whilst in migraine the aura is very frequently wanting, and when present is usually visual. Nevertheless, possibly in the majority, certainly in a large proportion, of the cases of epilepsy which I have personally seen (and they are numbered by hundreds), the aura has been absent, and every now and then the region of the special senses is invaded, and the epileptic paroxysm is ushered in by bright light or by an hallucination or a vision, such as the case reported, I think, by Dr. Weir Mitchell, in which always a little woman in a red cloak came forward and struck the patient with a hammer, when he fell unconscious; in one case attacks that I believed to be of the nature of migraine were ushered in by a violent, bad odor, showing that it was the nasal and not the visual tract which first felt the commencement of the storm.

Further, in both epilepsy and migraine the whole series of phenomena may be reduced to an aura. I have watched for years three or four cases in which a child would suddenly turn pale, cry out with pain, run to its mother, and in a moment without any loss of consciousness be itself again; the pain recurring at irregular intervals, always in the individual case maintaining the same type, always absolutely intractable to any treatment; going on year after year until there appeared among these paroxysms others plainly epileptic; and until the pain-paroxysms themselves by imperceptible degrees put on the marks of the major disorder, and the whole case ended in hopeless, unmistakable idiopathic epilepsy.

In November, 1893, I was consulted about Miss M., a native of a neighboring city. Her father had all his life suffered from sick-headaches, and she herself in early childhood occasionally had similar attacks. Some months before I saw her, though in apparently good health, she began to have nerve-storms occurring at irregular intervals without apparent cause. Some of them were evidently attacks of ophthalmic migraine; the symptoms being a sudden obscuration of sight, becoming complete in the right eye and lasting two or three minutes; followed by intense headache, gradually increasing in intensity until, after from one to seven hours of mounting agony, there came nausea, vomiting, and relief. In very many of her attacks, however, these symptoms had been absent, save only the obscuration of sight. Here, then, was a typical case of ophthalmic migraine, with the series of phenomena in many attacks reduced to the visual aura.

The matter is made more interesting by the fact that in some cases of migraine the nerve-storm spreads beyond the territory in which it is usually confined, and yet does not distinctly involve consciousness. Thus, in June, 1890, I saw a gentleman from Chicago in whom, without flashes of light or other ophthalmic phenomena, at irregular intervals, a hemiopic blindness developed so abruptly that on several occasions he had put forth his hand to seize an object, but before he reached he had lost it out of vision. This aura is commonly followed by a furious supra-orbital and temporal pain, often ending after a time in very pronounced numbness on one side of the face, including the tongue, and extending into the arm; moreover, in some of the most violent paroxysms there has been very pronounced but not a complex aphasia.

The parallelism between migraine and epilepsy is indeed so curiously complete that at first it seems difficult to escape the conviction that we have two closely related disorders to deal with. This conclusion is strengthened by the occurrence of cases like that of the man before you, in which the symptoms seem half-epileptic and half-migrainous. As showing the rarity, however, of these cases, I may say that in an experience that includes really hundreds of cases of epilepsy and very numerous cases of migraine, I have seen, beside the present case, only two in which there was any reason for suspecting the coexistence of the two disorders. In one case there were paroxysms both of migraine and of epilepsy, one form of paroxysm appearing to me to replace the other. Unfortunately I am unable to put my hand upon the notes that were taken of this case. In the second case, which was remarkable for the character of its visual

aura, it has seemed to me impossible to decide whether the delirium and the unconsciousness, neither of which I witnessed personally, should be considered epileptoid or hysteroid. The patient was a lady twenty-four years of age, with a distinct family history that whilst her mother was free from headaches her grandmother had suffered from the same sort of spells as herself. In this case the paroxysms were very violent, often commencing with a chill, but almost invariably having a visual aura that was variable in character. At times this aura took the form of true megalopsia, her hands and objects in her neighborhood growing in size, until, to use her own words, "they were terribly large," and things in the room finally becoming more than twice the natural size. In some paroxysms this megalopsia was replaced by a vision of her dead aunt or of her grandmother, dressed as for burial, floating in the air. In the most violent attacks this patient would become actively delirious, and in a number of cases this delirium had ended in unconsciousness.

A very strong reason for not believing in the identity or close relationship of migraine and epilepsy is in the apparent lack of hereditary connection between them. But are we sure this apparent lack of connection really exists? My own observation seems to show that the two disorders have no family connection, and I think this is in accord with common observation; but a very careful inquiry for migraine in the family history of a large number of epileptics would be interesting. If the record of such a research exists in literature, it has escaped my reading or my memory.

So far as the present case is concerned, what is the sum of all our ratiocinations? Should the diagnosis be migraine or should it be epilepsy? To the patient himself I would say migraine, but I would caution the family doctor and the parents of the patient that the case may be epilepsy. The attacks of loss of consciousness and the convulsions that preceded the present series of paroxysms certainly make one hesitate to believe that the man suffers only from an innocent migraine.

Even more significant than the phenomena just noted, however, are the peculiar tendency that the paroxysms once had to occur in groups and the present failure of mental power. I cannot remember ever to have seen a case of undoubted migraine in which three or four attacks would occur in twenty-four hours, to be followed by many months of freedom from pain; and although severe migraine sometimes racks the bodily health, it does not impair mentality. Further our patient not only had nocturnal attacks during the first period of his illness, but there is reason for strongly suspecting that during the last two years he has had nocturnal paroxysms that have escaped notice. I myself doubt whether hysteria or migraine or any other functional disorder simulating epilepsy ever comes on during sleep at night, though, curiously enough, in artisans and others who habitually work at night and sleep during the day, the ordinary diurnal attacks may become nocturnal. I have seen a night watchman, who suffering from a severe tertian fever contracted in the Jersey swamps, always had his febrile paroxysms at night.

Dr. F. L. Sim, a prominent physician of Memphis, Tenn., and editor of the *Memphis Medical Monthly*, died recently.

CLINICAL MEMORANDA.

MANIA AND CATARRHAL PNEUMONIA FOLLOWING LABOR.

BY M. M. FRANKLIN,
OF PHILADELPHIA;
SENIOR STUDENT IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

CLARA W., twenty-one years of age, white, a primipara, fell in labor on July 3d. Upon being called in attendance it was found by examination that the vertex was presenting, its position being left occipito-anterior. The structures of the birth-canal and the pelvic outlet were normal. Labor proceeded fairly rapidly, and terminated at 12 o'clock the same night. It was not until about the end of the second stage of labor that the patient's mental condition first attracted my attention. These manifestations consisted in incoherent statements and hallucinations, which at the time were thought to be caused by the excitement of labor, and would pass away in due season.

Upon examination of the perineum it was found to be partially lacerated; the wound, after being properly cleansed, was approximated by silk sutures, and an iodoform occlusion-pad was placed over the vulval orifice, after which the woman was given a vaginal douche of a solution of mercuric chlorid, 1:5000, twice a day until the wound healed and the stitches were removed.

Upon visiting her the following day I found her mental condition slightly improved, yet it was with the utmost difficulty that the patient was kept under control and in bed from the second day on. From the morning after labor her temperature and pulse remained practically normal, with one exception, when, on the 5th of July, the second day after labor, it rose to 100.2° F. This rise was attributed to constipation, the bowels not having been moved for two days. The woman was then given an enema, which was followed by a bowel-movement, after which the fever subsided. The fluctuations in temperature are shown in the annexed table:

Date.	Temperature.	Pulse.	General condition.
July 3, P. M.	100.4°	80	Good.
" 4, A. M.	99	74	Excellent.
" 4, P. M.	99.1	68	"
" 5, A. M.	98.4	78	"
" 5, P. M.	100.2	78	Fair.
" 6, A. M.	98.4	80	Excellent.
" 6, P. M.	98.3	84	"

On the afternoon of the 11th of July, eight days after labor, the temperature suddenly rose to 103.3°; the pulse was 100 per minute, and there were increased nervous disturbance and severe headache. The bowels, having been neglected for twenty-four hours, were then opened,

and a powder of potassium bromid and caffein citrate administered. Iced cloths were applied to the head. A sample of urine was procured at this visit and carefully examined, both chemically and microscopically, but was found to be normal.

The next visit was made early the following morning; the temperature was found to be 104.4° and the pulse 156 per minute. The general condition was alarming, and a consultant was called in, who, after a thorough examination of the pelvis and chest, thought it best to curet and douche the uterus to make certain as to septic infection, and this was done with entirely negative results.

After the operation was concluded the patient was put in an ice-pack to reduce the hyperpyrexia, and was also given $\frac{1}{10}$ grain of the mild chlorid of mercury every thirty minutes until the bowels were freely moved. Her general condition being very poor and the heart's action weak, she was ordered strychnin sulphate, grain $\frac{1}{60}$, and a half ounce of brandy in milk every two hours. At the evening visit her fever was still increasing, the temperature in the axilla reaching 105° and the pulse 158 per minute.

Finding that her general condition was growing steadily worse, it was decided to call in a second consultant, who, after repeated examinations of the chest and pelvic cavity, concluded the case to be one of septicemia, although no local evidence upon which to base the diagnosis could be found.

The physical signs of disease of the lungs were absent, and kidney-disease was also excluded. No evidence of disease existed in the pelvis, and by a process of exclusion the diagnosis of septicemia was tentatively made, not because there was evidence of sepis, but because of the absence of signs of other disease, and from the fact that sepsis has been known to occur when it has been carefully guarded against.

The patient was placed at once upon tincture of ferric chlorid, quinin, and the infusion of digitalis; also ice-packs to reduce the fever were ordered. On seeing her late that evening her condition was the same as in the afternoon.

The following morning she was found to be moribund, her fever still increasing, the axillary temperature reading 108.1°. The pulse could not be counted. Her condition that afternoon remained practically the same as in the morning. The ice-packs and treatment were vigorously kept up, but without avail; her fever continued to rise, and finally reached 109.2° in the axilla a few hours previous to death, which occurred July 14th at 2 P.M.

The autopsy showed a normal abdominal cavity, the peritoneum not injected, and no signs of inflammation were present. The appendix was free, the mesenteric glands were not enlarged and the intestines were normal. The uterine appendages were free and normal; the uterus was slightly larger than it should be twelve days after delivery. Upon opening the uterus there was no odor and no evidence of suppuration, the appearances being entirely normal. The spleen was slightly larger than usual; the liver was normal, likewise the kidneys, the capsule stripping off easily. The heart was rather larger than normal, flabby, and the right ventricle seemed dilated. The valves were normal, with the exception of a slight calcareous deposit on one leaflet of the mitral valve. There was a diminution in the amount of the pericardial fluid, but the pericardium was normal. There were a few adhesions at the apex of the right lung posteriorly, and slight crepitation throughout. On section the lower lobe was congested, and there were some small areas of consolidation. The left lung was adherent throughout, the entire parietal pleura stripping off, leaving a raw, rough, red appearance; there was some slight crepitation throughout, which was more marked at the apex. The lower lobe had a more solid, firmer feeling. On section there was some edema, with small areas of consolidation distributed throughout the entire lung, but more marked at the lower portion. These areas appeared reddish-brown, and the section presented a peculiar mottled appearance. The pathologic diagnosis was catarrhal pneumonia, which was confirmed by microscopic examination.

AN ABSCESS OF THE BRAIN CAUSED BY A NAIL IN THE HEAD.

BY J. W. FELTY, M.D.,
OF ABILENE, KANSAS.

DURING the latter part of September, 1893, a call was left for me to see Mrs. R., fifty-six years old, living in our city. My brother answered the call and reported a case of apoplexy. Upon inquiry he learned that Mrs. R. (who lived with her son-in-law) had been unusually despondent for a week or more, and had been "in a rage" for some days, refusing food and drink. The necessity for these preliminary remarks will become apparent. There was in her case a history of insanity for five or six years, and the woman had been unusually eccentric and queer all through life. The family had noticed nothing very unusual about her demeanor of late except her despondency, and paid little attention to her actions. They heard her walk about in her room during the night, and as usual, on the following morning she was called for breakfast. She would not respond, calling instead for one of her grandchildren to come and see her foot and leg jerk. When asked by her daughter to move the leg, she did so, but with the greatest difficulty, and in a few days was entirely unable to move it. When asked how and when this happened, she appeared to know nothing about it.

When visited she complained of no pain at any point, but said "my legs feel funny," and a choreic, spastic or convulsive movement of the lower extremity was observed. On the following day similar symptoms affecting the whole left side and upper extremity could be discerned. She was seen from day to day for six weeks, but treatment with ergot, iodids, and later with electricity, was of no avail. I should add here that her temperature was a degree or a degree-and-a-half above normal, her pulse 90. Her speech was hesitating, but correct; her eyes somewhat blurred, and her general mental condition more or less sluggish. By the end of the tenth day she had lost control of her left lower extremity, side, and upper extremity, with paralysis of sensation as well as of motion, and she grew rapidly worse. By the end of the second week her temperature became subnormal, her pulse remaining normal. The case was regarded as a hopeless one. About six weeks after my brother first saw her the family reported that she was having quite a rest-

less spell, and also that she had a very hard scab on the top of her head, which was discharging pus and causing some pain.

It was at this time that I made my first visit. The woman had complete paralysis of motion and sensation of the left side and the upper and lower extremities. She was averse to interference of any kind. She was suspicious that something was wrong when so many doctors were needed. Upon examining the ulcerated surface on her head I found what I first thought was a large-headed carpet-tack. The ulceration at this point did not exceed a half-inch in diameter. I removed from this spot a nail one-and-a-half inches long, which had been driven down on a level with the scalp, at a point one-half inch back of the coronal suture over the longitudinal sinus. Up to this time we could elicit no history of injury, no evidence of violence, no signs of blood. The woman was walking about in her room six weeks before, but she undoubtedly had the nail in her head six weeks after she became paralyzed. The question naturally arose, "Was it possible for her to drive the nail where I found it, and how was it done?"

Upon calling her to task about her actions, I asked her how this nail got into her head. She denied all knowledge of it, and claimed to know nothing about it, or of any injury she had sustained. I reported the facts in the case to her daughter, for I suspected that the woman had herself driven the nail in her head, and asked the daughter to get a confession from her mother if possible.

The following day the woman confessed to having placed the nail there herself, the motive given being that Satan must have been with her when she did so. I could not establish accurately how it was done, but surmised that she placed the point of the nail on her head and then forced her head against the solid headboard.

From the history of wounds generally, the nature of this particular one, and the appearance of the nail, I believed, after a careful study of the case with my brother, that we had a case of fracture of the internal table of the skull, and primarily a depression; the nail being septic, a secondary abscess resulted. How the nail could be driven down through the skull over the median line, corresponding to the longitudinal sinus, and not pass through it, seemed strange, but such was certainly the case.

We had first a septic wound; second, in all probability, a depressed fracture; third, paralysis indirectly due to the nail. Our line of duty was very apparent, and we told the family what should be done, and they readily consented.

Believing that the nail passed through the longitudinal sinus, the skull was trephined one-half an inch to the right of the median line, thus giving an opportunity to ascertain the nature of the fracture and the injury. The nail had not penetrated the sinus, and it made an opening almost as smooth and clean-cut as if made with an auger or gimlet. My second trephine-opening was then made through the course of the nail. After removing the trephine-discs, I opened the abscess with a grooved director and forceps, and removed about two ounces of pus. I made a free incision through the abscess-sinus and washed out the cavity with warm boric-acid solution. In exploring the abscess my grooved director was passed to a depth of three or three-and-a-half inches without the least resistance, the abscess apparently communicating with the right ventricle of the brain. A rubber drainage-tube was left in the abscess-cavity, and the wound closed. On the following day the temperature rose to 100.5° and the pulse to 100, but at no time was there an appreciable change in the paralyzed muscles. The woman remained conscious until the fifth day after the operation, when she became semi-conscious, and died on the seventh day after the operation.

The autopsy revealed the fact that the abcess had communicated with the right ventricle of the brain, which was found filled with pus and cerebral fluid. The brain-substance surrounding the abcess and the walls of the ventricle were highly congested.

Two interesting questions arose in my mind in connection with this case: First, where would the point of a six-penny wire nail be found in the brain under the conditions described? Second, was there any hemorrhage at all, or were the convulsive movements due to the inflammation around the nail from septic infection? It will be noticed that paralysis did not take place at once, as in case of hemorrhage, but five or six days afterward.

DIARRHEA FROM POTASSIUM IODID.

By DOUGLASS W. MONTGOMERY, M.D.,
Professor of Diseases of the Skin, Medical Department of the University of California; Consulting Physician for Diseases of the Skin and for Pathology, German Hospital.

If a drug is given in order to compass some distinct purpose, and succeeds, we call its action a direct effect, and retire, like King Malcolm, in measureless content, as nothing is quite so satisfactory as the successful administration of a remedy. But, if, in addition to or instead of the action desired, some unexpected or disagreeable result follows, we are correspondingly chagrined, and we call this an oblique action of the drug. When potassium iodid is prescribed it is not intended as a purgative; nevertheless, in rare instances, it causes, as an oblique action, a severe diarrhea.

An accountant, aged twenty-five, came to me March 6, 1892. He had been exposed to venereal infection five months previously, and shortly afterward had noticed a stickiness of the meatus and an indolent swelling in the right groin, which did not break down. He had also remarked some pain and induration along the urethra, near the meatus. When he first came to me the right lip of the meatus was slightly enlarged and bluish in color. There were a roseola on the trunk, especially on the abdomen, without subjective symptoms; patchy thinning of the hair of the head and a papular rash on the scalp. He had also enlargement of the posterior cervical glands, and of those in the right groin, but no enlargement of the epitrochlear lymphatic glands. There was one flat condyloma on the left natis, and two smaller ones on the right. He suffered from habitual, though slight constipation, which was easily corrected by eating brown bread and molasses for breakfast. He afterward had a papular rash on the head of the penis, and from time to time suffered from mucous patches in the mouth.

Toward the end of August, 1892, that is, about six months after first coming to me, and in the eleventh month of his disease, his hair began to fall out again,

and a red, ill-circumscribed, slightly raised roseola appeared, principally on the back and belly, and distinguishable from urticaria by the absence of itching. This was an instance of the rarely observed late roseola of syphilis, which often assumes the form of rings over the trunk and limbs, and is likely to be mistaken for erythema multiforme.

The man afterward suffered from an excoriation or ulcer on the outer wall of the right nostril, which healed in a reasonable time under black wash locally and mercuric iodid internally.

On May 15, 1893, in the twentieth month of his disease, potassium iodid was prescribed for the first time, and in moderate doses—sixteen grains a day for sixteen days. As soon as he commenced taking the drug, copious watery diarrhea set in, and persisted during the whole time of its administration. The patient, thinking the diarrhea part of the effect desired, continued the remedy until the bottle was finished, without returning to consult me. When I saw him shortly afterward he was reduced from a robust, fine-looking fellow to a pale, wan shadow, with the appearance of being in the last stages of pulmonary tuberculosis. He quickly regained his lost flesh and ordinary health.

There can hardly be any doubt that the diarrhea was caused by the iodid, as it commenced on taking the drug, continued during its administration, and ceased when the medicine was discontinued. Moreover, the man remembered having had a similar diarrhea on taking a "blood-purifier," and patent medicines of this class almost always contain potassium iodid.[1]

This man was getting one of the best brands of the drug, so it is not likely that the diarrhea was caused by the presence of free iodin or iodates, frequent impurities in the cheaper grades. It seems to be very difficult for manufacturers to make pure potassium iodid, and for this reason the good brands are dear, but in no case does their price preclude their being dispensed at the usual rates, leaving a fair margin of profit.[2]

Both Fournier[3] and L. Lewin say that although sometimes the inconveniences complained of in taking potassium iodid may be due to impurities in the drug, yet such impurities are not always the cause of the accidents, as they may happen in the course of the use of an absolutely faultless salt.

An Early Sign of Pericarditis.—At a recent meeting of the Société de Biologie JOSSERAND (*La Médecine Moderne*, 1894, No. 89, p. 1386) called attention to a clanging murmur heard in the pulmonary area more distinctly than to the right of the sternum at an early stage in a case of pericarditis, and which he considered of diagnostic value.

[1] Diarrhea, either with or without vomiting, has been observed even after small doses of potassium iodid. Sometimes the dejections contain blood. (Nebenwirkungen der Arzneimittel. L. Lewin. Zweite Auflage, S. 407.)

[2] In Henry Koplik's case of iodism in a nursing infant (The Medical Record, September 24, 1887), the drug seems to have given rise to irritation all along the alimentary canal, for there were dyspeptic symptoms, some looseness of the bowels, and a little increased secretion in the nose, in addition to the skin-eruption.

[3] Fournier (Traitement de la Syphilis, p. 418) tells of an eminent chemist who himself used to purify the potassium iodid prescribed for him.

MENINGITIS COMPLICATING INFLUENZA; AUTOPSY.

BY HERMAN B. ALLYN, M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN PHYSICAL DIAGNOSIS, UNIVERSITY OF PENNSYLVANIA.

THE patient was a man eighty-two years old, a widower, temperate, and of excellent habits. He had enjoyed good health until the past five years, in which time he is said to have had one or two illnesses in which he became violently delirious. He has for several years suffered with vertigo, dyspepsia, lumbago, and constipation, largely the result of a general arterio-sclerosis. He presented mitral and aortic systolic murmurs not associated with any edema. On March 9, 1894, I found him suffering with influenza, brought to him, no doubt, by another member of the family, who, suffering with the disease, had returned a few days before from a distant city. The patient complained of headache, sore-throat, and cough, but especially of the cough, and of severe pain on the right side, anteriorly at about the seventh rib. This spot was extremely tender as well as painful. There was pain also in the back and in the left side of the abdomen. There was general bronchitis. On account of the fever and severe pain in the right side it was feared that a pleurisy or pleuro-pneumonia might develop, but no dulness or friction-sounds appeared. Gradually the patient became more and more delirious at night. The delirium would begin in the afternoon and last until morning, when he would become rational, but not uninterruptedly. He seemed to feel worse when he was lying down, and it was with great difficulty that he was kept in bed. Sleep was in short snatches, and was very uneasy. At times he was violent, and once he tried to jump out of the window. His most constant delusions were that he was away from home and that he was compelled to work at night in a mill, although, as he would explain to me pitifully, "I am no longer strong enough for such hard work!" Bromids, chloral, morphin, sulphonal, and trional were successively tried in an effort to overcome persistent insomnia and to lessen delirium; each drug failed in turn, and was discontinued. Finally, hyoscin hydrobromate, in doses of gr. $\frac{1}{96}$, repeated once when necessary, proved comparatively satisfactory. It was given in the latter part of the afternoon and at night.

At first the man took sufficient nourishment, but in the last two weeks of his life it was difficult to get him to take anything. During most of his time, especially during the last week, his arms and legs would twitch, and they were kept pretty constantly in motion. His urine contained only a small amount of albumin. Through some oversight it does not seem to have been examined for casts, or the record has not been preserved. Previous to the last illness the urine contained neither albumin nor casts. During the last week of his life his urine was passed involuntarily in bed, and his bowels were not moved. During this time coma succeeded gradually upon delirium, and the patient remained in bed. He seemed to have pain when moved, and to be disagreeably conscious of touch when no longer able to see or hear. He died in coma, April 7, about one month, therefore, from the beginning of his influenza.

The autopsy was performed thirty-six hours after

death by Dr. W. S. Carter and myself. The lungs were found normal. The heart-muscle was soft and friable; the mitral orifice was dilated, while the aortic cusps had on them a few atheromatous nodules. The left ventricle was somewhat dilated and hypertrophied. The liver was fatty and cirrhotic. The kidneys were contracted; they contained a few old infarcts and one recent infarct and a few minute cysts. The cortex was much shrunken, especially in the left kidney. The right suprarenal body was replaced by an old cyst enclosing rough, brownish material. The colon contained a number of scybalous masses. There was no peritonitis. The stomach was not examined. The spleen was not enlarged. The cortex of the brain showed much injection of the vessels and opacity of the pia and arachnoid, which were somewhat adherent to the brain-substance. The lymph-spaces were dilated and prominent. A gelatinous substance was seen over the cortex. There was no pus. At the base of the brain the changes were the same, but without the gelatinous substance. The arteries of the circle of Willis were atheromatous, and a few minute aneurisms were visible. The lateral ventricle was dilated. The cortical brain-substance was of deeper color than normal.

In THE MEDICAL NEWS, May 14, 1892, I reported three fatal cases of cerebro-spinal meningitis, with autopsies. In these cases the clinical history was very different from that of influenza. In the case just reported the ordinary symptoms of influenza were well marked, and other members of the family suffered with it in its ordinary catarrhal form.

NEW DEVICE.

A FACE-GUARD FOR EXAMINING INFECTIOUS THROATS.[1]

BY J. MADISON TAYLOR, M.D.,
PROFESSOR OF DISEASES OF CHILDREN, PHILADELPHIA POLYCLINIC, ETC.

THIS simple device for protecting the operator's face while examining the throats of those who are suspected of diphtheria or other contagious disorders serves a good

end very practically. There is constant need in dispensary-work among children to deliberately and fully explore the throat, and during this process much spluttering of mucus and saliva occurs, which flies in the direction of the physician or nurse, and might well be spared them. In making the needful applications to diseased parts, too, this can be done more quietly and thoroughly if one's face be protected. The chief value of the guard I find in enabling me to secure material for bacteriologic research, which often requires some judgment in selecting the precise area from which to take it. An assistant can best hold the guard, made of plain glass in a thin metallic frame, or the mother can do so. The size is small, 5 x 8 inches, just enough to cover the face, and not too large to carry in the ordinary small instrument-satchel used by physicians. The glass slides out of the frame readily for thorough cleansing, or the whole can be laid in a sterilizing tray. This is found more useful than anything attached to the head, more likely to be promptly used, and its convenient size enables it to be carried about.

[1] Exhibited before the Philadelphia County Medical Society, December 12, 1894.

MEDICAL PROGRESS.

The Toxins and Antitoxins of Typhoid Fever.—As the result of experimental observation, PFEIFFER (*Deutsche medicin. Wochenschrift*, 1894, No. 48, p. 898) has found that the poison of typhoid-bacilli is contained principally in the bodies of the bacilli, and that by treatment of cultures with chloroform-vapor or by heating at a temperature of 129.2° F. for an hour the bacilli may be destroyed, without injury to their contained toxins. In the blood-serum of animals rendered immune by means of the typhotoxin antitoxins appear capable of exerting a specific bacteriologic influence upon typhoid-bacilli, but without greater effect upon colon-bacilli and other microörganisms resembling typhoid-bacilli than is produced by normal serum. Similar antitoxic substances are demonstrable in the blood of convalescents from typhoid fever.

Pre-tuberculous Albuminuria.—At the recent French Congress of Internal Medicine, TEISSIER (*Le Mercredi Médical*, 1894, No. 46, p. 559) cited a number of cases that led him to believe that some cases of tuberculosis were preceded by the development of albuminuria. The most striking features of this condition observed were its intermittence, with irregularity of recurrence, its occurring most commonly in the morning, and its association with phosphaturia. It alternated with attacks of catarrhal bronchitis or congestive phenomena of varied kind, disappearing with the development of the pulmonary disease. The condition is attributed to renal congestion of toxic origin from the action of the products of the tubercle-bacillus.

Orchitis due to Effort.—D'HAENENS (*La Policlinique*, November 1, 1894, p. 352) has reported the case of a man, forty-nine years old, who, following a violent effort, was seized with extreme pain followed by swelling of the left testicle. The epididymis also became enlarged to thrice its normal volume. The patient denied venereal infection, and examination failed to disclose a lesion of the genito-urinary tract. The pain was intense, and symptoms of local peritonitis appeared. The explanation of the occurrence is that the testicle was injured by

contractions of the cremaster muscle in great physical effort. The indications in treatment include rest, together with the application of moist warm dressings and compression.

Hodgkin's Disease in Children.—KISSEL (*Wratsch*, Nos. 23 and 24; *St. Petersburger medicinische Wochenschrift*, 1894, No. 42, Suppl. No. 9, p. 49) has reported the case of a boy, eleven years old, who presented submental glands as large as a goose-egg, with enlargement of the remaining glands. The spleen extended four fingers' breadth below the costal margin. The number of white blood-corpuscles was not increased, that of the red was diminished, and there were numerous poikilocytes. Periodically the temperature would rise as high as 105.4°, with increased size of spleen and lymphatic glands, followed by reduction in size. Two other cases of similar kind were observed in children aged four and four-and-a-half years respectively.

Ablation of the Supra-renal Capsules in Dogs.—As the result of an experimental investigation, PAL (*Wiener klinische Wochenschrift*, 1894, No. 48, p. 898) concludes that in dogs the supra-renal capsules are not essential to life, and that their extirpation is not attended with symptoms that could be ascribed to the removal of the influence of an inhibitory center governing the bowel. On the other hand, there results profound derangement of the nutrition, which the animal may overcome. The relation between the operation and this alteration in nutrition requires explanation.

Scarlatina and Measles in the Same Person.—FERGUSON (*British Medical Journal*, No. 1764, p. 868) has reported the case of a boy of nine years in which, during the progress of an attack of scarlatina, severe coryza and a constant irritating cough developed, shortly followed by a most intense eruption of measles. Desquamation, which had begun at the onset of the complicating condition, seemed to be accelerated. The child made an excellent recovery. It was not possible to trace the source of infection.

THERAPEUTIC NOTES.

Treatment of Diphtheria with the Antitoxin.—HAGER (*Centralblatt für innere Medicin*, 1894, No 48, p. 1121) reports the results obtained from the employment of the antitoxin in the treatment of 25 cases of diphtheria between August 20th and November 1st, 1894, and in the prophylaxis of 35 children in the infected families. The children attacked were between eight months and sixteen years of age. Recovery took place in all but one. This occurred in an infant, eight months old, that was almost moribund when the treatment was undertaken. Of the 25 cases 8 were mild, 6 of moderate severity, and 10 severe and grave. In some cases an urticaria-like erythema appeared at the site of injection, but other complications were not noted. Of the 35 cases treated prophylactically one was subsequently attacked, but reacted favorably to 500 antitoxin-units and recovered. Two other children had light attacks, but recovered without treatment. In the majority of cases the diagnosis was established by bacteriologic examination.

MOELLER (*Centralblatt für innere Medicin*, 1894, No. 48, p. 1130) reports the results obtained from the employment of the antitoxin in the treatment of diphtheria at the Magdeburg-Alstadt Hospital between August and November, 1894. Mild and moribund cases were excluded from this mode of treatment. From April 1st until November 8th there came under observation 388 cases, of which 162 required tracheotomy. Of the whole number 76 were treated with the antitoxin; 48 of these required tracheotomy, with 19 deaths and 22 recoveries, while 7 were yet under observation. Of the 28 not requiring tracheotomy 8 died, 15 recovered, and 5 were yet under observation. Of the 312 cases not treated with the antitoxin, 114 required tracheotomy; of these 57 died, 45 recovered, while 12 were yet under observation. Of those not requiring tracheotomy, 34 died, 136 recovered, and 28 were yet under observation. From April 1st, 1888, to March 31, 1889, the mortality of cases in which tracheotomy was required was 59 per cent.; from 1889 to 1890, 57 per cent.; from 1890 to 1891, 51.43 per cent.; from 1891 to 1892, 48.6 per cent.; from 1892 to 1893, 63.4 per cent.; from 1893 to 1894, 64.2 per cent.; from April 1st to November 8th, 1894, 55.6 per cent. among cases not treated with the antitoxin and 39.6 per cent. among cases treated with the antitoxin.

Picrotoxin, in doses of gr. $\frac{1}{60}$, three times a day, is recommended by TALLEY (*Philadelphia Polyclinic*, vol. iii, No. 49, p. 482) for the relief of the severe nervous symptoms often coexisting with uterine and ovarian diseases. The symptoms usually complained of are flashes of heat, cold creeping sweats, cold hands and feet, flatulence, constipation, palpitation of the heart, and melancholia. The patients are easily confused; are suspicious and brooding; flush when addressed; have a sensation of impending calamity; and are generally wretched; memory is impaired; there occur spells of crying; crowds and public places are avoided. Constipation when present should be relieved.

The External Application of Guaiacol.—BRILL (*Centralblatt für innere Medicin*, 1894, No. 47, p. 1097) has employed guaiacol by external application in four cases of pneumonia, five of typhoid fever, four of pulmonary tuberculosis, one of bronchitis, and two of articular rheumatism, and found that the remedy in doses of from 23 to 45 minims could be relied upon to energetically reduce the temperature, although it also caused extremely unpleasant secondary manifestations. In eighteen other cases, principally of rheumatic character, the agent in doses of from 12 to 24 minims exercised an analgesic influence without unpleasant complications.

The Therapeutic Use of Extract of Bone-marrow.—BILLINGS (*Bulletin of the Johns Hopkins Hospital*, vol. v, No. 43, p. 115) has reported a case of chlorosis, one of chloro-anemia and two of pernicious anemia, treated with a glycerin extract of bone-marrow. The two cases of chlorosis were benefited, while the two cases of pernicious anemia remained unimproved.

SATURDAY, DECEMBER 29, 1894.

A COLONY FOR EPILEPTICS.

No more deserving scheme appeals, or ever has appealed, to the people of Philadelphia, and, in fact, of the State of Pennsylvania, than that which has for its object the establishment of a farm, or colony, for epileptics. It is a marvel, indeed, that such a scheme was not suggested long ago, and that among the innumerable charities of this great city and commonwealth this plan for the comfort and welfare of epileptics has been neglected until this late date.

The epileptic is, or ought to be, in a peculiar sense, the ward of the State. His disease exposes him to the curiosity of the vulgar and to the aversion of the ignorant, but it ought rather to win for him the protection and encouragement of the public. Since the evil days when he was regarded as specially afflicted by Providence, and possessed of a sacred malady, until the present era, when he is confined in almshouses or made to associate with lunatics, he has apparently been avoided by humanitarians as a strange and bad case. It is too true that a certain proportion of epileptics are mentally impaired, and that this class may continue to require restraint; but it is also true that a large number of them are, for all practical purposes, of sound mind for the vastly greater part of their time. The lot of one of these unfortunates is a particularly hard one. He lives constantly under the terrifying shadow of an impending calamity. The blow, which may fall but seldom, and the effects of which may endure for but a few hours, does more injury to his fortune and career as a citizen of the State than would many of the worst deformities or the most disabling accidents. His is a disease that respects neither time nor place, and in its mere potentiality for evil is worse than an actual disaster. Its mysterious character, which so struck the ancients, is one of its most dreadful features. Its victim is never exempt from the suspicion of impending doom. He can neither thwart nor provide against the inevitable but invisible foe, and the fact of his uncertain tenure of his own free-will and consciousness is the cause at once of his shunning and being shunned. He may be actually impaired for but a few hours in every month, but those few hours dominate and give character to his whole life.

For a person so grievously and yet, in some cases, so slightly afflicted the urgent need is for an environment amid which the evil effects of the malady can be discounted, and even to some extent eliminated. This can be accomplished only in a special settlement. The average epileptic cannot succeed in business, nor in even the most humble service. The story of his career in ordinary social and industrial life is a sad one. According to the report of the National Hospital for the Paralyzed and Epileptic, of London, "out of seventy epileptic patients, thirty-eight had lost situations owing to fits, and could get no one to employ them; twenty-seven could get no work, as they required too much supervision; two worked at their own homes; two got work occasionally, but nothing permanently—always discharged on account of fits; one had to leave a well-paid place on the railway, and become a road-sweeper."

The necessity for proper provision for epileptics may be appreciated when it is stated that in the United States there are probably 120,000 of these unfortunates; in Pennsylvania, between 5000 and 10,000; and in Philadelphia at least 2000. What other class, so numerous and so afflicted, has been so ignored in our midst? With the exception of one ward in the Philadelphia Hospital, there is no special public provision for these patients in this

city; but the scheme at Blockley does not, and, of necessity, cannot, provide them with occupation and diversion.

The one institution in this city and State which has shown an intelligent appreciation of the claims and wants of the epileptic is the St. Clement's Hospital. Originally established by a church as a general hospital, its design was changed, and it has been devoted exclusively to epileptics now for two years. It was thus the first institution in this country devoted to the care of epileptics, but it has since been outstripped by similar institutions in two other States. In its annual report, just issued, a statement is made of the design of the managers to establish a colony-farm. Such farms have been established in Germany, Holland, Switzerland, France, and England; and in several States of the Union movements toward the establishment of similar colonies have been started. A strong appeal, signed by the medical staff, accompanies the report of St. Clement's. In this it is stated that the main object is the establishment of a colony-farm where all of the patients could have employment of some kind, which would not only aid in their support, but would make them happier and better, and—it might be added—healthier and more exempt from their fits.

We are gratified to see that this subject of the proper care of epileptics receives special notice in the Eleventh Annual Report of the Committee on Lunacy for Pennsylvania. The report includes a letter from DR. HACK TUKE, referring to the colony for 800 epileptics which it has been decided to found near London. It also gives a brief account of the admirably-planned institution near Gallipolis, Ohio, which has been established by a liberal grant from the Legislature of that State.

It thus seems that the subject of a colony-farm for epileptics is well under consideration in this State. With the recommendation of the Lunacy Committee, with an aroused public and professional interest, and with a small, well-equipped special hospital already existing as an example, it is more than probable that both public and private funds may be called upon confidently for help.

In this connection we may suggest that State charity should be relied upon to support especially the more chronic and insane cases; while the efforts of St. Clement's Hospital might be directed to ameliorating the condition of the milder cases and of those who are capable of profitable toil and even of intellectual pursuits.

THE MILK-QUESTION.

FARMERS naturally resent the recent rules of the Board of Health, but it would be well for them to remember that the board is rather behind than ahead of educated public sentiment. The first rule was an order for inspectors' certificates to be signed by a local reputable veterinarian, and no demand was made for the tuberculin-test. This position was found to be untenable, and reluctantly the tuberculin-test applied by an expert was required, as inspection even by the best-educated eyes notably failed to detect tuberculosis in diseased cattle.

It is quite safe to say that the present movement has "come to stay." For years we have been improving or trying to improve our surroundings, sewering, trapping, and ventilating traps, putting all our ingenuity at work to remove the known sources of disease, while all the time the advanced science of the day knew that we were throwing wide our doors and inviting the most deadly contagion into our houses, and offering it to our friends and children in our milk-supply. This knowledge, once the possession of the few, is now rapidly becoming the possession of the many, and either milk must go or it must come to us in unquestionable shape.

It is no longer its integrity, the amount of cream that rises, the amount of suspected diluents in it, or even the artificial aid of color, thickening or preservative. It is simply the question of germs, and already the use of milk is lessening. Thousands of families boil it. Thousands avoid it when possible, and with good reason, for milk has been proved to have conveyed to the human race:

Tuberculosis, typhoid fever, scarlet fever, diphtheria, dysentery (amebic), cholera infantum, cholera, and ulcerative stomatitis.

It also labors under far more than a suspicion of having extensively carried influenza, especially in its gastric and enteric forms. It would not be impossible, under a universal public disgust, for the whole business to be ruined. The conservatism of the kitchen still holds on to it in cooking; but it seems probable that very soon we shall have recipes for all necessary dishes without it. Science can do that much if called upon.

Cream, so difficult to sterilize, will find less and less use. The farmer will not need to rob the few quarts he handles; and butter—well, the Eastern nations clarify it by heat into a sort of oil, which they admire, and which the biologist will probably

consider safe; but lands flowing with milk and honey will no longer excite longing anticipations or cause wars for the acquisition of such enticing territory, for the honey of to-day, if we believe the food-pessimist, is but a flavored glucose in artificial combs, and the milk that should normally flow beside it may well, in the coming days, be also a chemic product. So it seems possible that the only thing that can arrest the rapid descent of the cow and her products is this very inspection—an inspection so thorough as to command—that hardest of all things to command—perfect confidence.

EDITORIAL COMMENTS.

The Combination of "Piety," "Journalism," and Quackery. for exploitation of the bamboozled public continues, but there are evidences of some differences of opinion among the partners in the unholy business. That sturdy exposer of electric humbugs, *Electricity*, is giving out some studies that add greatly to "the mirth of nations." The agents and proprietors of a widely-advertised bit of trumpery have met some editors and publishers of religious journals who refused their proffered advertisements. Prominent among these we are pleased to honor by mention MR. TRUMBULL, editor of the *Sunday-School Times*, who justly takes pride in the fact that his journal rejected an advertisement "before the members of the electrical profession seemed to be aware of its unsavory character," and DR. BUCKLEY, of the *Christian Advocate*. But Dr. BUCKLEY'S letter containing his indignant assertion that the advertisement was "rejected on the ground that it was a transparent humbug" was written on official paper containing the name as assistant editor of one W. H. DE PUY, A.M., D.D., LL.D., who persists in public and unqualified praise of the "transparent humbug," and of those controlling it as "persons of conscience and incapable of practising fraud upon the public;" and MR. DE PUY'S eulogy is signed from "the *Christian Advocate* office."

But the *Christian Nation*, editorially and in its advertising columns, cracks the nostrum up heaven-high as, *e. g.*, curing "disappointed invalids who have suffered many things of many physicans, spent their means, and are no better, but rather worse," etc. In this charming company of the ethical and the pious is to be classed the *New York Observer*. We would also point our praiseworthy contemporary to the proprietors and publishers of the *Literary Digest*, to whom we sent a letter of protest and received in reply a most discreet silence. For the benefit of these delightful humorists the editor of *Electricity* indites the following lesson in jingle, which these gentlemen should "paste in their hats" right over the phrenologic bump of veneration:

"INCONSISTENCY.

"Some moral teachers of the press
Seem much averse to others' teaching,
And writhe in evident distress
When one condemns their mode of preaching.
These now with monumental gall,
The right to criticise deny us,
Yet, spurning proof of fraud, they call
Electropoise electro-pious."

The Encouragement of Suicide by Insurance-Companies.—Among the agencies of civilization there are few that are more certainly beneficial than properly-conducted life-insurance. But it may not be doubted that the companies need public and scrutinizing oversight by the government to avoid the great evils that so easily slip in with the good. The imperfection of control, nay, the absolute non-control by the members leads almost inevitably to abuse of power, waste of the common capital, and the capital-engorged plethora of huge companies, whose corporate interests threaten the stability and purity of legislation and social life. Among the evils may be reckoned some aspects of the commercialization of risks. Men get insured as a business matter, "for the benefit of their creditors," etc. From family reasons or by the agents of the companies they are teased and tormented into taking a larger insurance than their income justifies, and rather than keep up the struggle, they "die to win." They also, it seems, insure with a possible view of committing suicide, especially if business is poor, or other misfortune should happen. A medical director of a large company writes: "Most of our suicides were heavily embarrassed financially, and in several instances there seemed to be a well-laid plan to secure all the insurance possible." Another says: "An insured person has the thought when financial trouble and despondency overtake him, especially if he finds it hard to continue his assessments, that suicide will end his earthly troubles and possibly benefit his family more than he might be able to do by continuing the struggle against his environments."

Emmenagogue-Dealers, Literature, and Druggists.—The following letter lies before us:

NEW YORK, November 2, 1894.

BROTHER DRUGGIST: Knowing as we do by our own experience that you have constant inquiries almost daily for a reliable emmenagogue, we beg to inform you we have just placed upon the market such an article under the name of ———, which we offer as an article you can recommend to your customers as such, also a perfect cure for all diseases peculiar to women.

The article is in liquid form, beautifully put up in pint bottles enclosed in cartoons, and sold as a dollar preparation, and should not be sold for less, as we confine our business to the drug trade exclusively. You can get it from your jobber at $8.00 per dozen or from us direct.

We will send our interesting reading matter on the subject direct to your female customers with or without your name printed on if you give us the names.

By giving this matter your attention it will no doubt prove to our mutual advantage.

Yours very truly,
———MEDICINE CO.,
Druggists & Chemists.

The physician who sends us this nasty bit of literature says that "half the *brother-druggists* in this country do it." In the circular accompanying this letter the advantage of this "Vegetable Female Regulator" is especially doubly emphasized "in irregular and obstructed menstruation which will surely be cured." We think the

U. S. Post-office authorities should get on the track of this enterprising firm.

"*Maternity Retreats*," so called, seem to be multiplying in a rather suspicious way and to be sheltering themselves under the protection of medicine or pseudo-medicine. We are not able to say in special cases whether the medical ethics and science are true or false, but the appearances are often much against them as being of the highest order. A circular before us suspiciously emphasizes the "absolute privacy" part a good deal, and offers the physician sending patients, ten per cent. of the fees paid. Upon consulting the scale of prices we find that the entrance fees are from $75.00 to $100.00, and if the infant is surrendered (which can be done "if so desired") the minimum terms are $100. "Homeopathic" and "regular" are both encouraged to come, and physicians of either category are supplied on demand.

REVIEWS.

HUMAN PHYSIOLOGY. By JOHN THORNTON, M.A., author of Elementary Physiography, Advanced Physiography, etc., with 268 illustrations, some colored. New York: Longmans, Green & Co., 1894.

THE demand for small-sized, compact text-books adapted to the use of medical students during college-life grows with the advance of medical education, and the near future will probably see the voluminous systems and manuals relegated to post-graduate work and reference-libraries. Dr. Thornton's handy little volume contains everything that a medical student can hope to learn before graduation; it is clearly written, fully up to date, and in addition to this it is cheap, a point which usually tells with students of medicine.

We are pleased to note that the author follows the lead of Prof. Foster and discards the *mechanical* theory of filtration and osmosis when speaking of absorption and assimilation, and makes the living cell something more than a mere combination of matter and force.

MEDICAL AND SURGICAL REPORTS OF THE BOSTON CITY HOSPITAL. Fifth series. Edited by DAVID W. CHEEVER, M.D., GEORGE B. SHATTUCK, M.D., and ABNER POST, M.D. Boston: 1894.

THIS report is a credit to the great institution it represents and to all the contributors. Dr. Cheever's report on 1238 operations, from 1864 to 1890, most prominently attracts attention. Dr. Councilman's studies of gonorrheal myocarditis and of syphilis of the heart are important, but we lack space to particularize further.

THE MEDICAL REGISTER OF NEW YORK, NEW JERSEY AND CONNECTICUT, FOR THE YEAR COMMENCING JUNE 1, 1894. Published under the Supervision of the New York Medico-Historical Society. John Shrady, M.D., Editor, Vol. XXXII. G. P. Putnam's Son's · New York.

WE are grateful to the editor and publisher for their conscientiousness and enterprise in preparing this excellent example of a medical register. Similar books should exist in every State.

BREAD FROM STONES. A NEW AND RATIONAL SYSTEM OF LAND FERTILIZATION. Translated from the German. Philadelphia: A. J. Tafel.

THIS is a small book devoted to showing the advantage of the use of the primitive rock, granite, etc., for fertilizing purposes. There is a probability that the statements have some value, but the subject is one on which a medical journal is not in a position to give an opinion.

NEWS ITEMS.

Meetings of Philadelphia Medical Societies:

	Meets.	Next meeting.
Academy of Surgery,	1st Monday of month, Oct.—June.	Jan. 7
College of Physicians,	1st Wednesday of month, Sept.—June.	Jan. 2
Section of Ophthalmology,	3d Tuesday of month, Sept.—May.	Jan. 15
Section of Orthopedic Surgery,	3d Friday of month, Oct.—April.	Jan. 18
Section of Otology,	1st Tuesday of month, Oct.—May,	Jan. 1
Section of Surgery,	2d Friday of month, Oct.—May.	Jan. 11
County Medical Society,	2d and 4th Wednesdays of month, Sept.—June.	Jan. 9
Neurological Society,	4th Monday of month, Oct.—April.	Jan. 28
Obstetrical Society,	1st Thursday of month, Sept.—June.	Jan. 3
Pathological Society,	2d and 4th Thursdays of month, Sept.—June.	Jan. 10

The Academy of Stomatology is a new association of dental practitioners in Philadelphia, organized for the purpose of investigating and studying all matters connected with the mouth, its functions in health and their aberrations in disease. A handsome suite of rooms has been secured at 1731 Chestnut Street for the holding of meetings, clinics, etc. In connection with these, a dental library and museum are being established, together with a reading-room, where it is proposed to keep on file all of the leading dental periodicals of the world. The ultimate purpose of the Academy is to establish a library and museum related to stomatology, which will be consulted by dental practitioners throughout the entire country.

Dr. Hare and the Philadelphia Hospital.—Dr. H. A. Hare, who was appointed visiting physician to the Philadelphia Hospital, in place of Dr. Judson Daland, has sent the following letter to the Board of Charities and Correction: "While appreciating the honor you have conferred upon me, I feel that under the circumstances I shall have to decline the appointment."

Prof. Isidore Schnabel, of the University of Prague, has been selected as the successor to the late Prof. Mauthner in the Chair of Ophthalmology in the University of Vienna.

A Pasteur Institute at Algiers was opened on October 1st, and on that very day a woman and a child that had been bitten by stray dogs were brought to the institute for treatment.

Diphtheria, bacteriology of, 549
cerebral palsy of childhood following, 124
clinical report of five cases of, injected with the antitoxin, 556, 615
of the genitals, paralysis following, 220
specific cure of, by antitoxin, 429
traumatic, with the demonstration of diphtheria-bacilli, 495
treatment of, with the antitoxin, 521, 551, 590, 609, 636, 670, 671, 692, 693, 714
of, with antitoxin derived without the intermediation of the animal organism, 610
widespread paralysis following, 188
Diphtheriæ, bacillus, occurrence of, outside of the body, 549
Diphtheric angina, potassium permanganate for, 272
conjunctivitis, methyl-violet in the treatment of, 16
croup, pseudo-membranous croup, and the value of intubation, 507
Dispensaries and hospitals, abuse of, 194
Divers' palsy, pathology of the spinal lesions of, 670
Dock, flagellate protozoa in the freshly-passed urine of a man; preliminary note, 690
Donnellan, a case of electric shock of one-thousand volts; insensibility of patient to pain; recovery, 126
Drainage-tube, self-retaining, after suprapubic cystotomy for chronic cystitis and prostatic obstruction, 662
Dressings, certain surgical, on the preparation of, 663, 681
Drinking-water, purification of, 698
Druggists, emmenagogue-dealers and literature, 717
Duffield, syphilis by conception, 295
Dukeman, a résumé of twelve-hundred examinations for life-insurance, 263
Dulles, hydrophobia-statistics desired, 309
the meetings of the College of Physicians, 226
treatment of typhoid fever, 651
Dundore, three cases of laminectomy, 578
Dyer, the use and abuse of arsenic in the treatment of skin-diseases, 227
Dyspnea after excision of the tonsils, 634

Ecthyma, inoculability of, 151
Eczema, for, 16, 496
Edinburgh congress, ophthalmology and, 249
Editors, publishers, etc., who are the, 472
Education, medical, higher, and the need of its endowment, 63
Electric illumination in abdominal surgery, 382
shock of one-thousand volts; insensibility of patient to pain; recovery, 126
Electricity as a cosmetic, 399
localized, treatment of chronic oöphoritis by, 423, 455
Emmenagogue-dealers, literature and druggists, 717
oxalic acid in combination with iron and manganese peptonates as, in chlorosis, 358
Empyema, pulsating, 246
Engineering undertaking, greatest, of today, 336
England, low death-rate in, 697
Enuresis, nocturnal, eye-strain a cause of, 668
Epilepsy, chronic, medicinal treatment of, 362
in early life, with especial reference to the colony-system in the care and treatment of epileptics, 291
trephining in three cases of, 395
Epileptics, colony for, 715

Epileptoid migraine, 707
Epiplocele, femoral, in a woman; radical operation, 635
Erysipelas, for, 610
traumatic origin of, 518
Eskridge, multiple neuritis, with the development of unilateral facial paralysis late in the course of the disease, 686
trephining in three cases of epilepsy: two of the Jacksonian variety; one due to old meningeal hemorrhage; improvement, 395
Esophagus, carcinoma of, gastrostomy by the method of Witzel for, 219
Ether-anesthesia, 260
Examinations, State, and licenses to practice, 446
Examiners, medical, State board of, 417
Examining boards, medical, duty and privilege of, 469
Exstrophy of the bladder, 489
Extremities, congenital deformity of upper and lower, and of the spinal column, 545
Eye-strain a cause of nocturnal enuresis, 668
-tuberculosis, experimental, ultimate results obtained in, by tuberculin-treatment and anti-tuberculous inoculation, 346
Eyes of motormen, engineers, etc., examination of, 471

FACE-GUARD for examining infectious throats, 713
-presentation, management of, 45
Facilis est descensus, 223
Felty, an abscess of the brain caused by a nail in the head, 710
Fetation, coincident intra-uterine and extra-uterine, 219
Fever in the infectious diseases, cause of, 127
without pyrexia, 48
Fevers, continued, of Louisiana, remarks on, 666
Fibro-myomata, intra-ligamentous, new and rapid method of dealing with, 602
Filters, small, efficiency of, 697
Filtration, actual experience in, 446
of water-supply, effect of, 447
Fincke, the hypodermic injection of magnesium sulphate as a purgative, 218
Fischer, the treatment of diphtheria with the antitoxin, 590
Fisk, abortive and afebrile typhoid fever, 479
a treatment of typhoid fever, 42
Flexner, the pathologic changes caused by certain so-called toxalbumins; an experimental study, 116
Food-adulteration laws, mistakes in the execution of, 640
poisonous, effects of, 501
Foot-ball accident, 701
casualties, reliability of newspaper reports as to, 415
craze, 385
disgrace, 615
indirect injury to health from, 528
rowdyism, 673
Forbes, indigo calculus from the kidney, 187
Forceps, new cover-slip, 360
new post-nasal, 381
Formalin, use of, in the treatment of chancroids and venereal warts, 465
Foster, the marriage of syphilitics, 365
Fracture of the skull, case of compound depressed, 520
Fractures of the arm, mooted points as to, with notice of an improved splint, 6
treatment of, in children, 582
Franklin, mania and catarrhal pneumonia following labor, 709
French, the Johnston Emergency Hospital at Milwaukee, 448
Friedenwald, atony of the intestine, 143

GALL-STONES, hepatic colic without, 549
Gasserian ganglion, excision of, 155
Gaston, mooted points as to fractures of the arm, with notice of an improved splint, 6
Gastric disorders, functional, nature and treatment of, 655
Gastrorrhaphy, successful, for perforated gastric ulcer, 245
Gastrostomy by a new method, 324
by the method of Witzel for carcinoma of the esophagus, 219
Gastrotomy, successful, for the removal of three pocket-knives, 609
Gaylord, a new cover-slip forceps, 360
notes on the use of formalin in the treatment of chancroids and venereal warts, 465
Gibb, zinc stearate in the treatment of atrophic rhinitis, 629
Gigantism, unilateral, 306
Glaucoma simplex, 576
Glycosuria complicating appendicitis, 357
urticaria with coincident, 301
Goiter, exophthalmic, myxedema and, relationship between, 16
thyroid gland for, 636
treatment of, with thyroid gland, 636
Gonococci in the blood in cases of gonorrheal rheumatism, 697
Gonorrhea, complications of, 20
in the female, 213
Goodell, Dr. William, 499
Gould and Hewish, a case of glaucoma simplex, 576
charity-organization and medicine, 407
eye-strain a cause of nocturnal enuresis, 668
Graves, some interesting surgical cases, with the exhibition of an original instrument, 267
Griffith, mid-systolic mitral murmurs, 477
Guaiacol, external use of, as an antipyretic, 527, 714
externally in tuberculosis, 570
Gunshot wound of the spleen and kidney, 546
wounds, forty cases of, 339
Gynecology among the insane from the gynecologist's point of view, 11

HALL, an undescribed heart-murmur, 439
Hansell, hypermetropia and heterotropia, 405
Harrell, cow-pox, 337
Harris, some observations on a method of multiplication of the amœba dysenteriæ (amœba coli), 567
Hawkins, a foot-ball accident, 701
Haynes, F. L., are ligature-fistulæ after celiotomies avoidable? 488
control of hemorrhage from the spleen and other abdominal viscera, 701
R. W., the dangers of cocain, 14
Head-movements, rhythmic, associated with nystagmus occurring in infants and young children, 512
Health, National Bureau of, 129
Heart, gunshot wound of, 464
valvular disease of, and chronic rheumatism, 265
-murmur, undescribed, 439
Hematemesis, gastric ulcer unattended with, 157
Hematokrit, Hedin's, 348
Hematometra from retained menses, abscess of vagina with, 269
Hemeralopia, nyctalopia and, abolish the words, 614
Hemianopsia, homonymous, posterior spinal sclerosis with, 100
Hemoptysis, chloral hydrate for, 190
for, 636
of pulmonary tuberculosis, for, 72
Hemorrhage, accidental, 188
Hemorrhage, control of, from the spleen and other abdominal viscera, 701
fatal, from rupture of an aneurysm of the hepatic artery, 71
subdural, 494
traumatic, into the brain, successful trephining in, 305
umbilical, 569
Hepatic abscess, 303
colic without gall-stones, 549
Hernia, gangrenous, treatment of, 15
Herpes zoster, salol in, 550
Herrick, C. B., a case of double vagina, 15
J. B., and Hektoen, myeloma, report of a case, 239
Hickman, a case of appendicitis, 547
Hindus, cruelty among, 446
Hinsdale, the comparative rarity of pulmonary tuberculosis in the highlands of Pennsylvania and the adjacent counties of New York, 113
Hip, congenital dislocation of, 236
old dislocations of, operative treatment of, 330
-disease, the need of rest in the treatment of, 516
-joint, amputation at, by Wyeth's method, 493
Hirst, obstetric memoranda, 667
suppurative metritis; ulcerative endometritis and metritis; double pyosalpinx and an ovarian abscess; embolic pneumonia following labor; hysterectomy; recovery, 217
Hoffman, vital statistics of the negro, 320
Hodgkin's disease in children, 714
Hog-cholera and swine-plague, 502
Holmes, Bayard, a case of acute osteomyelitis in an adult, with early operation and complete recovery, 668
Oliver Wendell, 413
Homeopathy, humors of, 417
Honor to whom due, 530
Horsley, a case of subdural hemorrhage, 494
Horwitz, organic stricture of the urethra; methods of treatment recommended, with indications for their employment, 255
Hospitals, dispensaries and, abuse of, 194
for the tuberculous poor, 555
small, 445
Hovnanian, potassium nitrate in the treatment of phlegmasia alba dolens, 95
Hydatid cyst in the neck of a child, 46
of the brain, 189
Hydrocele of the neck, congenital, cured by drainage and compression, 189
Hydrogen dioxid, intra-uterine application of, 337
Hydrophobia, case of, 243
statistics desired, 309
Hygiene, rural, 705
Hypermetropia and heterotropia, 405
Hypertrophy, prostatic, successfully treated by castration, 441
Hypnotism and crime, 47
Hypnotized subjects, some physiologic effects of music in, 89
Hysterical arm in court, 583
ataxia, with retained muscle-reflexes, 1
muscular atrophy, 18

ICE, therapeutic value of, in ophthalmic surgery, 582
-cold applications in acute pneumonia, 403
Idiot, congenital, hopelessly insane, etc., what is the duty of the State and medicine as regards, 336
Impressions, maternal, 451
Index medicus, 640
subscriptions to, 697
Indigo calculus from the kidney, 187
Infants, scorbutus in, 219
Infection, air-borne, 365

Infection, venous septic, in the puerperal state, intravenous injections of mercuric chlorid in the treatment of, 496
Infectious diseases, cause of fever in, 127
treatment of, with antitoxin, 685
Infiltration-anestbesia, 442, 503
Influenza, meningitis complicating, 712
urine of, ptomain obtained from, 157
Initial lesion, plea for the excision of, 206
Inoculation, protective, against cholera, 696
Insane, gynecology among, from tbe gynecologist's point of view, 11
hopelessly, congenital idiot and, what is the duty of the State as regards, 336
responsibility of, 307
Insanity, popular errors concerning, 563
with goiter, thyroid extract in, 636
Insurance-companies, encouragement of suicide by, 717
Intestine, atony of, 143
Iodoform for fibrinous rhinitis, 100

JAPANESE NAVY, medical statistics of, 416
Jejunum, traumatic rupture of, without external lesion, 332
Jenckes, resection of the ankle-joint, with removal of the os calcis, for acute osteomyelitis, 330
Johnston Emergency Hospital at Milwaukee, 448
Jonas, operative treatment for the cure of vascular nevi, 543
Jones, A. A., painful gastric neuroses; tbeir nature, symptomatology, etiology, diagnosis, and treatment, 343, 371
the treatment of lactic-acid excess in the stomach, 703
P. M., forty cases of gunshot wounds, 339
W. D., a case of fatal nausea and vomiting of pregnancy, 242
Journal, medical, every physician to have his own, 640
of the American Medical Association, 386
Journalism, piety and quackery, 717
Judicial Council, 48

KEELEYISM, data on, 417
Kerr, J. G., the bubonic plague in South China, 449
J. M., typhoid fever, 689
Kidney, ruptured, treatment of, 272
King, a plea for the excision of the initial lesion, 206
Kolipinski, the treatment of appendicitis, 644
Kyle, bacteriologic report, 559
illumination and examination of the anterior and posterior nasal cavities, 188

LABOR, induced, rapid retrocession of sarcomata after, 220
mania and catarrhal pneumonia following, 709
Laboratory, biologic, for the Philadelphia Board of Health, 529
-teacher and laboratory-specialist, encouragement and support of, 287
Lactic-acid excess in the stomach, treatment of, 703
Lactophenin as an antipyretic, 468
Laminectomy, 578
Lead-palsy in children, 85
-poisoning, for, 46
Leidy, three cases of glycosuria complicating attacks of appendicitis, with the report of a case illustrating Nature's rôle in effecting a cure, 357
Leuf, suppurative sacro-iliac disease due to indirect violence, with nervous symptoms, 492
Leukemia, bone-marrow in the treatment of, 468
Leukoplakia, for, 458, 550
Lewi, rhythmic bead-movements associated with nystagmus occurring in infants and young children, 512
Library of the office of the surgeon-general of the United States army, 641
Lichen urticatus, for, 550
Lichty, abdominal aneurism, 440
Life-insurance, résumé of twelve-hundred examinations for, 263
statistics, 19
Ligament, broad, cyst of, 213
Ligation, of the splenic arteries, one, and eight splenectomies, 100
Ligature-fistulæ after celiotomies, are they avoidable? 488
Lipuria, medicamentous, 382
Lister, Sir Joseph, testimonial to, 644
Literature, emmenagogue-dealers and druggists, 717
Littig, an intra-cranial tumor, 522
Liver and stomach, excised wounds of, successful celiotomy for, 582
cirrhosis of, nervous symptoms of, 637
hypertrophic cirrhosis of, in a boy of fourteen, 659
influence of, in the development of pancreatic diabetes, 193
Lobingier, nephrectomy, with report of a case, 283
Locomotor ataxia, pathology and treatment of, by suspension and by apparatus, 571
Lovett, the need of rest in the treatment of hip-disease, 516
Lung, gangrene of, following pleuro-pneumonia, 670
Lymphadenitis, general tuberculous, without involvement of other organs, 186
Lysidin, 616

MACPHAIL, an epidemic of paralysis in children, with a report of one-hundred-and-twenty cases, 619, 685
Magnesium sulphate, hypodermic injection of, as a purgative, 218
Malaria, toxins of, 613
Malarial origin, vasomotor rhinitis of, 495
Mania, acute, following traumatism, craniectomy for, 157
Manley, contusion of the abdomen, with rupture of the thoracic duct, 491
Mann, gonorrhea in the female; cyst of the broad ligament, 216
Manometer, convenient clinical, 548
Manton, gynecology among the insane, from the gynecologist's point of view, 11
Masland, a case of exstrophy of the bladder, 489
Massage, aural, by condensation and rarefaction of the air in the external meatus and middle ear; its value in the treatment of various diseases of the ear, 596
direct, of the cornea, as an agent in the treatment of corneal opacities, 244
immoral, 129, 194
influence of, upon the body-metabolism, 528
Matas, Professor R., 386
remarks on the continued fevers of Louisiana, 666
Maternity retreats, 718
Mays, ice-cold applications in acute pneumonia, 403
McCartney, retention of urine for eleven days, 305
McCormick, inoculability of ecthyma, 151
McFarland, a large round-cell sarcoma of the uterus, 632
Measles and phenacetin, 577
and scarlatina in the same person, 714
malignant, 57
Meat from tuberculous animals, infectiveness of, 194
infected milk and, transmission of tuberculosis through, 102
Medical matters, shall physicians, or shall lay trustees, boards of charities, etc., decide as to, 695
Medicine, religion and, among the American negroes, 500
charity-organization and, 407
newspaper, 274
teaching of, in different countries, 500
Meningitis complicating influenza, 712
Menopause, premature, 461
Mercurials, hypodermic injections of, treatment of syphilis by, 550
Methyl-violet in the treatment of diphtheric conjunctivitis, 16
Metritis, suppurative; ulcerative endometritis and metritis; double pyosalpinx and an ovarian abscess; embolic pneumonia following labor; hysterectomy; recovery, 217
Metrorrhagia, for, 550
Midwifery among the Somalis, 471
Migraine and kindred nervous diseases, uric-acid leukomains as factors in the etiology of, 482
epileptoid, 707
Milk and meat, infected, transmission of tuberculosis through, 102
-inspection, 49
-question, 716
Miller, W. D., bacterio-pathology of the human mouth and its significance in relation to systemic disease, 641
case of general tuberculous lymphadenitis without involvement of other organs, 185
Miscarriage, two cases illustrating the importance of completely emptying the uterus immediately after, 298
Mitchell, motor ataxia; ataxia in a child of three years, with retained muscle-reflexes; hysterical ataxia, with retained muscle-reflexes, 1
Montgomery, D. W., diarrhea from potassium iodid, 711
E. E., address on obstetrics, 180
premature menopause; retroversion; removal of appendages; retro-displacement with fixation, 461
Morris, amputation at the hip-joint by Wyeth's method, 493
Morton, a note upon the value of direct massage of the cornea as an agent in the treatment of corneal opacities; presentation of a new instrument, 244
Mouth, human, bacterio-pathology of, and its significance in relation to systemic disease, 641
Munn, the Colorado climate for tuberculous patients, 171
the operative treatment of inflammatory phimosis and the use of the sharp curet and strong bichlorid solution for chancroids, 706
Murmurs, mid-systolic mitral, 477
Musbrooms, edible, 530
Music, some physiologic effects of, in hypnotized subjects, 89
Musser, the mild character and the diminished prevalence of syphilis, and the infrequency of visceral syphilis, 149
Mustard, on the value to the surgeon of, 663, 681
Myeloma, 239
Myxedema and exophthalmic goiter, relationship between, 16
and its differential diagnosis from chronic nephritis, 649, 683
degeneration of the thyroid gland in a case of arthropathic psoriasis followed by, 100

Myxedema due to actinomycosis, 635
in children, 635
thyroid gland and its relation to, 381

NASAL CAVITIES, anterior and posterior, illumination and examination of, 188
of non-tuberculous patients, presence of tubercle-bacilli in, 192
Nausea and vomiting of pregnancy, fatal, 242
Ne quid nimis, 554
Neapolitan children, rickets among, in American cities, explanation of great frequency of, 316
Negro physicians, 385, 555
the question of the need of, again, 615
vital statistics of, 320, 392
Negroes, American, religion and medicine among, 500
and brunets, are they peculiarly subject to electric retinitis, 365
Nephrectomy, 283
Nephritis, chronic, myxedema and its differential diagnosis from, 649, 683
latent and intermittent, without albuminuria, nervous and mental symptoms of, 435
strontium lactate in, 243
Nerve-suturing, 374
Nervous system, syphilis of, 37
Neuritis, multiple, with the development of unilateral facial paralysis late in the course of the disease, 686
puerperal, 555
simulating progressive muscular atrophy, associated with nystagmus and increase of knee-jerks, 635
Neuralgia, for intercostal, 670
Neuroses, painful gastric, 343, 371
Nevi, vascular, operative treatment for the cure of, 543
NEWS, THE, and the American Medical Association, 193
Newspaper advertising, 697
Nitro-benzol intoxication, 382
-glycerin for singultus, 670
Nose, the, as a social test, 252
Nucleo-albumin (erroneously styled mucin), reactions of, with the commonly-employed urinary albumin-tests; the difficulty of distinguishing these reactions from those of serum-albumin, globulin, etc., 29
Numbness of the extremities, acro-paresthesia, treatment of, 178
Nurses, quack, 194
Nyctalopia, and hemeralopia, abolish the words, 614

OBSTETRIC INSTRUCTION, 372
memoranda, 667
Obstetrics, address on, 180
Ocean, from across, 587
Ocular ballottement, 501
Ohlmacher, the encouragement and support of the laboratory-teacher and laboratory-specialist, 287
Oöphoritis, chronic, treatment of, by localized electricity, 423, 455
Opacities, corneal, treatment of, direct massage of the cornea as an agent in, 244
Ophthalmia neonatorum, 129
Ophthalmology and the Edinburgh Congress, 249
Ophthalmoplegia, traumatic, improved by operation, 669
Opium-poisoning, inhalation of oxygen in, 75, 96
Optician's impudence, 529
Orchitis due to effort, 713
pneumonic, 549
Organs, new, formation of, to replace others destroyed, removed, or wanting, 273
Ortho-chlorphenol and para-chlorphenol in the treatment of tuberculous and other affections of the upper air-passages, 190
Osteomyelitis, acute, in an adult, with early operation and complete recovery, 668
resection of the ankle-joint with resection of the os calcis for, 330
Otitis media, chronic purulent; with facial paralysis, 579
Ott, a case of strychnin-poisoning, 270
Oxalic acid in combination with iron and manganese peptonates as an emmenagogue in chlorosis, 358
Oxygen, inhalation of, in opium-poisoning, 75, 96
Oxygenation, ratio that alimentation should bear to, in disease of the lungs, 311
Oxyuris, treatment of, 496
Oyster as a medium of transmitting typhoid fever, 641

PAGE, measles and phenacetin; which killed the patient—the disease or the treatment? 577
Palsy, cerebral, of childhood, following diphtheria, 124
periodic, 443
Papain as a remedy for teniæ, 380
Para-chlorphenol, ortho-chlorphenol and, in the treatment of tuberculous and other affections of the upper air-passages, 190
Paralysis agitans, elevation of temperature as a symptom of, 74
without tremor, 46
following diphtheria of the genitals, 220
in children, epidemic of, with a report of one-hundred-and-twenty cases, 619, 685
motor, unique form of, due to cold, 210
unilateral facial, multiple neuritis with the development of, late in the course of the disease, 686
widespread, following diphtheria, 188
Park, congenital dislocation of the hip, 236
on the value to the surgeon of antipyrin, of mustard and sugar, and on the preparation of certain surgical dressings, 663, 681
Parotid gland, gumma of, 442
Paskola, 615
Patent-medicine disgrace, 586
Pathogenic lectures on hygiene and medicine, 586

Somalis, midwifery among, 471
Souchon, a plea for a methodically-written text-book on anatomy, 539
Spartein, use of, as an adjunct to chloroform-anesthesia, 190
Spasm, reflex, of the tongue, lips, and pharynx induced by irritation of the great occipital nerve, 220
Spastic paralysis, trephining of the skull for, 382
Spinal column, congenital deformity of upper and lower extremities and, 545
Splenectomies, eight, and one ligation of the splenic artery, 100
Spratling, on epilepsy in early life, with special reference to the colony-system in the care and treatment of epileptics, 291
Sputum, examination of, centrifugal force as an aid to, 367
Stamm, gastrostomy by a new method, 324
Starr, myxedema and its differential diagnosis from chronic nephritis, 649, 683
Stenosis of the upper air-passages from syphilitic adhesions, 691
Stewart, D. D., the reactions of nucleo-albumin (erroneously styled mucin), with the commonly employed urinary albumin-tests; the difficulty of distinguishing these reactions from those of serum-albumin, globulin, etc.; remarks on the occurrence of a normal, constant trace of albumin in the urine, 29
trichloracetic-acid test for the detection of serum-albumin in urine, 132
R. W., excision of the Gasserian ganglion, 155
Stockinet cotton as a material for bandages, 351
Stockton, the nature and management of functional gastric disorders, 655
Stomach, dilatation of, posterior sclerosis and, in the same patient, 213
liver and, excised wounds of, successful celiotomy for, 582
rupture of, death from convulsions following, 72
Stover, a case of angina ludovici, 70
Straight, syphilis and apex-catarrh, 600
Streptococcus pyogenes and the streptococcus of erysipelas, identity of, 554
Stricture, organic, of the urethra, 255
stricture, urethral, radical cure of, by the restoration of the mucous membrane to a healthy condition, 230
Strychnin-poisoning, 270
Student versus medical school, 12
Sugar, on the value to the surgeon of, 663, 681
Suicide, encouragement of, by insurance companies, 717
Supra-renal capsules, ablation of, in dogs, 714
gland, functions of, 549
and its relation to Addison's disease, 71
Surgical cases, some interesting, 267
Sweating, treatment of anemia, particularly chlorosis, by means of, 670
Sweat-shops and smallpox in Chicago, 251
Swine-plague, hog-cholera and, 502
Sydenham, 234
Syphilis and apex-catarrh, 600
by conception, 295
mild character and diminished prevalence of, and the infrequency of visceral, 149
of the nervous system, 37
treatment of, by hypodermic injections of mercurials, 550
unusual case of, 379
mode of transmission of, 306
Syphilitic adhesions, stenosis of the upper air-passages from, 691
cicatricial adhesion of the tongue to the palate and pharyngeal walls, with notes of operation, 606
Syphilitics, marriage of, 365

TANNIC acid, idiosyncrasy to topical applications of, 468
Taylor, face-guard for examining infectious throats, 713
Teachers, we must educate our, 614
Teaching, American medical, 337
of medicine, English and American, 583
Tea intoxication, 486
Temperance reform league of Massachusetts and the Keeley cure, 529
Temperature, elevation of, as a symptom of paralysis agitans, 74
Teniæ, papain as a remedy for, 380
Teratologia, 615
Tetanus, antitoxin-treatment of, 550
Thigh, three amputations of; two in the upper third, one at the middle, 152
Thompson, a new wool-test for the detection of color-blindness, 175
Thoracentesis, indications for, 362
Thoracic duct, rupture of, contusion of the abdomen, with, 491
Thornbury, the specific cure of diphtheria by antitoxin, 429
Throat-affections, membranous, necessity of bacteriologic examination in, 221
Throats, infectious, face-guard for examining, 713
Thyroid extract in insanity, with goiter, 636
gland and its relation to myxedema, 381
degeneration of, in a case of arthropathic psoriasis followed by myxedema, 100
for exophthalmic goiter, 636
treatment of goiter with, 636
Thyroiditis, post-pneumonic, due to pneumonia-cocci, 332
Tiffany, gunshot wound of the spleen and kidney; abdominal section; hemostasis by deep suture; recovery, 546
Tonsillolith, 580
Tonsils, dyspnea after excision of, 634
Tooth-pulp, bacterio-pathology of, 466
Toxalbumins, pathologic changes caused by certain so-called, 116
Trephining in three cases of epilepsy, 395
of the skull for spastic paralysis, 382
Trichloracetic-acid test for the detection of serum-albumin in urine, 129, 132
Tricks, ophthalmologic, 471
Triple births, 495
Triplett, one case of compound depressed fracture of the skull and one of a bullet-wound of the brain, 520
Trolley-gong nuisance, 587
Trudeau, a report of the ultimate results obtained in experimental eye-tuberculosis by tuberculin in treatment and anti-tuberculous inoculation, 346
Tube-casts and other organic urinary deposits, staining and mounting of, 381
Tubercle-bacilli in butter, 417
presence of, in the nasal cavities of non-tuberculous patients, 192
-bacillus, effect of creosote upon the virulence of, 524
Tuberculin treatment and anti-tuberculous inoculation, ultimate results obtained in experimental eye-tuberculosis by, 346
Tuberculosis, acute miliary, of pharyngo-laryngeal type, 74
anal, unusual form of, 99
attenuated bacillus, its use in producing immunity to tuberculosis in guinea-pigs, 625
extensive resection of the bowel for: implantation of the ileum into the colon; extirpation of the excluded bowel, 608
for pulmonary, 72, 496
for the night-sweats of, 362
guaiacol externally in, 570
pulmonary, comparative rarity of, in the highlands of Pennsylvania and the adjacent counties of New York, 113
for the hemoptysis of, 72
for the night-sweats of, 442
treatment of, with petroleum, 72
relationship between bovine and human, 524
transmission of, from mother to fetus, 160

Tuberculosis, transmission, of, through infected milk and meat, 101
treatment of, with yeast-nuclein, 657, 675
Tuberculous and other affections of the upper air-passages, ortho-chlor-phenol and para-chlorphenol in the treatment of, 190
animals, meat from, infectiveness of, 194
lymphadenitis, general, without involvement of other organs, 185
patients, Colorado climate for, 171
registration of, 526
poor, hospitals for, 555
Tube-stripper, 360
Tulane university, medical department of, 472
Tumor, intra-cranial, 522
Turnbull, aural massage, by condensation and rarefaction of the air in the external meatus and middle ear; its value in the treatment of various diseases of the ear, 596
Typhoid fever, 689
abortive and afebrile, 479
oyster as a medium of transmitting, 641
successful celiotomy and resection of the bowel for perforation in the course of, 609
toxins and antitoxins of, 713
treatment of, 42, 651
of, with cold baths, 555
ulcer, perforation of, in a young child, 635

ULCER, gastric, unattended with hematemesis, 157
perforated gastric, successful gastrorrhaphy for, 245
successful suture of, 331
of the duodenum, successful excision of, 99
Umbilical hemorrhage, 569
Universities, State, suggestion to, 525
Urea, seat of the formation of, in the animal organism, 220
Urethra, organic stricture of, 255
ruptured, successful suture of the divided ends of, 272
Urethritis, arsenical, 72
Urethrotomy, external perineal, 352
Urine, freshly passed, of a man, flagellate protozoa in, 690
retention of, for eleven days, 305
Urticaria with coincident glycosuria, 301
Uterus, carcinoma of, ptomain in the urine in, 158
large, round-cell sarcoma of, 632
treatment of rupture of, during labor, 467
trifid, 245

VACATION, the physician's, 333
Vagina, absence of, with hematometra from retained menses, 269
double, 15
Vansant, a case of syphilitic cicatricial adhesion of the tongue to the palate and pharyngeal walls, with notes of operation, 606
Varicella and scarlet fever in the same patient, 706
Vas deferens, castration for rupture of, 495
Vaughan, G. T., hepatic abscess, 303
V. C., the treatment of tuberculosis with yeast-nuclein, 657, 675
Veeder, three unusual cases of abscess, 440
Vegetations, urethral, treatment of, by means of a circular cutting curet, 98
Vertigo, auditory, caused by working in compressed air, 691
Vesicles, seminal, chronic inflammation of, 92
Villainy, atrocious, 529
Volvulus, the prevention of the recurrence of, 496
Vomiting, nausea and, of pregnancy, fatal, 242
of chloroform-narcosis, to control, 126
Vulvitis, treatment of, of little girls, 412

WALKER, dyspnea after excision of the tonsils, 634
Warthin, some physiologic effects of music in hypnotized subjects, 89
Water, electric purification of, 587
purification of, 159
iron process of, 364
-supplies in Pennsylvania, 501
-supply of Philadelphia, 337
Watson, a new post-nasal forceps, 381
Weiland, simple and efficient test for binocular reading, 359
Weiser, a case of carbolic-acid poisoning; recovery, 271
Welch, W. H., higher medical education and the need of its endowment, 63
Welch, W. M., clinical report of five cases of diphtheria injected with the antitoxin, 565, 615
Whooping-cough, for, 46
for, in an infant, 707
resorcin for, 332
White, castration for the cure of hypertrophied prostate, 664, 674
Willard and Hinsdale, antero-lateral sclerosis; posterior sclerosis; pathology and treatment of locomotor ataxia by suspension and by apparatus, 571
nerve-suturing; neurorrhaphy, nerve-grafting, 374
Wilson, a case of malignant measles, 57
Wood, H. C., epileptoid migraine, 707
James, tea-intoxication, 486
Wool-test, new, for the detection of color-blindness, 175
Work, maternal impressions, 451
Würdemann, the traumatic origin of erysipelas, 518

XERODERMA pigmentosum, two cases of, in one family, 246

YEAST-NUCLEIN, treatment of tuberculosis with, 657, 675

ZINC stearate in the treatment of atrophic rhinitis, 629
